As already stipulated by Prestwich and Atzet, while we must embrace the complexity of biology, we cannot let this complexity dominate the design of a clinical biomaterial (Prestwich and Atzet, 2012). There will be not one formulation that can fulfill every need. As seen lately in therapeutic approaches, personalized medicine, in this case personalized materials design, will likely dominate the future. Technologies such as 3D (bio) printing and electrospinning will further allow us to design and shape the ideal biomaterial for a defined clinical application. However, the penetration of a new technology into any market is not only determined by improvement in patient outcome, but also by the true limiting factors of cost, familiarity, and ease of use (Prestwich and Atzet, 2012).

Introduction

Biomedical composites are materials that are formed by combining multiple components of materials such as metals, polymers, and ceramics. For certain targeted biomedical applications, they provide improved properties that a typical metal, polymer, or ceramic material alone cannot provide. A main advantage of composites is that their properties can be tailored by changing the composition ratio of constituting materials, their placement, and the interfaces. In the history of biomaterial developments, the class of biomedical composites is relatively young. But its unmatchable advantage in certain implants and medical devices makes this class of biomaterials desirable for applications ranging from orthopedics, dentistry, and drug delivery to frontiers such as cancer theragnostics.

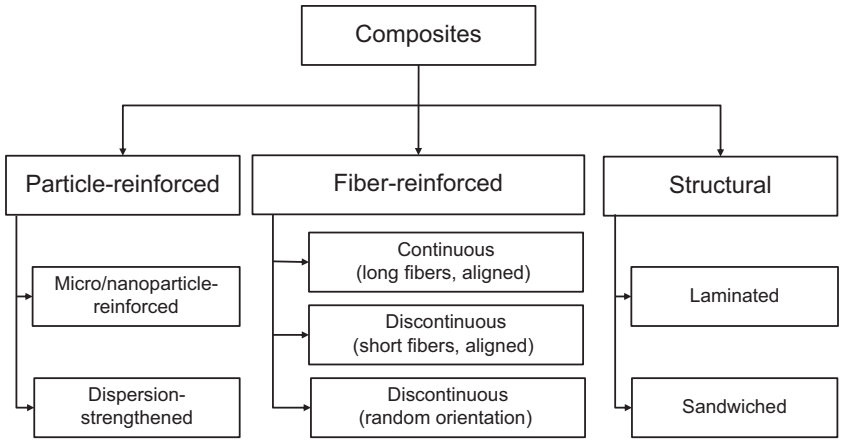
In a composite material, the component forming the major and continuous phase (>50% by volume, usually having relatively low stiffness and strength) is termed "matrix" and the component existing as a minor, discontinuous, and dispersed phase (<50% by volume, usually exhibiting relatively high stiffness and strength) is termed "reinforcement." The boundary between matrix and reinforcement is the "interface." Depending on the types of matrix materials, composites may be classified as polymer, metal, or ceramic matrix composites. Alternatively, composites are often categorized by the geometry of the reinforcement, for example, particle-reinforced composites, fiber-reinforced composites, and structural composites (Fig. 1.3.7.1). Generally, particle-reinforced composites use micro- or nanosized particles as reinforcements. In fiber-reinforced composites, fibrous reinforcements can be in a form of long continuous fibers either aligned or woven, or of short fibers either aligned or randomly oriented.

Fiber-reinforced composites generally exhibit significant improvements in stiffness and strength, which are required for load-bearing implants. For example, continuous carbon fiber (CF)-reinforced polymers have been explored as the stem of hip prosthesis. Mechanical properties of fibrous composites are highly related to the type, volume fraction, length, and orientation of fibers. Structural composites are laminates and sandwich panels. They are not often designed and studied for implants or medical devices. Like other biomaterials, biomedical composites can also be made as bioactive and biodegradable. Bioactivity here means the ability of the material to form a chemical (or physiological) bond with a tissue in a human body (typically, the bone). A bioactive composite must have at least one component (either matrix or reinforcement) that can bond to a tissue. A biodegradable composite can be totally degradable or partially degradable.

Matrix and Reinforcement in Composites

Matrix Materials

Because of the availability of many biomedical polymers, their good biocompatibility, excellent ductility and flexibility, low cost, and ease of fabrication into final products (as compared with metals and ceramics), polymer matrix composites are the most investigated biomedical composites. The polymer matrices have been mainly synthetic polymers, though natural polymers are making good inroads into composite development due to their own distinctive advantages. For synthetic polymers, polyethylene (PE), polypropylene, polyurethane (PU), poly(ethylene terephthalate) (PET), polytetrafluoroethylene (PTFE), poly(methyl methacrylate) (PMMA),



• **Figure 1.3.7.1** Classification of composites according to the geometry of reinforcements.

polycarbonate, polyetheretherketone (PEEK), polysulfone (PSU), and ultra-high molecular weight polyethylene (UHMWPE) have been used for biomedical composites for different applications. PTFE/PU artificial vascular grafts and UHMWPE tendon/ligament/joint substitutes are good examples. Moreover, biodegradable polymers such as poly(L-lactic acid) (PLLA), poly(lactic-*co*-glycolic acid) (PLGA), poly(ε-caprolactone) (PCL), and poly(3-hydroxybutyrate-*co*-3-hydroxyvalerate) (PHBV) are used as matrices for composites. An example is a PLLA-matrix bone fracture fixation plate. Natural polymers such as collagen, gelatin, hyaluronic acid, silk fibroin, chitosan, alginate, and PHBV are now frequently used for different biomedical devices because of their excellent biocompatibility. Hydrogels also find their way into composites. For example, poly(hydroxyethyl methacrylate) (PHEMA), poly(vinyl alcohol), poly(ethylene glycol), poly(acrylic acid), PMMA, and thermoresponsive poly(*N*-isopropylacrylamide), and natural polymers, such as collagen, gelatin, hyaluronic acid, and alginate, are now used to make nanocomposite hydrogels with improved mechanical properties and tailored functions such as desired physical, chemical, electrical, and biological properties. Even though there are many advantages for using polymers for biomedical composites, the low stiffness and strength and other properties (e.g., creep) of polymers have limited their scope for biomedical applications. There have also been investigations using metals or ceramics as matrices for biomedical composites. For example, a Ti–6Al–4V matrix with dispersed hydroxyapatite (HA) particles was made for potential load-bearing orthopedic applications. Ceramic matrix composites are investigated, in fact more often than metal matrix, for biomedical applications. One major effort in the field is the toughening of weak bioceramics (e.g., HA, $Ca_{10}(PO_4)_6(OH)_2$)) using biocompatible glasses. There is also the development of biphasic calcium phosphate, which is a physical mixture of HA and tricalcium phosphate (TCP, $Ca_3(PO_4)_2$) in different proportions. The biodegradation rate of this material can be controlled by varying the HA-to-TCP ratio, giving it an advantage for some clinical applications.

Reinforcements

To overcome some shortcomings of polymers, ceramics and metals in medical applications, hard bioceramic particles are often used for achieving different effects or properties such as strengthening, bioactivity, or wear resistance. They are usually dispersed in ductile matrices (commonly, polymers but sometimes metals). Mechanical and biological properties of particle-reinforced composites are significantly affected by the characteristics (e.g., type, composition, size, shape, etc.) of reinforcing particles. Decades ago, microparticles were the main particulate materials used for composites. With advances in nanotechnology, recent years have seen the surge of applying nanoparticles in composites, which can offer both mechanical and biological benefits. Bioactive bioceramic particles, such as HA, TCP, Bioglass, and apatite–wollastonite (A–W) glass-ceramic particles are used for making bone-mimicking bioactive composites for orthopedic and/or dental applications. Many micro- or nanoparticles are spherical in shape. But commercially available particulate calcium phosphates (e.g., HA and TCP) and Bioglass particles are usually irregularly shaped. Particulate reinforcements with irregular shapes are preferred for their surface to form a stable mechanical interlock with the matrix, whereas smooth-surfaced and spheroid-shaped particulate reinforcements are easily detached from the matrix when stressed in the absence of chemical bonding between the reinforcement and matrix. Apart from these particulate bioceramics, it has been shown that alumina particles can be mixed with dental resins for filling cavities in the teeth, with these alumina particles providing enhanced wear resistance for the dental filling. For "brittle" polymers such as PMMA, which is commonly used as bone cement in total hip replacement, toughening of the polymer is needed and hence in some investigations rubber particles are mixed with PMMA, resulting in a toughened bone cement.

Biomedical composites with fibrous reinforcements can provide much improved mechanical properties (modulus, strength, etc.), which are heavily influenced by the mechanical properties of the fibers used, fiber diameter, fiber volume fraction, aspect ratio (i.e., the fiber length-to-fiber diameter ratio) in the case of short fibers, etc. For continuous fiber-reinforced composites, long fibers are generally polymer

fibers or ceramic fibers. Polymer fibers often include Kevlar fibers, nylon fibers, PE fibers, PLLA fibers, PLGA fibers, PCL fibers, and more recently cellulose fibers. PLLA, PLGA, PCL, and cellulose fibers are very useful for developing biodegradable composites. Commonly used ceramic fibers for biomedical composites are the very fine carbon fibers (CFs) whose diameters are about 10 μm. These CFs possess high modulus (200–500 GPa) and high strength (over 2 GPa) and are also flexible. They can be braided with polymer fibers to form artificial ligaments/tendons. A common example is CF-reinforced PEEK or PSU for the stem of hip prostheses. Absorbable calcium phosphate or glass fibers have also been used to reinforce biodegradable polymers to make internal fracture fixation devices.

In manufacturing biomedical composites in a large quantity, producing particle-reinforced composites is the most economical, whereas fabricating long fiber-reinforced composites is the most time-consuming and expensive. When significant improvements in stiffness and strength are required for the materials and particle-reinforced composites cannot meet the requirements, short-fiber reinforced composites can fill this need. Depending on the manufacturing technology and processing parameters, the short fibers in composites can be either aligned or randomly oriented. Mechanical properties of composites reinforced by aligned short fibers are anisotropic, while randomly oriented fiber-reinforced composites appear to be nearly isotropic. The aspect ratio of short fibers significantly affects properties of the composite. Also, short fibers must be longer than a critical length to provide the desired reinforcing effect. Short fibers can be whiskers or chopped fibers cut from long fiber strands. Whiskers can be viewed as much elongated particulate materials and are produced by carefully controlling the synthesis parameters. They are generally thin single crystals of materials such as calcium phosphates, alumina, and silicon carbide and have nearly perfect crystalline structures. Therefore they possess extremely high stiffness, enabling significant mechanical property improvements for metal or ceramic matrices. Chopped CFs or polymer fibers can be used as reinforcements in polymer matrix composites. A few investigations have found chopped stainless-steel wires (which can be viewed as chopped fibers) useful in reinforcing and toughening bioactive HA or glass matrices.

Nonporous and Porous Composites

From a structure standpoint, biomedical composites can be either nonporous or porous (with pore sizes ranging from a few micrometers to hundreds of micrometers). Bulk, nonporous composites exhibit good structural integrity and normally possess required mechanical properties. They can be used for biomedical applications under high mechanical loading such as bone substitution and dental filling. For manufacturing these composites, various conventional technologies are available (Wang et al., 2019). For example, particle-reinforced polymer matrix composites can be conveniently and efficiently made using extrusion and injection molding. Ceramic matrix composites can be produced using pressureless sintering, hot pressing, or hot-isostatic pressing. In comparison, a porous composite usually has a much lower strength than the nonporous composite of the same composition but has advantages such as light weight and high surface area-to-volume ratio. Porous biodegradable composites are now extensively investigated as novel tissue engineering scaffolds, which can provide microenvironments with suitable physical, chemical, and biological cues for living cells, leading to new tissue formation. The fabrication of porous polymer matrix composites can use solvent casting, freeze drying, electrospinning, 3D printing, etc. All these techniques can form porous composites with interconnected pores, which are essential for cell migration, cell–cell connection, and tissue formation and growth. The size of the interconnected pores in porous composites must be controlled and also tailored for different tissue engineering applications. Porosity is another important parameter that must be controlled for porous composites as tissue engineering requires high porosity in scaffolds. A balance then needs to be struck to achieve high porosity while maintaining sufficient mechanical strength for the porous structures.

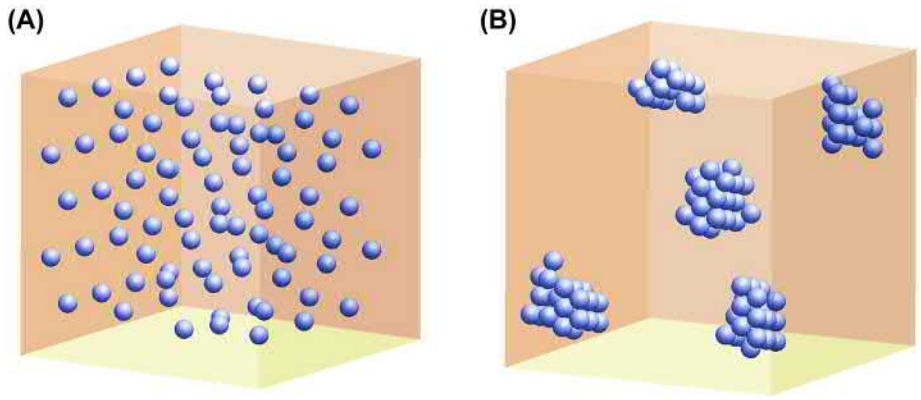
Properties of Composites

Major Influencing Factors

Properties (physical, structural, mechanical, electrical, biological, etc.) of composites can be affected by many factors. The major influencing factors for biomedical composites include:

1. matrix property (the average molecular weight of a polymer, average grain size of a metal or ceramic, strength, stiffness and ductility of the material, etc.);
2. stability or biodegradability of the matrix or reinforcement;
3. bioactivity of the reinforcement or matrix;
4. reinforcement shape, size, and size distribution;
5. reinforcement property (strength, stiffness, ductility, etc.) and volume percentage in the composite;
6. distribution (and orientation) of the reinforcement in the composite;
7. reinforcement–matrix interfacial state.

Biomedical composites have gone through different stages of development from nonporous biostable composites to nonporous biodegradable composites to porous tissue engineering scaffolds. Biodegradable materials, including biodegradable polymers such as PLLA, PLGA, PCL, collagen, chitosan, and alginate, and biodegradable ceramics such as TCP and a few bioactive glasses are increasingly used for biomedical composites. The bioactivity of composites is usually achieved by the incorporation of bioactive bioceramics (HA, TCP, Bioglass, etc.) in composites. To achieve enhanced tissue repair or regeneration, bioactive molecules such as growth factors can be encapsulated in biodegradable composites, which are released later *in vivo* in a controlled manner. To combat bacterial infection, antibiotics can be incorporated in biodegradable composites for their later release. The manufacture of biodegradable composites and composites containing biomolecules or drugs



• **Figure 1.3.7.2** Schematic 3D views of dispersion and distribution of particulate reinforcements in composites: (A) ideal dispersion and distribution of the particles; (B) particles existing as aggregates in composites.

can be a challenge and hence different fabrication techniques are needed for achieving the optimal outcome.

Geometry and Size of the Dispersed Phase and Its Distribution in Composite

For a particle-reinforced composite, the geometry and size of particles are important in determining composite properties such as mechanical properties. Particle dispersion and distribution in a composite play a critical role in determining composite properties. To form high-quality and high-performance particulate bioceramic–polymer composites, the particle agglomerates or aggregates must be broken down during composite processing into primary particles (i.e., the smallest particulate pieces of the minor component existing in as-fabricated or as-received ceramic powder), which show sufficient dispersion and reasonable distribution in the polymer matrix (Fig. 1.3.7.2A). Dispersing particles from the condensed state only to the aggregate state (Fig. 1.3.7.2B) is not adequate as the particle contacting points in aggregates will provide crack initiation sites or act to enhance crack propagation, thus causing premature failure of the composite when the composite is under mechanical stresses. Ideally, particles present in the composite should be in a dispersed state. Therefore specially designed processing equipment and/or good fabrication procedures are often required, which produces shear forces large enough to overcome various particle adhesion forces during composite processing so that particle agglomerates or aggregates can be reduced to primary particles and primary particles can be evenly distributed in the composite. Generally, there is a critical amount of particulate reinforcement for the composite, only above which desired properties can be obtained for the composite. In such a situation of highly filled polymers, processing of the composites becomes a challenge, sometimes insurmountable. Surface treatment of bioceramic particles may ease processing difficulties but may not necessarily lead to enhanced particle dispersion.

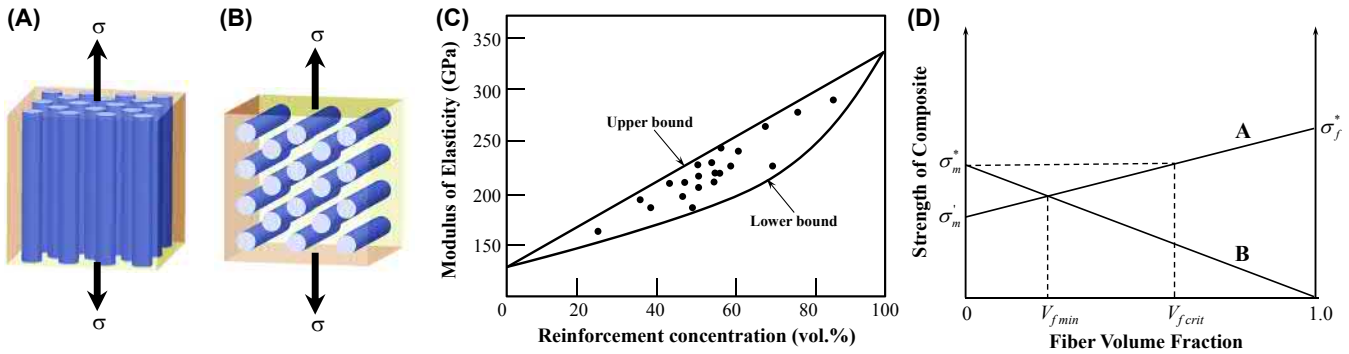
Fiber Arrangement

For long-fiber composites, fiber arrangement such as fiber orientation, fiber stacking pattern, and the angle and packing sequence of fiber-reinforced sheets is a critical factor affecting the performance of long-fiber reinforced composites. For short-fiber composites, the fiber length, aspect ratio, and fiber orientation are key influencing factors. While the fiber length affects the load transfer between short fibers and the matrix locally, fiber orientation affects the macroscopic properties of the composite. The random orientation or alignment in one direction of short fibers in composites results in isotropic or anisotropic materials. However, isotropic short-fiber composites (i.e., those with randomly oriented short fibers) can become "anisotropic" upon unidirectional tension when the fibers are "forced" aligned to some extent due to the effect of the elongational flow.

For uniaxial long-fiber composites, the fiber-stacking pattern is an important factor that influences their mechanical properties as the interfiber spacing is varied by different fiber stacking arrangements. For example, in a cross-sectional view, fibers can be arranged in a hexagonal pattern or square array. For other fibrous composites, woven, braided, and knitted fiber arrays are used, which affect macroscopic properties of the composites because different texture patterns result in distinct fiber arrangements. In structural composites, laminates are formed by the sequential stacking of continuous and aligned long-fiber composite ply sheets. Therefore the angle and the sequence for stacking must be carefully considered. Each of the unidirectional sheets is stacked according to a certain sequence and with a certain angle by design to produce the composite to meet the requirements for specific anisotropic mechanical properties in the targeted composite applications. Because this laminate class of composites is rarely used in the biomedical field, we intentionally leave it out, since it would take a whole chapter to discuss it at a level to benefit readers. We therefore encourage readers to consult other books on this specific subject should such a need occur.

Interfaces in Composites

The interface between the reinforcement and matrix in a composite is governed by the bonding mechanism(s) involved, which in turn strongly affects the properties of



• **Figure 1.3.7.3** Two simple models for long-fiber reinforced composites: (A) Voigt model; (B) Reuss model. Upper and lower bounds of composite modulus of elasticity as a function of fiber volume fraction (C). Longitudinal tensile strength of long-fiber composites as a function of fiber volume fraction (D), where σ_m^* = strength of the matrix, σ_f^* = strength of the fiber, and σ_m^* = strength of the matrix at the fiber fracture strain.

the composite. Normally, a strong interface results in a high strength but a low toughness of the composite. Conversely, a weak interface leads to a composite with a low strength but a relatively high toughness. There are different bonding mechanisms at the interface, from physical or mechanical bonds to chemical bonds. The interface formed by chemical bonding is several orders of magnitude stronger than that by physical bonding. However, chemical bonding, in which the reinforcement chemically reacts with the matrix at the interface, is generally avoided for biomedical composites due to biocompatibility concerns of these composites. Therefore most composite interfaces rely on physical bonding, including mechanical interlocking, electrostatic attraction, cation–anionic interaction, and molecular entanglement following interdiffusion at the interface. Consequently, surface features and properties (surface topography, surface electric charge, surface energy, etc.) of reinforcements and matrices are highly important for interfacial bonding.

Mechanical Properties of Composites

Tensile Properties of Fibrous Composites

The mechanics of composites have been well established. The micromechanics of long-fiber reinforced composites can be dealt with by using relatively simple models with simplified assumptions. In determining the elastic properties (e.g., Young's modulus) of unidirectional fibrous composites, it is often assumed that (1) the fiber and matrix have different elastic moduli but identical Poisson's ratio, (2) fibers are perfectly aligned, (3) fibers and matrix are perfectly bonded, and (4) initially, there are neither voids nor internal stresses in the composite.

There are two distinct limiting cases on the elastic properties of long-fiber composites. The first case possesses the upper limit for the modulus of the composites. It is when the composite is stretched along the fibers' axis as illustrated in Fig. 1.3.7.3A for a two-component composite (a matrix with only one type of fibers as the reinforcement), and the following equation can be deduced for the modulus using the concept of a Voigt model:

$$E_c = E_f \cdot V_f + E_m \cdot V_m \qquad (1.3.7.1)$$

where E_c, E_f, and E_m are elastic moduli of the composite, reinforcing fiber, and matrix, respectively, and V_f and V_m are volume fractions of the fiber and matrix, respectively. The second case is when a tensile force is applied perpendicular to the fibers' axis in the two-component composite, as shown in Fig. 1.3.7.3B, and for this situation the following equation is deduced based on the concept of a Reuss model, giving the lower bound:

$$1 / E_c = E_f / V_f + E_m / V_m \qquad (1.3.7.2)$$

While neither of these models is rigorously correct, the two models do provide the upper and lower bounds, respectively, for the Young's modulus of a long-fiber reinforced composite (Fig. 1.3.7.3C). When the moduli of the reinforcement and matrix differ by no more than a factor of two or three, the simple linear superimposition of Voigt and Reuss values provides a good approximation. When the Poisson's ratios of the reinforcement and matrix are not equal, a correction term needs to be introduced into the equations.

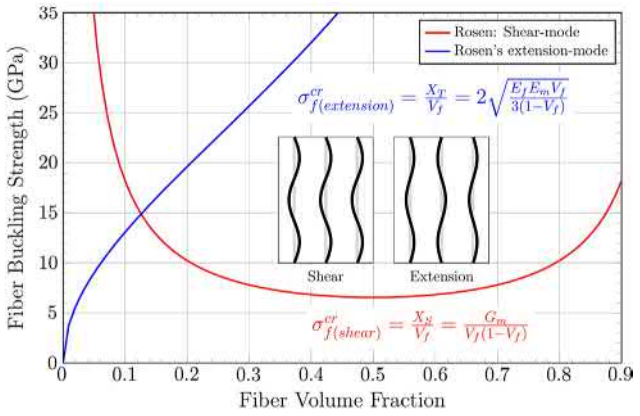
Using the Voigt model, the longitudinal strength of the composite can be deduced:

$$\sigma_c = \sigma_f \cdot V_f + \sigma_m \cdot V_m \qquad (1.3.7.3)$$

where σ_c, σ_f, and σ_m are the strength of the composite, reinforcing fiber, and matrix, respectively assuming that (1) all fibers have equal strength, (2) both matrix and fibers exhibit linear elastic behavior up to failure, and (3) there is equal longitudinal strain in the composite, fibers, and matrix.

When the fiber failure strain is smaller than that of the matrix, for fibrous composites to achieve the reinforcing effect of fibers, the fiber volume fraction must exceed a critical value $V_{f\,crit}$, as illustrated in Fig. 1.3.7.3D. For short-fiber composites, the critical fiber length l_c is

$$l_c = \sigma_f^* \, r / \tau \qquad (1.3.7.4)$$



• **Figure 1.3.7.4** Variation of fiber compressive strength with volume fraction when undergoing microbuckling in a uniaxial composite as predicted by Rosen's model.

where σ_f^*, r, and τ are fiber fracture strength, fiber radius, and interfacial shear strength, respectively.

Compressive Properties of Fibrous (CF/PEEK) Composites: A New Perspective

Rosen's Microbuckling Model and the Contradictions

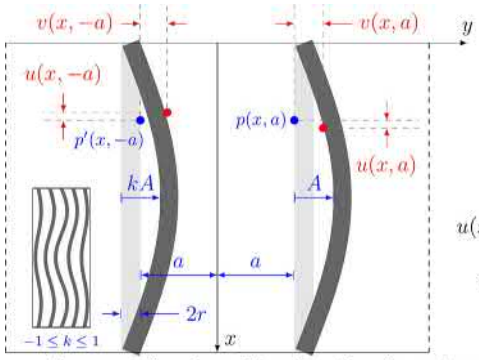
The compressive behavior of uniaxial long-fiber composites has been the subject of many investigations since the development of these materials. Many factors, including manufacturing processes, material constituent properties, specimen geometry, method of load introduction, fiber orientation and waviness, voids, and stress concentration, have all been shown to play a role in affecting the predominant mode of compressive failure. The failure mode includes global Euler buckling, microbuckling, transverse tension, fiber kinking, and fiber or matrix delamination, among others. One of the first analytical models predicting the compressive strength of such composites through addressing fiber microbuckling was presented by Rosen (1965). Using a 2D model, Rosen suggested that compressive failure for a uniaxial composite material occurs when the fibers buckle into either an extension mode or a shear mode. In the extension mode, the deformation of the matrix material between fibers was solely by extension or compression in a direction perpendicular to the fibers. In the shear mode, pure shear deformation was considered to occur in the matrix material between fibers. Fig. 1.3.7.4 shows the variation of fiber buckling strength based on Rosen's equations as a function of fiber volume fraction (V_f) for a CF/PEEK uniaxial composite, where X_T and X_S are composite compressive strength in the extension and shear mode, respectively, and σ_f^{cr} represents the corresponding buckling strength of a fiber.

The curves exhibit two different trends for the shear and extension modes. Rosen argued that the likely failure mode for such a composite is the one that exhibits a lower strength value, hence the conclusion that the shear mode will prevail when V_f is high and the extension mode when V_f is low. This was the prevailing knowledge for predicting the microbuckling behavior for uniaxial composites for many decades. However, a close inspection reveals a contradiction when V_f becomes very small: the diverged fiber-buckling strength values in the shear and extension modes when V_f becomes very small. It does not make any sense because as $V_f \to 0$, fibers in both the extension and shear mode cases will be located far away from each other, such that they could be regarded as individual ones. So, a converged, not a diverged, result should be expected. Another issue is that the theoretical predicted strength values are much higher than the experimentally observed values. Moreover, in a uniaxial composite with fiber volume fraction in the range of 55%–60%, shear mode long wavelength microbuckling is predicted, but experimentally, short wavelength fiber kinking is typically observed as the compressive failure mode.

A First-Principles-Based Compressive Microbuckling Model

Zhang and Latour (1994) used the first-principles approach to reexamine the microbuckling problem of uniaxial fibrous composites and developed an analytical model based on the theory of elasticity. Unlike in Rosen's model, where only extension deformation of the matrix was considered in the extension mode, and shear deformation was considered in the shear mode, this elasticity-based analytical model accounts for both the shear and normal interfacial stresses because of fiber and matrix deformation and establishes relationships between microbuckling strength, microbuckling wavelength, fiber volume fraction, and interfacial stresses, among others. Here we briefly discuss the important aspects of this new model.

***Deformations in fibers and matrix*:** A 2D unidirectional composite model with a unit thickness under uniform compression is considered as depicted on the left in Fig. 1.3.7.5. Fibers are assumed to have a width of $2r$ and placed at a distance $2a$ apart from each other. When this uniaxial composite is subject to compressive loading, fibers are assumed to undergo in-plane microbuckling in the Cartesian xy-coordinate system. When microbuckling of fibers occurs, each fiber is assumed to deform in a sinusoidal pattern: $Y = A \sin \alpha x$. For considering a general case, it is assumed that neighboring fibers can undergo microbuckling with different amplitudes. For example, for the two fibers shown in Fig. 1.3.7.5, one is assumed to deform in a sinusoidal pattern with amplitude A, and the other kA, where k is an interaction coefficient varying from −1 to 1 ($-1 \le k \le 1$). When $k = 1$, the situation reduces to Rosen's shear mode, and when $k = -1$, it becomes Rosen's extension mode. This general consideration can be termed the k-mode of microbuckling.



$$\frac{\partial^4\Phi}{\partial x^4} + 2\frac{\partial^4\Phi}{\partial x^2\partial y^2} + \frac{\partial^4\Phi}{\partial y^4} = 0$$

$$\sigma_x = \frac{\partial^2\Phi}{\partial y^2},\ \sigma_y = \frac{\partial^2\Phi}{\partial x^2},\ \tau_{xy} = -\frac{\partial^2\Phi}{\partial x\partial y}$$

$$Y = A\sin\alpha x,\ \ \alpha = \frac{m\pi}{L} = \frac{\pi}{l_0}$$

$$u(x,a) = A\alpha r\cos\alpha x,\ \ v(x,a) = A\sin\alpha x$$

$$u(x,-a) = -kA\alpha r\cos\alpha x,\ \ v(x,-a) = kA\sin\alpha x$$

$$\epsilon_x = \frac{1}{E_m}(\sigma_x - \nu_m\sigma_y),\ \ \epsilon_y = \frac{1}{E_m}(\sigma_y - \nu_m\sigma_x)$$

$$\epsilon_x = \frac{\partial u}{\partial x},\ \ \epsilon_y = \frac{\partial v}{\partial y},\ \ \gamma_{xy} = \frac{\partial u}{\partial y} + \frac{\partial v}{\partial x}$$

Airy stress function: $\Phi(x,y) = \sin\alpha x[c_1\cosh\alpha y + c_2\sinh\alpha y + c_3 y\cosh\alpha y + c_4 y\sinh\alpha y]$

• **Figure 1.3.7.5** A 2D uniaxial composite undergoing microbuckling, along with a list of equations describing the deformations of fibers and matrix, the constitutive relations, the induced stresses and strains, and an Airy stress function.

In the sinusoidal expression ($Y = kA\sin\alpha x$), α is a microbuckling parameter expressed as $m\pi/L = \pi/l_0$, where L is the length of fibers, m is the buckling wave number, and l_0 is the microbuckling wavelength. To consider the deformations in the fibers, matrix, and at the interfaces, the displacements of two arbitrary points, $p(x,a)$ and $p'(x,-a)$, are considered. With the sinusoidal expression for fiber microbuckling, the displacement components in the x and y directions of the points p and p', namely, $u(x,a)$, $v(x,a)$, $u(x,-a)$, and $v(x,-a)$, are expressed as given in the equation list on the right in Fig. 1.3.7.5.

The matrix is considered as an isotropic linear elastic medium. The deformation of the matrix is caused by the microbuckling deformation of the fibers, assuming the fibers and matrix to be perfectly bonded. Due to the 2D consideration, the matrix deformation problems can be treated as a plane-stress problem, for which an Airy stress function Φ (given at the bottom of Fig. 1.3.7.5) satisfying the biharmonic equation (given at the top of the equation list in Fig. 1.3.7.5) is used. With the selected Airy stress function, in which c_1 through c_4 are constants to be determined, the stresses in the matrix (σ_x, σ_y, τ_{xy}) are derived as:

$$\begin{aligned}
\sigma_x &= \sin\alpha x\left[\begin{array}{l} c_1\alpha^2\cosh\alpha y + c_2\alpha^2\sinh\alpha y + c_3\alpha \\ (2\sinh\alpha y + \alpha y\cosh\alpha y) + c_4\alpha \\ (2\cosh\alpha y + \alpha y\sinh\alpha y)\end{array}\right] \\
\sigma_y &= -\sin\alpha x\left[\begin{array}{l} c_1\alpha^2\cosh\alpha y + c_2\alpha^2\sinh\alpha y + \\ c_3\alpha^2 y\cosh\alpha y + c_4\alpha^2 y\sinh\alpha y\end{array}\right] \qquad (1.3.7.5) \\
\tau_{xy} &= -\alpha\cos\alpha x\left[\begin{array}{l} c_1\alpha\sinh\alpha y + c_2\alpha\cosh\alpha y + c_3 \\ (\cosh\alpha y + \alpha y\sinh\alpha y) + c_4 \\ (\sinh\alpha y + \alpha y\cosh\alpha y)\end{array}\right]
\end{aligned}$$

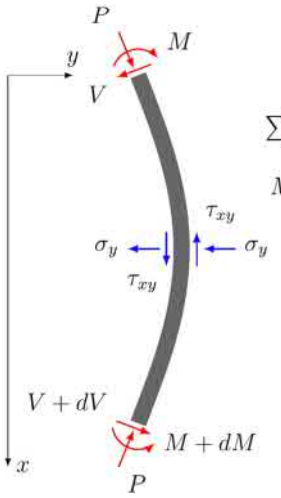
Through the stress–strain relationships and the strain-displacement expressions listed in Fig. 1.3.7.5, the displacement fields of the matrix, $u(x,y)$ and $v(x,y)$, are solved as follows, where E_m is the matrix Young's modulus and ν_m is the matrix Poisson's ratio:

$$\begin{aligned}
u(x,y) = &-\frac{(1+\nu_m)\cos\alpha x}{E_m}\Big\{c_1\alpha\cosh\alpha y + c_2\alpha\sinh\alpha y \\
&+ c_3\left[\frac{2}{1+\nu_m}\sinh\alpha y + \alpha y\cosh\alpha y\right] \\
&+ c_4\left[\frac{2}{1+\nu_m}\cosh\alpha y + \alpha y\sinh\alpha y\right]\Big\} \qquad (1.3.7.6)
\end{aligned}$$

$$\begin{aligned}
v(x,y) = &-\frac{(1+\nu_m)\sin\alpha x}{E_m}\Big\{c_1\alpha\sinh\alpha y + c_2\alpha\cosh\alpha y \\
&+ c_3\left[\alpha y\sinh\alpha y - \frac{1-\nu_m}{1+\nu_m}\cosh\alpha y\right] \\
&+ c_4\left[\alpha y\cosh\alpha y - \frac{1-\nu_m}{1+\nu_m}\sinh\alpha y\right]\Big\}
\end{aligned}$$

Applying Eq. (1.3.7.6) to the four displacement expressions given in Fig. 1.3.7.5 for $u(x,a)$, $v(x,a)$, $u(x,-a)$, and $v(x,-a)$, we find the four unknown constants as

$$\begin{aligned}
c_1 = &(1-k)\frac{E_m A\{[2-a\alpha^2 r(1+\nu_m)]\cosh a\alpha}{\alpha(1+\nu_m)[2a\alpha(1+\nu_m)} \\
&\frac{+[a\alpha(1+\nu_m) + (1-\nu_m)\alpha r]\sinh a\alpha\}}{-(3-\nu_m)\sinh 2a\alpha]} \\
c_2 = &-(1+k)\frac{E_m A\{[2-a\alpha^2 r(1+\nu_m)]\sinh a\alpha}{\alpha(1+\nu_m)[2a\alpha(1+\nu_m)} \\
&\frac{+[a\alpha(1+\nu_m) + (1-\nu_m)\alpha r]\cosh a\alpha\}}{+(3-\nu_m)\sinh 2a\alpha]} \\
c_3 = &(1+k)\frac{E_m A(\sinh a\alpha - \alpha r\cosh a\alpha)}{2a\alpha(1+\nu_m) + (3-\nu_m)\sinh 2a\alpha} \\
c_4 = &-(1-k)\frac{E_m A(\cosh a\alpha - \alpha r\sinh a\alpha)}{2a\alpha(1+\nu_m) - (3-\nu_m)\sinh 2a\alpha}
\end{aligned} \qquad (1.3.7.7)$$



$$E_f I\frac{d^4Y}{dx^4} - 2r\frac{d\tau_{xy}}{dx} + 2\sigma_y + P\frac{d^2Y}{dx^2} = 0$$

$$\sum F_y = 0:\ \frac{dV}{dx} - 2\sigma_y - P\frac{d^2Y}{dx^2} = 0;\ \sum M = 0:\ \frac{dM}{dx} + 2r\tau_{xy} - V = 0$$

$$M = -E_f I\frac{d^2Y}{dx^2},\ I = \frac{2r^3}{3},\ \sigma_f = \frac{P}{2r},\ \beta = \frac{a}{r} = \frac{1}{V_f} - 1,\ t = \alpha r,\ a\alpha = \beta t$$

$$\sigma_y = E_m A\alpha f_1 \sin\alpha x,\ \tau_{xy} = E_m A\alpha f_2 \cos\alpha x$$

$$f_1 = (1+k)\frac{(1+\nu_m)\beta t^2 + (1-\nu_m)t\sinh\beta t\cosh\beta t + 2\sinh^2\beta t}{(1+\nu_m)[2\beta t(1+\nu_m) + (3-\nu_m)\sinh 2\beta t]}$$
$$+(1-k)\frac{(1+\nu_m)\beta t^2 - (1-\nu_m)t\sinh\beta t\cosh\beta t - 2\cosh^2\beta t}{(1+\nu_m)[2\beta t(1+\nu_m) - (3-\nu_m)\sinh 2\beta t]}$$

$$f_2 = (1+k)\frac{(1+\nu_m)\beta t + (1-\nu_m)\sinh\beta t\cosh\beta t + 2t\cosh^2\beta t}{(1+\nu_m)[2\beta t(1+\nu_m) + (3-\nu_m)\sinh 2\beta t]}$$
$$+(1-k)\frac{(1+\nu_m)\beta t - (1-\nu_m)\sinh\beta t\cosh\beta t - 2t\sinh^2\beta t}{(1+\nu_m)[2\beta t(1+\nu_m) - (3-\nu_m)\sinh 2\beta t]}$$

• **Figure 1.3.7.6** A free-body diagram of a fiber segment undergoing microbuckling, along with a list of equations describing the governing equilibrium equations and interfacial stresses.

Plugging Eq. (1.3.7.7) into Eq. (1.3.7.5) along with letting $y = a$, or $y = -a$, we arrive at the expressions for the normal and shear interfacial stresses as listed in Fig. 1.3.7.6.

***Fiber equilibrium equation*:** Fibers are considered as elastic beams supported by a surrounding elastic matrix. A free-body diagram of a fiber segment is shown on the left in Fig. 1.3.7.6, where P is the applied longitudinal compressive force, M is the bending moment in the fiber, V is the transverse shear force, and σ_y and τ_{xy} are the interfacial normal and shear stresses, respectively, acting on the fiber surface.

From the force and moment equilibrium equations, namely $\sum F_y = 0$ and $\sum M = 0$, the governing equivalent equation for the fiber is derived as given at the top of the equation list on the right in Fig. 1.3.7.6, in which E_f is the fiber axial Young's modulus and I is the fiber's area moment of inertia.

By substituting the interfacial stresses into the microbuckling governing equation along with the following expressions: $I = 2r^3/3$, $P = 2r\sigma_f$, $\beta = a/r = (1/V_f - 1)$, $t = \alpha r$, and $a\alpha = \beta t$, the compressive stress in a fiber is derived as a function of E_f, E_m, ν_m, k, β, and t, as follows:

$$\sigma_f = \frac{E_f t^2}{3} + (1+k)E_m \frac{2\beta t(1+\nu_m) + (1-\nu_m)\sinh 2\beta t + \dfrac{2\sinh^2\beta t}{t} + 2t\cosh^2\beta t}{(1+\nu_m)[2\beta t(1+\nu_m) + (3-\nu_m)\sinh 2\beta t]}$$
$$+ (1-k)E_m \frac{2\beta t(1+\nu_m) - (1-\nu_m)\sinh 2\beta t - \dfrac{2\cosh^2\beta t}{t} - 2t\sinh^2\beta t}{(1+\nu_m)[2\beta t(1+\nu_m) - (3-\nu_m)\sinh 2\beta t]} \quad \textbf{(1.3.7.8)}$$

TABLE 1.3.7.1 Material Properties of CF/PEEK and CF/PSF Composite Systems

Young's modulus for AS4 fibers (E_f, GPa)	248.0
Young's modulus for PEEK matrix (E_m, GPa)	4.646
Radius of AS4 fibers (r, μm)	3.5
Poisson's ratio for PEEK matrix (ν_m)	0.42

CF/PEEK, Carbon fiber/polyetheretherketone; *CF/PSF*, carbon fiber/poly(sulfone)

For the two particular cases, the shear mode of the microbuckling case can be obtained by letting $k = 1$, and the extension mode with $k = -1$. The critical compressive strength for a fiber (σ_f^{cr}) is obtained by finding the minimum value of σ_f with respect to t for a given set of E_f, E_m, ν_m, k, and β values, as

$$\sigma_f^{cr} = \sigma_{f(t=t_{cr})};\ \text{when}\ \frac{\partial\sigma_f}{\partial t}\Big|_{t=t_{cr}} = 0\ \text{and}\ \frac{\partial^2\sigma_f}{\partial t^2}\Big|_{t=t_{cr}} > 0 \quad \textbf{(1.3.7.9)}$$

The associated microbuckling wavelength, normalized by the fiber diameter, is then determined as

$$l_r = \frac{l_0}{2r} = \frac{\pi r}{2rt_{cr}} = \frac{\pi}{2t_{cr}} \quad \textbf{(1.3.7.10)}$$

Selected Results

To illustrate the results as predicted by this first-principle-based analytical model, we consider an example case using the material properties of an AS4 (CF/PEEK composite (Table 1.3.7.1).

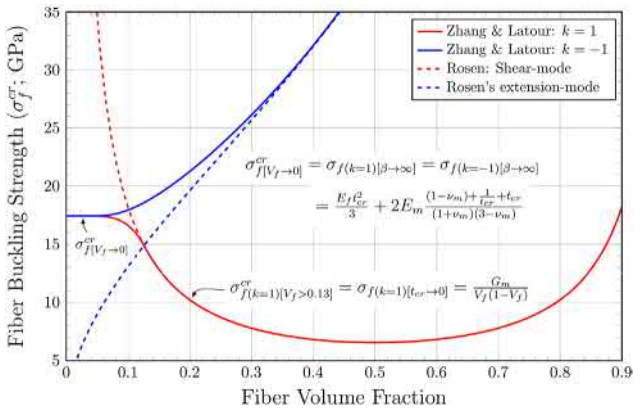
***Fiber critical compressive strength*:** Fig. 1.3.7.7 plots the variation of fiber critical compressive strength (or fiber buckling strength), σ_f^{cr}, with V_f for the CF/PEEK composite. The results of the $k=1$ and $k=-1$ cases are compared with those of Rosen's shear and extension modes. An excellent agreement exists between the two corresponding curves at high V_f, but agreement is not found at low V_f. In Zhang and Latour's model, however, when $V_f \to 0$, both the $k=1$ and $k=-1$ cases converge to a single value for the fiber buckling strength. The equation given in the inset, $\sigma_{f[V_f\to 0]}^{cr}$, provides the analytical expression for this converged buckling strength. The convergence predicted here makes perfect sense because as $V_f \to 0$, fibers in both cases will be located far away from one another such that they will deform individually as in a single fiber composite.

***Fiber–matrix interfacial stresses*:** This result sheds some important light on the contradiction in Rosen's model, whereas diverged strength values are predicted for the shear and extension modes when V_f becomes very small. It is known that in Rosen's model, only the matrix transverse deformation is considered in the extension mode (which accounts only for the interfacial normal stresses) and the shear deformation is considered in the shear mode (which accounts only for the interfacial shear stresses). In this first-principle-based model, all interfacial stresses resulting from fiber microbuckling deformation are inherently considered because of the use of Airy stress function. To show these stresses, their magnitude (note that $\sigma_{y\text{-}max}$ occurs at sin $\alpha x=1$, and $\tau_{xy\text{-}max}$ at cos $\alpha x=1$) normalized by $E_m A\alpha$ are determined and presented in Fig. 1.3.7.8A as a function of V_f.

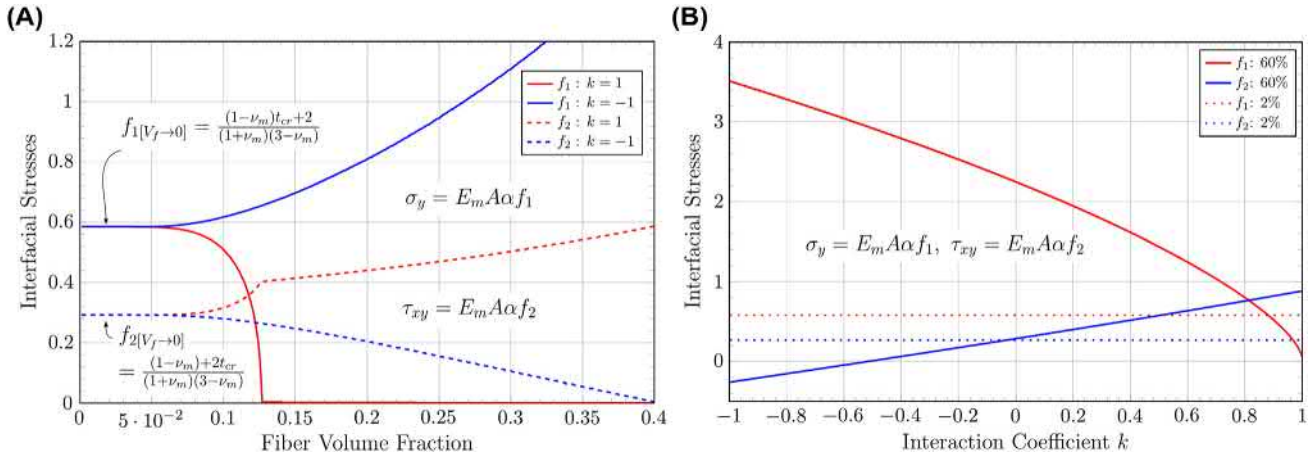
In the $k=1$ case, the normal stress (red solid line) drops quickly to zero as V_f increases from 0 to approximately 0.13, and in the $k=-1$ case, the shear stress (blue dashed line) decreases gradually with increasing V_f. These facts suggest that the contributions of normal stress in the shear mode ($k=1$) and the shear stress in the extension mode ($k=-1$) are only negligible when V_f is high, but they cannot be neglected when V_f is low. That these stresses are not accounted for in Rosen's model provides a reasonable explanation why good agreement is seen between the corresponding results when V_f is high and no agreement was seen at low V_f.

In Fig. 1.3.7.8A it is seen that for the case of $k=1$, both σ_y and τ_{xy} (red solid and dashed lines) curves exhibit a sharp transition at around $V_f=0.13$, marking a change in fiber microbuckling deformation from short to long wavelength buckling. Moreover, when $V_f \to 0$, both the $k=1$ and $k=-1$ cases see the same normal and shear stresses, confirming that in both situations fibers deform individually with the same support from the matrix, thereby yielding the same buckling deformation.

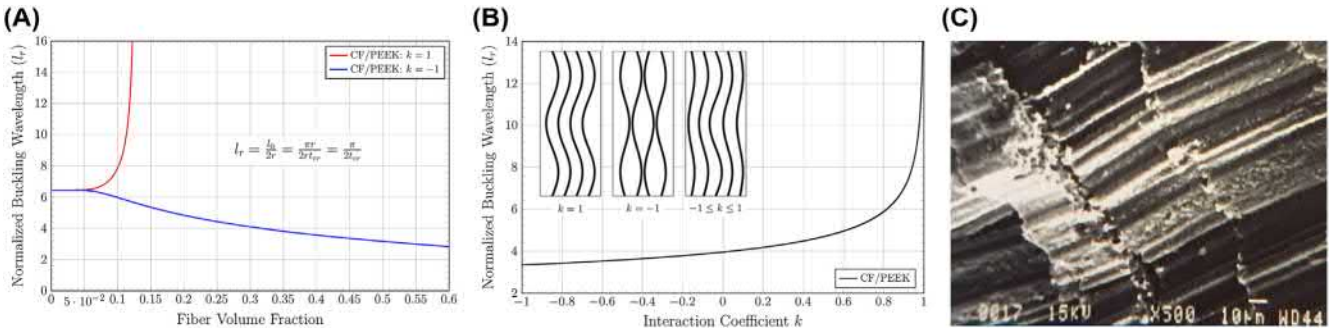
Fig. 1.3.7.8B looks at the variation of the normal and shear stresses with k when $V_f=2\%$ and 60%. When $V_f=2\%$, both stresses remain constant and they do not change with k. This result provides yet another confirmation that when V_f is very low, all fibers in the composite will deform individually, independent of what the value of k is. When $V_f=60\%$, the normal stress (red solid line) decreases from a high value at $k=-1$ to zero at $k=1$, while the shear stress



• **Figure 1.3.7.7** Variation of fiber compressive strength with volume fraction in a uniaxial carbon fiber/polyetheretherketone composite due to fiber microbuckling.



• **Figure 1.3.7.8** Variation of normal and shear interfacial stresses with fiber volume fraction (A), and variation of normal and shear interfacial stresses with interaction coefficient at $V_f=2\%$ and 60% (B).



• **Figure 1.3.7.9** Variation of normalized microbuckling wavelength with fiber volume fraction (A), and variation of normalized microbuckling wavelength with interaction coefficient (B). A scanning electron microscopy image of a fractured surface of a uniaxial carbon fiber/polyetheretherketone (CF/PEEK) composite ($V_f = 60\%$) tested under compression (C).

(blue solid line) increases from a slightly negative value at $k = -1$ to a positive value at $k = 1$. With this insight in mind, we can be certain that the $k = 1$ case always produces a lower σ_f^{cr} value, except for the condition of $V_f < 0.05$, in which case both the $k = 1$ and $k = -1$ cases converge to the case of individual fibers surrounded by an infinitely wide matrix.

***Microbuckling wavelength*:** Fig. 1.3.7.9A shows the variation of l_r with V_f. When $V_f < 0.05$, l_r is approximately 6.4 for the CF/PEEK composite for both the $k = 1$ and $k = -1$ cases. When $V_f > 0.05$, l_r for the $k = 1$ case increases rapidly toward infinity, and l_r for the $k = -1$ case decreases gradually from ~6.4 to ~3. Fig. 1.3.7.9B shows the variation of l_r with k (at $V_f = 0.6$). Clearly, l_r increases gradually as k increases, but it goes rapidly to infinity as k approaches 1. With a decrease in k value of only 0.1%, i.e., $k = 0.999$, the predicted l_r will take a value of ~13, which falls within the range for experimentally observed microbuckling wavelength, as confirmed by the scanning electron microscopy image of a compressively fractured surface of a uniaxial CF/PEEK composite (Zhang et al., 1996) shown in Fig. 1.3.7.9C. This fracture surface shows that fibers do appear to break due to short wavelength ($3 < l_r < 13$) buckling or kinking, supporting the argument for a k mode microbuckling with k being close to, but not equal to, 1.

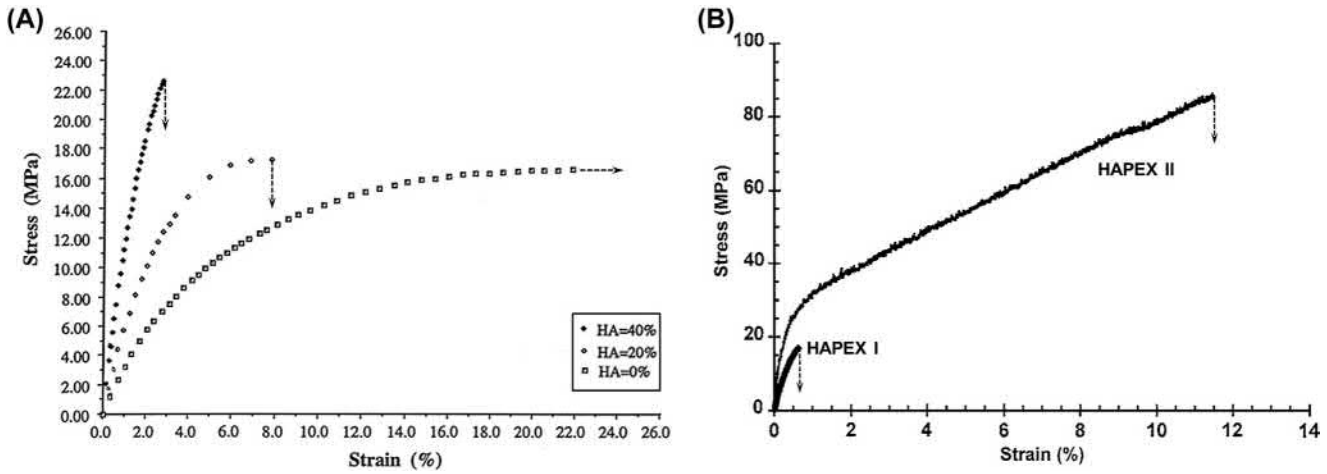
Contrary to Rosen's predictions, it is shown that shear mode is always the preferred microbuckling mode, except for the case where fibers perform individually in a single fiber composite. Based on the k-mode concept, a short microbuckling wavelength is predicted to occur in uniaxial fibrous composites because fibers in these composites will always have some degree of imperfection in their alignment (with k being close to but equal to 1). Regarding the resulting interfacial stresses, a k value less than 1.0 would lead to an increase in the normal stress and a decrease in shear stress. This result likely suggests that the combined effect of fiber misalignment, interfacial debonding, and matrix yielding would be responsible for the failure of uniaxial composites, thereby resulting in a lower than predicted experimental compressive strength. Hahn and Williams (1986) demonstrated that fiber misalignment did have a significant effect on the compressive strength of uniaxial composites. In addition, interfacial bond strength, void content, and matrix nonlinearity have also been recognized as factors influencing compressive strength (Zhang and Latour, 1994).

Medical Applications of Composites

Biomedical Composites in Orthopedic Applications

Biomedical composites have been investigated for different orthopedic applications, including bone fracture fixation devices (internal or external fixation), biodegradable bone screws, bone filling and grafting, total hip replacement, and repair of ruptured tendon or ligament. One of the earliest investigations was the use of CF to reinforce an epoxy resin to form nonbiodegradable internal fracture fixation plates in an attempt to solve the stress-shielding problem under metal fracture fixation plates. The Young's modulus of these composite plates could be tailored to approach that of cortical bone but there were other problems in the clinical application of these fixation plates.

Subsequent work in this area by other researchers looked into other nonbiodegradable composites such as CF/PEEK. This composite has been extensively used in various orthopedic applications. Brantigan et al. (1993) demonstrated successful radiographic results after 2 years when CF/PEEK implant cages were used for posterior lumbar interbody fusion. Clinically, 20 out of 26 patients were categorized as either excellent or good. Only two patients were considered to have poor results, but the reasons were not related to the material. CF/PEEK interbody cages were also used for the treatment of degenerative lumbar spine disorders and successful clinical as well as radiographic results were observed after an average follow-up period of 5.7 years. Definite fusion was observed in 56 out of 57 patients. Pace et al. (2008) reported a study where CF/PEEK was used for acetabular cup. Patients were followed up after 3 years. Harris hip score improved from 52 to 90. Radiographic examination revealed that every patient was stable. One revision surgery was performed due to septic



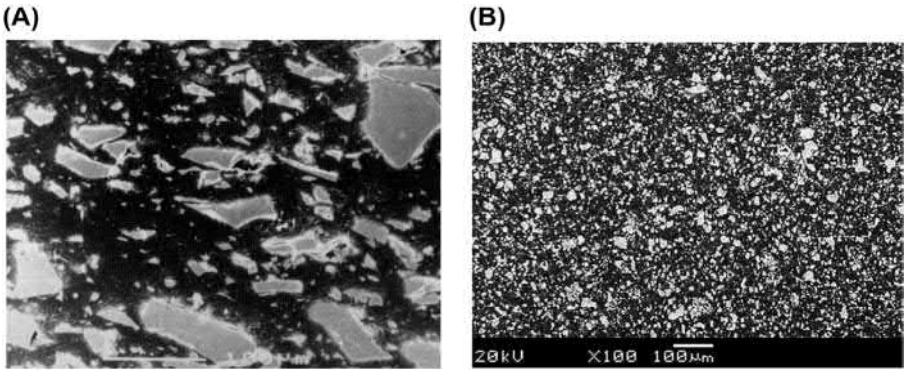
• **Figure 1.3.7.10** Typical tensile curves of HAPEX developed as bone substitutes: HAPEX I (A) and HAPEX II (B).

loosening. Heary et al. (2011) demonstrated excellent clinical and radiographic results in 39 out of 40 patients when CF cages were used for the treatment of thoracolumbar fusion. Misuse or wrong use of CFs to develop composites for orthopedic devices often occurs. For example, a CF-reinforced UHMWPE composite was investigated for the acetabulum cup of hip prosthesis. However, there are major concerns regarding the generation of CF debris during wear of the cup.

Biodegradable composites such as PLLA fiber-reinforced poly(glycolic acid) (PGA) or PCL and self-reinforced poly(D,L-lactic acid)(PDLLA)/PLLA composites are also investigated because they could be processed into the forms of rods, screws, tacks, plates, etc., which can be used in traumatology and orthopedic surgery. Using high-strength and high-modulus CFs to reinforce high-strength polymers can attain the strength of metallic biomaterials with a tailored modulus approaching that of bone. Fibrous composites have also been investigated for the substitution of tendon and ligament. In replacing a ruptured tendon or ligament in the body, some successes were achieved by using tendon/ligament prostheses made of either nonbiodegradable fibrous composites (CF/PTFE, aramid fiber/PE, PET/PHEMA, etc.) or partially degradable composites (CF/PLLA, CF/PU, etc.), which have comparable mechanical properties (elastic properties) to those of native tendon and ligament and also excellent fatigue performance. Problems with abrasion and abrasion products such as brittle ceramic fiber fragments have hindered their development and clinical use.

HA particles have been used as a bioactive and reinforcing phase for high-density polyethylene (HDPE) to produce HAPEX, a bone analog (Bonfield et al., 1998). Numerous bioactive composites consisting of bioactive bioceramic particles and biomedical polymers have been investigated for bone substitution. HAPEX is the first bioactive ceramic–polymer composite that is designed to mimic the structure and match the properties of bone. It is the first successful, commercialized composite for bone tissue substitution in the clinic. It can contain up to 40 vol% of HA with acceptable ductility and machinability when intricate small medical devices are made from it. HDPE was chosen as the matrix material because (1) it is a proven biocompatible polymer widely used in orthopedics, (2) it is a ductile polymer that allows the incorporation of a large amount of bioceramic particles in the system, (3) the polymer having high content of bioceramic particles can still be melt processed using conventional plastics technology, and (4) it is a linear polymer whose molecular chains can be aligned for property enhancement when advanced polymer processing technology is used. HA in the composite provides bone-bonding ability for HAPEX. Like other particle-reinforced composites, with an increasing amount of HA in the composite, the stiffness and strength of HAPEX increase but its ductility drastically decreases (Fig. 1.3.7.10). When the HA content is above 45 vol%, the composite is a very brittle material that is not suitable for bone implants. It has also been shown that to achieve good bioactivity for the composite, HAPEX must have at least 20 vol% of HA. The higher the HA content in the composite, the better the bioactivity of HAPEX.

Implants made of HAPEX can form good bonding with bone within 6 months after implantation. HAPEX has been used for bone substitution such as orbital floor implants and middle ear implants. Hydrostatic extrusion aligns HDPE molecule chains along the extrusion direction, resulting in much improved mechanical properties for HAPEX II. HA particles in HAPEX I and HAPEX II show excellent dispersion and even distribution, which are necessary for their high mechanical and biological performance. Many other bioceramic particle-reinforced composites were investigated for bone substitution, including Bioglass/HDPE, A–W glass-ceramic/HDPE, HA/PSU, and HA/PEEK. Seeking new biodegradable materials for bone tissue repair, many researchers have also investigated biodegradable particulate composites such as HA/PLLA, TCP/PLLA, HA/PHBV, and TCP/PHBV. Natural biodegradable polymers such as collagen and chitosan have also been used to incorporate HA or TCP as bioactive and biodegradable composites.



• **Figure 1.3.7.11** Scanning electron microscopy views of the microstructure of bioceramic particle-reinforced polymer composites: nonbiodegradable Bioglass/high-density polyethylene (A) and totally biodegradable tricalcium phosphate/poly(3-hydroxybutyrate-*co*-3-hydroxyvalerate) (B).

For attaining the desired performance for the composite, no matter what the combination is for the particle reinforcement and matrix and no matter what the fabrication technique is for composite manufacture, the bioceramic particles must be sufficiently dispersed and well distributed in the composite (Fig. 1.3.7.11). For obtaining high load-bearing capabilities, composites of metal matrices instead of polymer matrices are investigated. A typical example is the HA/Ti–6Al–4V composite. This composite can withstand much higher loads than polymer matrix composites because of the load-carrying ability of the metal alloy. However, the interfacial reaction between HA particles and Ti–6Al–4V matrix during composite manufacture involving high temperature is a serious problem. Ceramic matrix composites such as the HA particle–zirconia composite have appeared. But its development lacks sound justification and manufacture of this type of composite possesses particular technical challenges.

A composite of calcium sulfate, poly(D,L-lactide-*co*-glycolide), PGA, and surfactant has been developed and is in clinical use for bone grafting applications. In this case, addition of surfactant has made the composite easier to handle and moldable. In another case, a nanocomposite of calcium sulfate and PLLA was developed; however, it is not extensively used in practice (Mamidwar et al., 2008). An important lesson was that the manufacturing process of the composite had a huge impact on the properties of the composite that was developed. Composites formed by combining calcium sulfate and carboxymethyl cellulose or hydroxymethyl cellulose were also developed and extensively used clinically. Cellulose component mainly helped in the handling properties of the bone graft. A composite of calcium sulfate and PGA has been developed and commercialized by Osteobiologics under the trade name PolyGraft (Dahabreh et al., 2014; Kline et al., 2008). It is available in various forms such as wedges and granules. It has much better mechanical properties compared to calcium sulfate or HA alone. Although composites of bone graft such as calcium sulfate or HA and antibiotics were never approved in the United States, it is fairly common for surgeons to mix the two in the operating room and use them clinically.

Biomedical Composites in Dental Applications

One area where composites are extensively used clinically is dental restorative materials. Such dental composites are usually composites of polymeric acrylic or methacrylic matrix reinforced with ceramic particles. Clinically available formulations are made up of bisphenol-A-glycidyldimethacrylate (bis-GMA) and triethylene glycoldimethacrylate. The manufacturing process is again important as monomer–polymer conversion significantly effects the mechanical and biological properties of the composites. Bridges are made up of composites of carbon and UHMWPE or glass-reinforced polycarbonate (Schedle et al., 1999). Removable prostheses are made up of glass fiber-reinforced polycarbonate. Bone cements are used in orthopedics and dentistry. Usually, bone cement is PMMA powder mixed with a methacrylate-type monomer, which is polymerized during fixation. To increase fatigue life and reduce creep formation, small amounts of Kelvar, carbon, graphite, or ultrahigh molecular weight fibers are added to PMMA-based bone cement (Pillar et al., 1976; Pourdeyhimi et al., 1989).

Alumina micro- or nanoparticle-reinforced bis-GMA-based resins were investigated as new dental filling materials. It was shown that the particulate alumina filler can increase the wear resistance of the new filling material. However, issues relating to bonding of resin to the tooth need to be solved to avoid leakage of hot or cold liquid along the filling material–tooth interface, which can cause severe toothache. For the same purpose, others followed this idea and have produced other hard ceramic particle–resin composites as dental filling materials. Another area of high interest is the polymer fiber-reinforced or toughened denture for elderly dental patients. High-performance PE fibers, either woven or chopped (over 30 vol%), have been used to strengthen and toughen acrylic denture-based resin. The composite dentures have much higher stiffness and strength and do not break into fragments upon high impact. For artificial teeth, dental posts are traditionally made of metals, e.g., Co-Cr and Ti alloys. Along the same rationale for using long-fiber composites for the stem of hip prosthesis, dental posts comprising an epoxy resin matrix and carbon or glass fibers have

been investigated. In addition, finite element analysis indicates that ideal dental posts should possess varied stiffness along their length (with relatively low stiffness at the apical end and high stiffness at the coronal end), which are impossible to achieve using homogeneous materials. Composite dental posts with a specific design can meet this requirement. Overall, dental applications of biomedical composites are not as numerous as in the orthopedic field and hence there is still a large scope for exploration.

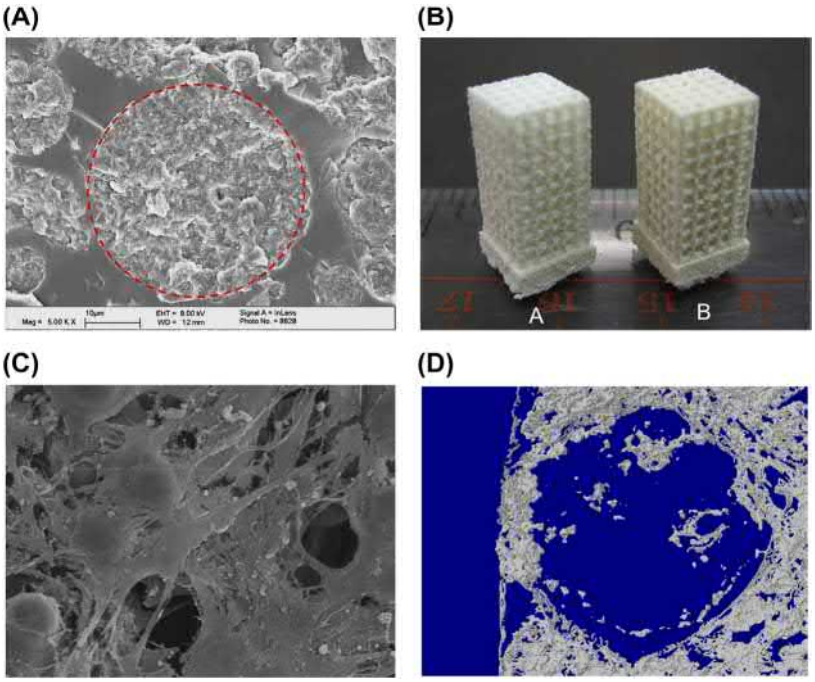
Biomedical Composites for Tissue Engineering

Biomedical composites can play a great role in forming the essential tissue engineering scaffolds. Tissue engineering scaffolds are biodegradable, porous, synthetic extracellular matrices that provide a conducive environment for cells to migrate, adhere, proliferate, and differentiate, leading to new tissue formation and growth in the body. The basic requirements for biodegradable scaffolds include (1) a highly porous body having a 3D, interconnecting pore network structure, (2) a controlled degradation rate, and (3) scaffold degradation and degradation products being unharmful to the tissue and body. Basic scaffolds are simple porous structures made of mostly biodegradable polymers such as PLLA, PLGA, and PCL, with porous metals and ceramics also being investigated. They are useful for regenerating "simple tissues" in the body (human body tissues are never simple). However, for achieving enhanced tissue regeneration or for regenerating complex tissues, advanced, multifunctional tissue engineering scaffolds are needed (Zhao and Wang, 2017).

Biomimetic composites have been investigated for bone tissue engineering. Selection of a proper material in the design of the bone regeneration process has some important implications to maintaining mechanical strength, structural support, and providing the optimal culturing environment for bone formation. The ideal composite for bone regeneration is biocompatible, supports bone formation (osteoconductive), induces bone formation (osteoinductive), is chemically bonded to bone (osteointegrative), is able to support angiogenesis, and is structurally and mechanically compatible to bone (Robinson et al., 2017). The development of bioactive ceramic-polymer composites has been largely inspired by the make-up of the native bone matrix, which is comprised predominantly of a biopolymer or collagen-rich matrix with a controlled dispersion of bone apatite nanoparticles. The native anisotropic microstructure formed by the biopolymer and mineral organization is responsible for the complex mechanical properties of bone and promotes bioactive signaling to stimulate remodeling. Particulate strengthening achieved via the addition of ceramic particles effectively reinforces and stiffens the polymeric matrix, resulting in a superior material for bone scaffolding.

The two most common types of ceramic-polymer composites are calcium phosphate-polymer composites and bioactive glass-polymer composites. Both biodegradable and nondegradable polymers have been explored as the matrix. Given its inherent biomimicry, calcium phosphate-polymer composites have been studied widely for bone regeneration. A range of bioactivity and degradation rates exist for calcium phosphates depending on the Ca/P ratio, crystallinity, and phase purity. Calcium and phosphate ions released from the ceramic serve as building blocks and nucleation sites for mineralization, with both particle size and ceramic degradation rate regulating cell response over time and resultant bone formation. With the increasing understanding of mechanisms underlying bone formation, bioactive materials have been developed to better guide the response of bone-forming cells and promote functional host integration. To this end, incorporation of bioactive glasses (Hench, 1991) into polymer-composite design has also been investigated. Bioactive glasses promote osteointegration by forming a surface calcium phosphate layer, from which bone cells can be remodeled and used to chemically integrate the material with the host bone, with superior bone bonding strength and osteoinductivity when compared to traditional HA. An additional advantage of these materials is the potential to neutralize the acidic degradation products with the alkaline ion released as bioactive glass transforms into calcium phosphate (Lu et al., 2003).

The majority of the earlier designs of ceramic-polymer composites were in the form of cement-like pastes and films, later progressing to 3D porous scaffolds as well as the introduction of ceramic and glass nanoparticles. More recent efforts have focused on recapitulating the native micro- and nanoscale topography and organization of the native bone matrix in ceramic-polymer composite design, with the aid of 3D printing and additive manufacturing. Advanced manufacturing technologies are now increasingly used to fabricate multifunctional composite scaffolds. For achieving enhanced regeneration of bone, nanocomposites, 3D printing, and controlled release of growth factor have been combined to produce advanced bone tissue-engineering scaffolds (Duan and Wang, 2010). First, nanocomposite microspheres comprising bioactive and biodegradable calcium phosphate (Ca–P) nanoparticles and biodegradable PHBV matrix are made. The Ca–P nanoparticles are evenly distributed inside the microspheres (Fig. 1.3.7.12A). Using selective laser sintering (a 3D printing technology), Ca–P/PHBV nanocomposite scaffolds are fabricated from the nanocomposite microspheres (Fig. 1.3.7.12B). Subsequently, the Ca–P/PHBV scaffolds are chemically modified and molecules of bone morphogenetic protein-2 (BMP-2), an osteoinductive factor, are attached to the struts of scaffolds. These 3D printed scaffolds are therefore both osteoconductive (due to the incorporated Ca–P particles) and osteoinductive (due to the attached BMP-2). After scaffold implantation in animal bodies, Ca^{2+}, PO_4^{3-}, and BMP-2 molecules can be gradually released from scaffolds, promoting bone tissue formation. The Ca–P/PHBV nanocomposite scaffolds have significant advantages for bone tissue engineering because of their designed architecture, biodegradability, osteoconductivity, osteoinductivity, and mechanical properties. *In vitro* experiments show that because of the



• **Figure 1.3.7.12** 3D printed Ca–P/poly(3-hydroxybutyrate-*co*-3-hydroxyvalerate) (PHBV) composite tissue-engineering scaffolds: microstructure of a nanocomposite microsphere (A), a photo showing 3D printed PHBV (*left*) and Ca–P/PHBV (*right*) scaffolds (B), mesenchymal stem cells seeded on a Ca–P/PHBV scaffold (C), and a microcomputed tomography image showing bone formation inside and outside a Ca–P/PHBV scaffold (D).

In vitro gradual release of BMP-2, Ca^{2+}, and PO_4^{3-} from nanocomposite scaffolds, human umbilical cord-derived mesenchymal stem cells seeded on scaffolds have proliferated and are induced for osteogenic differentiation (Fig. 1.3.7.12C). After 6 weeks of intraosseous implantation of the advanced nanocomposite scaffolds in animals, new bone forms inside as well as outside the original scaffolds (Fig. 1.3.7.12D).

The composite approach has achieved remarkable success in tissue engineering, particularly for bone tissue regeneration. However, successful tissue engineering strategies do not depend solely on scaffolds and scaffold materials. Cells and various cues (biochemical, topographical, mechanical, etc.) are also important. New manufacturing technologies need to be developed, which can produce directly composite scaffolds incorporated with living cells and delicate biomolecules.

Zhang, G., Latour, R.L., Kennedy, J.M., Schutte, H.D., Friedman, R.J., 1996. Long-term compressive property durability of carbon fiber-reinforced polyetheretherketone composite in physiological saline. Biomaterials 17, 781–789. ceramic-polymer composites.

Chapter Questions

1. A unidirectionally reinforced carbon fiber-polyetheretherketone (CF/PEEK) composite is investigated for the stem of hip prostheses. The composite contains 30% by volume of the carbon fiber. Properties of carbon fiber and PEEK are summarized in the table below.

Table 1 Properties of Carbon Fiber and PEEK

Constituent of the Composite	Property		
	Young's Modulus (GPa)	Tensile Strength (MPa)	Density (g/cm^3)
Carbon fiber	360	1800	2.10
PEEK	5.0	100	1.40

(A) Calculate the Young's modulus and tensile strength of this composite according to the composite theory.

(B) If an elderly man having a body weight of 800N has been implanted with a total hip prosthesis made of this composite and he is walking slowly, what is the maximum load borne by carbon fibers and what is the maximum load applied to the polymer matrix in the stem of the hip prosthesis? (You can assume that the direction of the load applied to the stem is parallel to carbon fibers in the stem.)

Solution:

(A) At V_f = 30%, we have V_m = 1 - V_f = 70%

Young's modulus of the composite:

$$E_c = E_f V_f + E_m V_m = 360\times0.3 + 5.0\times0.7 = 111.5 \text{ GPa}$$

Tensile strength of the composite:

$$\sigma_c = \sigma_f V_f + \sigma_m V_m = 1800\times0.3 + 100\times0.7 = 610 \text{ MPa}$$

(B) Knowing $P = \sigma A$, $L_c = L_f$, $\sigma = E\varepsilon$ and $\varepsilon_c = \varepsilon_f$, the loads shared by carbon fibers and PEEK can be found as

$$P_f/P_c = \sigma_f A_f/\sigma_c A_c = \sigma_f A_f L_f/\sigma_c A_c L_c = \sigma_f V_f/\sigma_c = E_f\varepsilon_f V_f/E_c\varepsilon_c = E_f V_f/E_c$$

During walking, the maximum force in the vertical direction of the hip is typically 5 times the body weight. The load borne by carbon fibers is

$$P_f = P_c E_f V_f/E_c = 5\times800\times360\times0.3/111.5 = 3874 \text{ N}$$

and the load borne by PEEK is

$$P_m = 5\times800 - 3874 = 126 \text{ N}$$

2. As discussed in this chapter, in the *k*-mode microbuckling the compressive strength of a uniaxial fiber embedded in a matrix as predicted by Equation (1.3.7.8) will reduce to that of a single-fiber composite case when the fiber volume fraction (V_f) becomes very small. Referring to Equation (1.3.7.8) and Figure 1.3.7.7, show the following relations

$$\sigma_{f(V_f\to0)} = \frac{E_f t^2}{3} + 2E_m\frac{(1-\nu_m)+\frac{1}{t}+t}{(1+\nu_m)(3-\nu_m)}$$

when $V_f \to 0$, or $\beta \to \infty$.

Solution:

With $V_f \to 0$ or $\beta \to \infty$, by applying the L'Hôpital's Rule with respect to β to the following expressions along with the relationships between the hyperbolic sine/cosine functions and the exponential function, one establishes the following relations

$$\lim_{\beta\to\infty}\frac{2\beta t}{\sinh 2\beta t} = \lim_{\beta\to\infty}\frac{2t}{2t\cosh 2\beta t} = \lim_{\beta\to\infty}\frac{1}{\cosh 2\beta t} = \lim_{\beta\to\infty}\frac{2}{e^{2\beta t}+e^{-2\beta t}} = 0$$

$$\lim_{\beta\to\infty}\frac{2\sinh^2\beta t}{\sinh 2\beta t} = \lim_{\beta\to\infty}\frac{2\sinh^2\beta t}{2\sinh\beta t\cosh\beta t} = \lim_{\beta\to\infty}\frac{\sinh\beta t}{\cosh\beta t} = \lim_{\beta\to\infty}\frac{e^{\beta t}-e^{-\beta t}}{e^{\beta t}+e^{-\beta t}} = 1$$

$$\lim_{\beta\to\infty}\frac{2\cosh^2\beta t}{\sinh 2\beta t} = \lim_{\beta\to\infty}\frac{2\cosh^2\beta t}{2\sinh\beta t\cosh\beta t} = \lim_{\beta\to\infty}\frac{\cosh\beta t}{\sinh\beta t} = \lim_{\beta\to\infty}\frac{e^{\beta t}+e^{-\beta t}}{e^{\beta t}-e^{-\beta t}} = 1$$

To take advantage of these relations, it is necessary to rearrange Equation (1.3.7.8) slightly, hence one has

$$\sigma_f = \frac{E_f t^2}{3} + (1+k)E_m\frac{\frac{2\beta t(1+\nu_m)}{\sinh 2\beta t} + \frac{(1-\nu_m)\sinh 2\beta t}{\sinh 2\beta t} + \frac{2\sinh^2\beta t}{t\sinh 2\beta t} + \frac{2t\cosh^2\beta t}{\sinh 2\beta t}}{(1+\nu_m)\left[\frac{2\beta t(1+\nu_m)}{\sinh 2\beta t} + (3-\nu_m)\right]}$$

$$+ (1-k)E_m\frac{\frac{2\beta t(1+\nu_m)}{\sinh 2\beta t} - \frac{(1-\nu_m)\sinh 2\beta t}{\sinh 2\beta t} - \frac{2\cosh^2\beta t}{t\sinh 2\beta t} - \frac{2t\sinh^2\beta t}{\sinh 2\beta t}}{(1+\nu_m)\left[\frac{2\beta t(1+\nu_m)}{\sinh 2\beta t} - (3-\nu_m)\right]}$$

Plugging in the above derived relationships, one obtains

$$\sigma_f = \frac{E_f t^2}{3} + (1+k)E_m\frac{(1-\nu_m)+\frac{1}{t}+t}{(1+\nu_m)(3-\nu_m)} + (1-k)E_m\frac{(1-\nu_m)+\frac{1}{t}+t}{(1+\nu_m)(3-\nu_m)}$$

Apparently, regardless what the *k* value is, one has

$$\sigma_{f(V_f\to 0)} = \frac{E_f t^2}{3} + 2E_m \frac{(1-\nu_m) + \frac{1}{t} + t}{(1+\nu_m)(3-\nu_m)}$$

By taking the critical value of the above expression with respect to t_{cr} one arrives at the following expression

$$\sigma^{cr}_{f(V_f\to 0)} = \frac{E_f t_{cr}^2}{3} + 2E_m \frac{(1-\nu_m) + \frac{1}{t_{cr}} + t_{cr}}{(1+\nu_m)(3-\nu_m)}$$

This relation supports the converged result for the k=1 and k=–1 cases of microbuckling when $V_f \to 0$, as shown in Figure 1.3.7.7.

3. Use the values provided in Table 1.3.7.1 for a CF/PEEK composite, determine the critical value for the compressive strength of a fiber undergoing microbuckling as predicted by the following expression

$$\sigma^{cr}_{f(V_f\to 0)} = \frac{E_f t_{cr}^2}{3} + 2E_m \frac{(1-\nu_m) + \frac{1}{t_{cr}} + t_{cr}}{(1+\nu_m)(3-\nu_m)}$$

Solution:

For the given expression, its critical value can be determined by finding its minimum with respect to t. So, by taking the first-order derivative of the above expression and setting it to zero, one can find the t_{cr} value for the given E_f, E_m and ν_m: t_{cr} = 0.243. By plugging this t_{cr} value and the known E_f, E_m and ν_m values into the above expression, one arrives at:

$$\sigma_f^{cr} = 17.417 \text{ GPa}$$

4. As shown in Figure 1.3.7.7, for $V_f > 0.13$, the compressive strength of a uniaxial fiber reinforced composite predicted by the k=1 case of the k-mode microbuckling will be the same as that predicted by Rosen's theory. Show that

$$\sigma_{f_{cr}} = \frac{G_m}{V_f(1-V_f)}$$

when V_f is sufficiently large (e.g., $V_f > 0.13$ for CF/PEEK composite).

Solution:

When V_f is sufficiently large, β will be a finite value. In this situation, the critical value of the compressive strength of a uniaxial fiber reinforced composite as predicted by Equation (1.3.7.8) will be reached when $t \to 0$. By applying the L'Hôpital's Rule with respect to t to the following expressions, one establishes the following relations

$$\lim_{t\to 0} \frac{\sinh 2\beta t}{2\beta t} = \lim_{t\to 0} \frac{2t\cosh 2\beta t}{2\beta t} = \lim_{t\to 0} \cosh 2\beta t = \lim_{t\to 0} \frac{e^{2\beta t} + e^{-2\beta t}}{2} = 1$$

$$\lim_{t\to 0} \frac{2\sinh^2 \beta t}{2\beta t^2} = \lim_{t\to 0} \frac{4\sinh \beta t \cosh \beta t}{4\beta t} = \lim_{t\to 0} \frac{\sinh 2\beta t}{2t} = \lim_{t\to 0} = \beta \cosh 2\beta t = \beta$$

$$\lim_{t\to 0} \frac{2t\cosh^2 \beta t}{2\beta t} = \lim_{t\to 0} \frac{\cosh^2 \beta t}{\beta} = \lim_{t\to 0} \left(\frac{e^{\beta t} + e^{-\beta t}}{2}\right) = \frac{1}{\beta} = \frac{1}{\beta}$$

Letting k=1 and rearranging Equation (1.3.7.8), one has

$$\sigma_f^{cr} = \lim_{t\to 0} \sigma f = \lim_{t\to 0} \left[\frac{E_f t^2}{3} + \frac{2E_m \left[(1+\nu_m) + (1-\nu_m)\frac{\sinh 2\beta t}{2\beta t} + \frac{\sinh^2 \beta t}{2\beta t^2} + \frac{2t\cosh^2 \beta t}{2\beta t} \right]}{(1+\nu_m)\left[(1-\nu_m) + (3-\nu_m)\frac{\sinh 2\beta t}{2\beta t}\right]} \right]$$

Plugging in the above derived relationships along with the relationships of $\beta = \frac{1}{V_f} - 1$ and $G_m = \frac{E_m}{2(1+\nu_m)}$, one obtains

$$\sigma_f^{cr} = 2E_m \frac{(1+\nu_m) + (1-\nu_m) + \beta + \frac{1}{\beta}}{(1+\nu_m)[(1+\nu_m) + (3-\nu_m)]} = \frac{E_m}{2(1+\nu_m)V_f(1-V_f)} = \frac{G_m}{V_f(1-V_f)}$$

5. Referring to Figures 1.3.7.6 and 1.3.7.8, find the expression for f_1 when $V_f \to 0$ (or $\beta \to \infty$) for an arbitrary k value ($-1 \le k \le 1$).

Solution:

From Figure 1.3.7.6 one copies the expression for f_1 as follows:

$$f_1 = (1+k)\frac{(1+\nu_m)\beta t^2 + (1-\nu_m)}{(1+\nu_m)[2\beta t(1+\nu_m) + (3-\nu_m)\sinh 2\beta t]} \frac{t\sinh \beta t\cosh \beta t + 2\sinh^2 \beta t}{} + (1-k)\frac{(1+\nu_m)\beta t^2 - (1-\nu_m)}{(1+\nu_m)[2\beta t(1+\nu_m) - (3-\nu_m)\sinh 2\beta t]} \frac{t\sinh \beta t\cosh \beta t - 2\sinh^2 \beta t}{}$$

With some rearrangement one further writes

$$f_1 = (1+k)\frac{(1+\nu_m)\dfrac{\beta t^2}{\sinh 2\beta t} + (1-\nu_m)\dfrac{t\sin\beta t\cosh\beta t}{\sinh 2\beta t} + \dfrac{2\sinh^2\beta t}{\sinh 2\beta t}}{(1+\nu_m)\left[(1+\nu_m)\dfrac{2\beta t}{\sinh 2\beta t} + (3-\nu_m)\right]}$$

$$+ (1-k)\frac{(1+\nu_m)\dfrac{\beta t^2}{\sinh 2\beta t} - (1-\nu_m)\dfrac{t\sin\beta t\cosh\beta t}{\sinh 2\beta t} - \dfrac{2\sinh^2\beta t}{\sinh 2\beta t}}{(1+\nu_m)\left[(1+\nu_m)\dfrac{2\beta t}{\sinh 2\beta t} - (3-\nu_m)\right]}$$

By substituting the limits relations obtained in Question 2 into the above f_1 expression along with some elimination and simplification, one obtains

$$\lim_{\beta\to\infty} f_1 = (1+k)\frac{(1-\nu_m)\dfrac{t}{2}+1}{(1+\nu_m)(3-\nu_m)} + (1-k)\frac{(1-\nu_m)\dfrac{t}{2}+1}{(1+\nu_m)(3-\nu_m)} = \frac{(1-\nu_m)t+2}{(1+\nu_m)(3-\nu_m)}$$

Apparently, the above expression is not a function of k, indicating that when $V_f \to 0$ (or $\beta\to\infty$), the function of f_1 is independent of the k parameter.

6. Referring to Figures 1.3.7.6 and 1.3.7.8, find the expression for f_2 when $V_f \to 0$ (or $\beta\to\infty$) for an arbitrary k value ($-1\le k\le 1$).

Solution:

From Figure 1.3.7.6 one copies the expression for f_2 as follows:

$$f_2 = (1+k)\frac{(1+\nu_m)\beta t + (1-\nu_m)\sinh\beta t\cosh\beta t + 2t\cosh^2\beta t}{(1+\nu_m)\left[2\beta t(1+\nu_m) + (3-\nu_m)\sinh 2\beta t\right]}$$

$$+ (1-k)\frac{(1+\nu_m)\beta t - (1-\nu_m)\sinh\beta t\cosh\beta t - 2t\cosh^2\beta t}{(1+\nu_m)\left[2\beta t(1+\nu_m) - (3-\nu_m)\sinh 2\beta t\right]}$$

With some rearrangement one writes

$$f_2 = (1+k)\frac{(1+\nu_m)\dfrac{\beta t}{\sinh 2\beta t} + (1-\nu_m)\dfrac{\sinh\beta t\cosh\beta t}{\sinh 2\beta t} + \dfrac{2t\cosh^2\beta t}{\sinh 2\beta t}}{(1+\nu_m)\left[(1+\nu_m)\dfrac{\beta t}{\sinh 2\beta t} + (3-\nu_m)\right]}$$

$$+ (1-k)\frac{(1+\nu_m)\dfrac{\beta t}{\sinh 2\beta t} - (1-\nu_m)\dfrac{\sinh\beta t\cosh\beta t}{\sinh 2\beta t} - \dfrac{2t\cosh^2\beta t}{\sinh 2\beta t}}{(1+\nu_m)\left[(1+\nu_m)\dfrac{\beta t}{\sinh 2\beta t} - (3-\nu_m)\right]}$$

By substituting the limits relations in Question 2 into the above f_2 expression along with some elimination and simplification, one obtains

$$\lim_{\beta\to\infty} f_2 = (1+k)\frac{\frac{1}{2}(1-\nu_m)+t}{(1+\nu_m)(3-\nu_m)} + (1-k)\frac{\frac{1}{2}(1-\nu_m)+t}{(1+\nu_m)(3-\nu_m)} = \frac{(1-\nu_m)+2t}{(1+\nu_m)(3-\nu_m)}$$

Apparently, the above expression is not a function of k, indicating that when $V_f \to 0$ (or $\beta\to\infty$), the function of f_2 is independent of the k parameter.

7. The biphasic calcium phosphate (BCP) bioceramic is actually a composite material. Its composition can be 60% of hydroxyapatite (HA) and 40% of tricalcium phosphate (TCP). It is developed for biodegradable implants for human hard tissue repair.

(A) Non-porous BCP rods are now used in *in vitro* degradation tests. It is found that the strength of this BCP decreases to 70% of the original strength after 10 weeks' immersion in phosphate buffered saline solution (PBS). It further decreases to 50% of the original strength after another 10 weeks' immersion. How many more weeks will it take for the strength of this BCP to be reduced to 5% of the original strength? You can assume that the strength (σ) of this BCP follows the relationship shown below:

$$\sigma = \sigma_o + C\ln t$$

where t is the immersion time (week) in PBS, and σ_o and C are constants.

(B) The degradation rate of BCP can be controlled by changing proportions of HA and TCP in the BCP. In order to increase the degradation rate of BCP, do you need to increase or decrease the percentage of TCP in BCP? Provide the reason for your decision.

Solution:

(A) Knowing

$$\sigma = \sigma_o + C\ln t$$

by assuming the original strength of BCP before degradation tests as σ_i

we have

$$0.70\sigma_i = \sigma_o + C\ln 10 = \sigma_o + 2.303C$$

and

$$0.50\sigma_i = \sigma_o + C\ln 20 = \sigma_o + 2.996C$$

By taking the difference of the two above equations, we have

$$0.20\sigma_i = -0.693C$$

This leads to

$$C = -0.289\sigma_i$$

and

$$\sigma_o = 0.70\sigma_i - 2.303C = 1.366\sigma_i$$

We can calculate the time required ($t_{0.05}$) for the strength of BCP to be reduced to 5% of the original strength by solving the following equation:

$$0.05\sigma_i = 1.366\sigma_i - 0.289\sigma_i \ln t_{0.05}$$

By elimination, we then have

$$\ln t_{0.05} = 1.316 / 0.289 = 4.554$$

therefore

$$t_{0.05} = 95.01 \text{ weeks}$$

$$t = 95.01 - 24 = 75.01 \text{ weeks}$$

that is to say, it would take another 75 weeks for the BCP rods to degrade to 5% of the original strength.

(B) Increase the amount of TCP in BCP will do.

HA is perceived to be stable in the human body environment and TCP is a proven biodegradable bioceramic. Increasing TCP in BCP enhances biodegradation of BCP.

1.3.8A
Microparticles

YANG LI, DANIEL S. KOHANE

Laboratory for Biomaterials and Drug Delivery, Department of Anesthesiology, Division of Critical Care Medicine, Boston Children's Hospital, Harvard Medical School, Boston, MA, United States

Introduction

Particulate drug-delivery systems (DDSs) can be advantageous for delivering therapeutic compounds, for local and systemic effects, providing extended duration of action, reduced systemic (although perhaps not local) toxicity, and improved patient compliance (Tiwari et al., 2012; Uhrich et al., 1999). Over the past several decades, particulate drug-delivery systems have gone from being scientific curiosities to areas of very active research interest, to clinical applications. Microparticles fabricated from natural or synthetic polymers have been used in a wide range of biomedical applications including drug delivery, molecular imaging, and immune adjuvants.

In general, the term "microparticle" refers to particles whose dimensions range from 1 to 1000 μm. There are no clear universally recognized cut-offs to differentiate microparticles from nanoparticles. The larger the particles are, the more likely they behave as microparticles (as will be discussed below), and require similar fabrication processes (Kohane, 2007).

This chapter outlines key concepts in the design of polymeric microparticles for biomedical applications. An overview of commonly used materials for the synthesis of microparticles is provided. Classic formulation and characterization techniques in the preparation of microparticles are covered. The mechanism of drug release from microparticles is summarized. This chapter also discusses several microparticle-based drug-delivery systems and analyzes the features that lead to success. This chapter emphasizes microparticles as drug-delivery systems for biomedical applications. Their use as embolic materials (Matsumaru et al., 1997), structural materials (Mikkelsen et al., 2017), radiotherapeutic agents (Hamoudeh et al., 2008), etc. is covered elsewhere, as are their applications in pet care (Singh and T O'Hagan, 2003), food science (Gharsallaoui et al., 2007), agriculture (Asrar et al., 2010), cosmetics (Li et al., 2011), and environmental remediation (Wang et al., 2008).

Why Size Matters

Particle size has a direct impact on the potential routes by which particles can be delivered. Perhaps the most notable limitation is that larger vehicles cannot be delivered directly into the circulation (e.g., intravenously), because of concerns over embolic phenomena (obstruction of blood vessels). Therefore, most intravenously delivered particles tend to be nanoscale. Microparticles tend to be depot formulations, taken orally, deposited on mucosae (e.g., inhaled), or injected into tissue (subcutaneous, intramuscular, etc.). From those sites, the microparticles release drugs to achieve effects locally (e.g., local anesthesia, bronchodilation) or systemically (e.g., growth hormone, antipsychotics). Particle size also has practical implications. For example, larger particles are more likely to clog needles, or settle in a solution intended for injection.

Size has a major impact on particles' abilities to cross biological barriers (Yang et al., 2017). Barriers can be large and obvious like skin, or finer structures like epithelia, that limit access to organs e.g, the blood–brain barrier (Chen and Liu, 2012). Mucus or loose connective tissue can be barriers. In general, microscale devices will not cross these barriers spontaneously; they have to be injected across them. As a corollary to that, microparticles injected into a tissue have a much greater tendency to remain where injected than do nanoscale devices (Kohane et al., 2006). Larger particles are less likely than smaller ones to be cleared from the bloodstream by the kidney, or to leave the bloodstream and enter tissues with highly permeable endothelia (e.g., tumors).

Microparticles are less likely to be able to penetrate into cells than nanoparticles. One exception to that is with phagocytic cells such as neutrophils and dendritic cells, which can ingest particles up to 10 μm in diameter (Tabata and Ikada, 1988). The fact that microparticles can only be taken up by such cells—which often have immunological roles—has been exploited to provide passive targeting to phagocytic cells, e.g., for vaccines. The nature of the cellular inflammatory response is also determined by particle size. While smaller particles can be ingested by the inflammatory cells that arrive at the site of injection, larger ones cannot and tend to become walled off by a syncytium of monocytes—the giant foreign body cells (Anderson, 1994).

Size affects many particle properties that are important for their function as drug-delivery systems, including drug loading, pharmacokinetics, and degradation rate. The surface area to volume ratio of particulate systems is inversely proportional to the diameter. Consequently, smaller particles tend to release encapsulated drugs more rapidly, both during some types of production processes (e.g., emulsion-based production) and after administration. Water will penetrate into smaller particles more rapidly, which accelerates drug release and—in particles that can be degraded hydrolytically—degradation.

Materials for the Synthesis of Microparticles

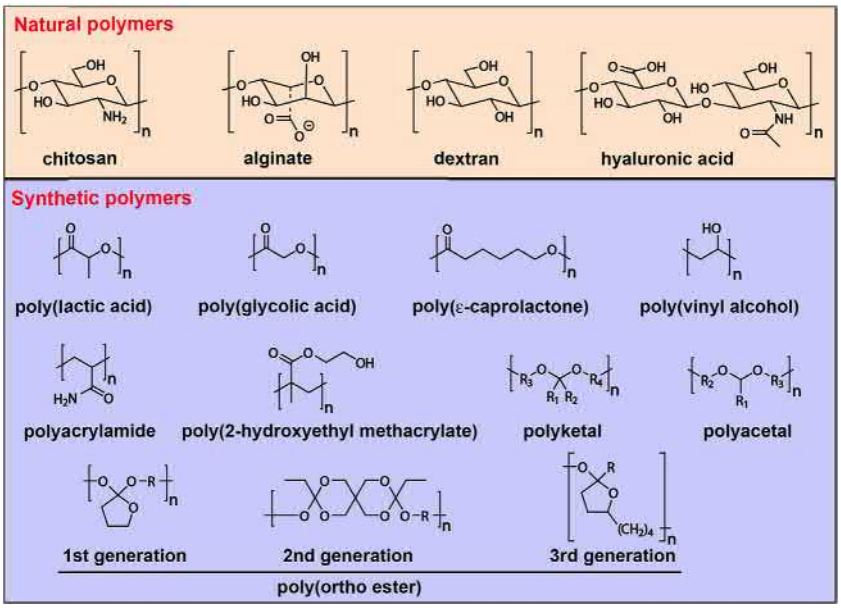
The composition of materials used for the fabrication of microparticles determines the mechanism and duration of drug release (Uhrich et al., 1999). Microparticles can be readily prepared with polymers or nonpolymeric materials by a variety of well-established formulation methods. Although there are examples of nondegradable polymeric microparticles (Kawashima et al., 1992; Ting et al., 1992; De Ascentiis et al., 1995; Köse et al., 2003; Kunioka and Doi, 1990; Chen and Tong, 2012), most microparticles for drug delivery are fabricated with biodegradable materials, especially degradable polymers. Commonly used polymers for the fabrication of microparticles fall into two categories: natural polymers and synthetic polymers (Fig. 1.3.8A.1).

Natural Polymers

Natural polymers have been widely applied in biomedical applications due to their intrinsic biocompatibility. Natural polymers like polysaccharides are abundant in nature, and are often inexpensive, nontoxic, and biodegradable, making them useful building blocks for the design of biomaterials including microparticles (Yang et al., 2015). Their production often does not require synthetic chemistry. Many natural polymer-derived self-assemblies have porous structures, which can be beneficial for drug encapsulation and release. Natural polymers can also be easily processed (Dang and Leong, 2006) and chemically modified (John and Anandjiwala, 2008). Polysaccharides usually contain multiple free carboxyl, hydroxyl, and amino groups which provide reactive sites for chemical modification and functionalization such as oxidation, esterification, amidation, and sulfation (Mizrahy and Peer, 2012). The hydrophobicity, surface chemistry, and adhesiveness of polymers can be tailored for the delivery of various drugs (Lehr et al., 1992; Surini et al., 2009).

Chitosan. Chitosan is a linear polysaccharide composed of β-(1–4)-linked D-glucosamine and N-acetyl-D-glucosamine randomly distributed within the backbone (Bhattarai et al., 2010). Chitosan is obtained by deacetylation of chitin, a main component of the exoskeleton of crustaceans. It has been approved by the Food and Drug Administration (FDA) for use in wound dressings (Wedmore et al., 2006). Chitosan is generally believed to have good biocompatibility (Croisier and Jérôme, 2013), although adverse tissue reactions have also been reported (Yeo et al., 2006). Chitosan is positively charged at physiological pH due to the protonation of primary amines, which facilitates its adherence to negatively charged tissues such as mucosal surfaces (He et al., 1998). Positively charged chitosan has been used to deliver payloads with negative charges, such as nucleic acids and some proteins (Bhattarai et al., 2010).

The degradation of chitosan microparticles can be accelerated by increasing the hydrophilicity of the chitosan backbone (Prashanth and Tharanathan, 2007), decreasing deacetylation (Tomihata and Ikada, 1997), decreasing molecular weight



• **Figure 1.3.8A.1** Structures of commonly used natural and synthetic polymers for the fabrication of microparticles.

(Zhang and Neau, 2001) and by chemical modification [e.g., PEGylation (Cui et al., 2012)]. The degradation rate of chitosan microparticles (1–10 μm) can also be fine-tuned by incorporation of electrostatic cross-linkers (Mi et al., 2002). Chitosan microspheres have been extensively used in drug delivery. For example, chitosan microparticles smaller than 20 μm have been used to encapsulate the antiviral drug acyclovir (Genta et al., 1997). Compared to free acyclovir, microencapsulation significantly prolonged the release of acyclovir following a single instillation into the conjunctival sac.

Alginate. Alginate is a linear anionic polysaccharide copolymer composed of 1,4-linked β-D-mannuronic acid (M) and α-L-guluronic acid (G) residues. It is obtained primarily from brown seaweed and bacteria (Lee and Mooney, 2012). Ionic bridges between divalent cations like Ca^{2+} and the G monomers of alginate can effective cross-link alginate chains to generate hydrogels and scaffolds. The mechanical rigidity, pore size, and degradation rate of ionically cross-linked alginate microspheres can be easily tuned by altering the cation to monomer ratio or M to G ratio (Lee and Mooney, 2012). Alginate is often combined with other polymers such as chitosan to generate a more rigid matrix for prolonged release of entrapped payloads (Ribeiro et al., 2005). Alginate has been used in drug delivery due to its biocompatibility, relatively strong mucosal adhesion, and abundance in nature (Lee and Mooney, 2012). For instance, alginate microspheres with diameters ranging from 20 to 300 μm have been designed to protect insulin from degradation by the harmful pH and enzymes in the gut (Silva et al., 2006).

Dextran. Dextran is a polysaccharide composed of glucan with side chains attached to the 3-positions of the backbone glucose units (Hovgaard and Brøndsted, 1995). Dextran can be produced by several bacterial stains, such as *Leuconostoc mesenteroides* (Suarez et al., 2013; Cheung et al., 2005). Dextran is available in various molecular weights, with differing degradation rates (Stenekes et al., 1998). Dextran microparticles have been used for encapsulation and sustained release of various payloads, such as chemotherapeutics (Cheung et al., 2005), proteins (Franssen et al., 1999), and nucleic acids (Cohen et al., 2010). Dextran can be easily modified via its reactive hydroxyl groups, e.g, by acetylation. For example, acetylated dextran microparticles 1–3 μm in diameter enabled prolonged release of protein antigens over 42 days (Chen et al., 2018).

Other natural materials. Many other natural materials have also been investigated for the preparation of microparticles. For example, collagen microparticles have been used for the delivery of glucocorticosteroids (Berthold et al., 1998) and lipophilic drugs (Swatschek et al., 2002). Hyaluronic acid microparticles have been studied to deliver biomolecules (e.g, recombinant human growth hormone) (Kim et al., 2005) and antibiotics (Park et al., 2004).

Synthetic Polymers

Progress in the methodology of polymer synthesis (Hawker et al., 2001), especially metal-free polymerization (Treat et al., 2014), has markedly facilitated the preparation of synthetic polymers (Ueda et al., 2005). Synthetic polymers can be prepared in a controlled manner, resulting in materials with well-defined compositions, low polydispersities, and predetermined molecular weights (Campos et al., 2013). By choosing appropriate monomers with specified physiochemical properties such as hydrophobicity or charge, polymers can be specifically designed for the delivery of various payloads ranging from hydrophobic or hydrophilic small molecules, proteins, and DNA (Duncan et al., 2006). Synthetic smart polymers have enabled triggerable drug release from microparticles (Schmaljohann, 2006; Haining et al., 2004). Although microparticles are predominantly prepared from degradable polymers, nondegradable polymers with high mechanical strength have also been used for the fabrication of microparticles for long-term use, such as orthopedic (Yaszemski, 2003) and dental applications (Fu and Kao, 2010; Cherng et al., 2013).

Poly(α-hydroxy acid). The best-known members of this family of molecules are composed of varying proportions of lactic and glycolic acids. Poly(lactic-*co*-glycolic acid) (PLGA) refers to a copolymer of lactic acid and glycolic acid (Makadia and Siegel, 2011). Hydrolysis of ester linkages leads to degradation into lactic and/or glycolic acids, which are natural products of human metabolism. PLGA has been approved by the United States Food and Drug Administration (FDA) and the European Medicines Agency (EMA) for use in a wide range of applications (Han et al., 2016). It has been extensively investigated for the delivery of nucleic acids, proteins, and peptides, and hydrophilic and hydrophobic small-molecule drugs (Makadia and Siegel, 2011).

Drug release from PLGA microparticles occurs via diffusion and homogeneous bulk erosion of the matrix (Klose et al., 2006). Drug release from PLGA microparticles can be extended by increasing the molecular weight of PLGA polymers (Klose et al., 2006). Lactic acid is more hydrophobic than glycolic acid because it has a methyl substituent at the α-carbon of glycolic acid rather than a hydrogen. As a result, increasing the molar ratio of lactic acid in PLGA polymers reduces their capability to absorb water molecules and decreases their degradation rate (Visscher et al., 1985; Visscher et al., 1986; Visscher et al., 1988).

Poly(ε-caprolactone) (PCL). Poly-ε-caprolactone (PCL) is an aliphatic polyester which is usually synthesized by ring-opening polymerization of **ε**-caprolactone using a wide range of catalysts (Chasin, 1990). The degradation rate of PCL is slow due to its hydrophobicity and high crystallinity (Sinha et al., 2004; Kweon et al., 2003). The hydrolytic degradation of PCL microspheres can proceed via both surface and bulk erosion pathways (Woodruff and Hutmacher, 2010). Increasing the molecular weight of PCL polymers decreases the drug release rate from PCL-based devices (Woodruff and Hutmacher, 2010). Modulation of porosity has also been used to alter the degradation of PCL microparticles. Strong hydrogen bonding between the encapsulated drug and the PCL matrix can further extend the duration

of drug release (Rai et al., 2016). PCL microparticles have been widely used for drug-delivery applications (Woodruff and Hutmacher, 2010). For example, 100 μm PCL microspheres showed sustained release of the antibiotic vancomycin over 50 days (Rai et al., 2016). Albumin-loaded PCL microparticles 30 μm in diameter exhibited burst release within the first 24 h followed by continuous release over 28 days (Youan et al., 1999).

Poly(ortho ester) (POE). Poly(ortho esters) (POEs) are another class of synthetic polymers designed specifically to inhibit drug release by diffusion and to only allow drug release after the hydrolysis of polymer chains on the surface of particles (Heller et al., 2002). POEs can be readily synthesized by addition of diols or polyols to diketene acetals (Heller, 1993). Poly(ortho esters) are surface-eroding polymers (Heller, 1985). The drug release duration from POE microparticles can be altered by changing the molecular weight and hydrophilicity of the diol monomers (Heller and Barr, 2004). Modification of the POE backbone with lactic acid or glycolic acid increases the degradation rate (Heller et al., 2002). POE microparticles have been used to deliver various payloads including hydrophobic (Deng et al., 2003) and hydrophilic (Schwach-Abdellaoui et al., 2002) drugs, proteins (van de Weert et al., 2002), and nucleic acids (Wang et al., 2004). For example, POE microparticles have shown continuous release of entrapped albumin for over 40 days. Poly(ortho ester) microspheres have been designed to protect loaded DNA from degradation and improve uptake by phagocytic antigen-presenting cells (Wang et al., 2004).

Polyanhydrides. Polyanhydrides are hydrophobic polymers with water-sensitive linkages, which can readily react with water molecules to form carboxylic acids (Rosen et al., 1983). They can be synthesized from aromatic or aliphatic diacids by many methods, including melt condensation, ring opening polymerization, and dehydration (Leong et al., 1987). The degradation of polyanhydride particles is believed to occur through surface erosion, and release kinetics can be close to zero-order (Rosen et al., 1983). The degradation rate can be controlled by changing the polymer composition. Polyanhydrides synthesized with more hydrophobic monomers have slower erosion by reducing water penetration. Aromatic polyanhydrides have much slower degradation compared to aliphatic ones (Leong et al., 1985). Polyanhydrides are FDA approved for use in humans (Katti et al., 2002; Kumar et al., 2002) and have been extensively studied for drug delivery (Mathiowitz et al., 1997).

Polyacetals. Polyacetals and polyketals are acid-labile polymers in which two ether bonds are connected to the same carbon atom. Their pH-triggered degradation is of interest since acidosis is associated with many diseases such as cancer and inflammatory diseases (Heffernan and Murthy, 2005). Degradation of ketal bonds produces neutral products (ketones and diols) instead of acidic ones (Lee et al., 2007). Polyketal microparticles have been used to deliver siRNA (Lee et al., 2009), DNA (Goh et al., 2004), and proteins (Kumar et al., 2002; Lee et al., 2007; Heffernan et al., 2009) for the treatment of acute inflammatory disease, ischemic heart disease, and cancer, respectively. Conventional polyketal particulate formulations have relatively short durations of drug release. Microparticles prepared from an estradiol–polyketal conjugate—in which the drug was incorporated into the polymer backbone—showed increased loading efficiency and significantly prolonged drug release (Guo et al., 2016).

PEGylation. Poly(ethylene glycol) (PEG) has been one of the most widely used polymers for biomedical applications including microparticle-based drug-delivery systems, due to its biocompatibility and low immunogenicity (Wattendorf and Merkle, 2008). Due to its neutral charge and hydrophilicity, PEG has been extensively used in tuning the loading efficiency and hydrolytic degradation rate of microparticles. For example, in the preparation of microparticles with diameters ranging from 2 to 10 μm for the delivery of ovalbumin, blending PLGA with poly(ethylene glycol) increased the protein entrapment fourfold (Yeh et al., 1995).

Smart polymers. Smart polymers are designed to undergo changes in conformation, phase, integrity, and volume due to physical, chemical, or biological changes (stimuli) in the surrounding environment (Aguilar and San Román, 2014). There has been considerable interest in the development of drug delivery systems made of such "smart" polymers (Liu et al., 2016), where the release of payload can be accelerated or slowed as a result of stimuli. There are numerous smart polymers for biomedical applications (Mura et al., 2013; Bajpai et al., 2008); here we will focus on pH- (Haining et al., 2004) and thermo-responsive polymers due to their prevalence in the field (Oh et al., 2008; Lyon et al., 2009).

Local pH can vary in different organs, tissues, and cellular compartments (Lu et al., 2017). pH-responsive polymers can allow the fabrication of devices that are intact (and don't release drug) at one pH, but swell or degrade or dissolve at another pH (and release drug). For example, pH-responsive poly(acrylic acid) microspheres 200–300 μm in diameter have been developed to deliver the antiinflammatory drug diclofenac sodium (DS) to the intestines following oral administration (Kurkuri and Aminabhavi, 2004). In the acidic environment of the stomach, the acrylic acid remains in a neutral, protonated state, and the microparticles therefore remain intact, preventing drug release. In the relatively alkaline intestine, the acrylic acid is deprotonated and the particles swell due to increased hydrophilicity and electrostatic repulsion, which induces the accelerated release of payload (Kurkuri and Aminabhavi, 2004). In another example, particles with an acid-labile polymer were used to produce 4–6 μm microparticles carrying a peptide antigen for a vaccine (Haining et al., 2004). Phagocytosis of the particles by antigen-presenting cells into the acidic environment of the phagosome led to rapid intracellular release of the antigen, enhancing antigen presentation and cytotoxic T lymphocyte responses (Haining et al., 2004).

Thermo-responsive polymers can undergo a dynamic phase transition as a result of a temperature-dependent

change in the hydrogen bonding network (Ward and Georgiou, 2011), usually called a "solution–gel transition" (Jeong et al., 2012). Temperature-induced transition from the solution state to the gel state may significantly decrease the release of encapsulated payloads. In one relatively common application, polymers have been made which are liquid at a lower temperature (e.g., room temperature) but become gel-like at a higher temperature (e.g., body temperature); this is referred to as reversed thermal gelation. Thus, when injected into the body, the polymers are heated above a given temperature (the lower critical solution temperature, LCST) and become gel-like, and, being more viscous, slow the release of drugs. For example, 1–3 μm N-isopropyl acrylamide (NIPAAm) microgels with an LCST of 32° enabled sustained release of fibroblast growth factor over 14 days (Joshi et al., 2013). Thermo-responsive microgels that undergo volume expansion at higher temperatures (above an upper critical solution temperature, UCST) have also been described (Serrano-Ruiz et al., 2013). These ~5 μm spherical microgels, composed of random copolymers of acrylic acid (AAc) and acrylamide (AAm), swelled by 60% when heated from 37 to 45°C.

Other degradable synthetic polymers. Many other biodegradable polymers have been synthesized for the fabrication of microparticles; we provide a few examples here. Poly(vinyl alcohol) (PVA) is a swellable hydrophilic polymer widely used for medical applications such as contact lenses, implants, and artificial organs (Baker et al., 2012). PVA microparticles 150–1400 μm in diameter have been studied for the prolonged release of proteins (Ficek and Peppas, 1993). Poly(2-hydroxyethyl methacrylate) (PHEMA) has been widely used in biomedical applications, such as contact lenses (Nicolson and Vogt, 2001) and implants (Chirila et al., 1993). Mucoadhesive PHEMA microspheres 300–400 μm in diameter have been studied for prolonged release of protein drugs to the intestine (Lehr et al., 1992). Poly(3-hydroxybutyrate-co-3-hydroxyvalerate) (PHBV) microspheres have also been studied for the delivery of chemotherapeutics (Khang et al., 2001) and antibiotics (Sendil et al., 1999).

Nonpolymeric Materials

Microparticles can also be prepared from nonpolymeric materials. We will focus on liposomes and lipid microparticles here since they are most extensively investigated for biomedical applications.

Liposomes are spherical particles composed of phospholipid bilayers. They can be smaller than 100 nm in diameter (Kirby et al., 1980), or tens of μm across (Akashi et al., 1996). Liposomes have been successfully translated into clinical use due to their biocompatibility (Bulbake et al., 2017), and can be used to encapsulate hydrophilic drugs within the inner water phase and hydrophobic drugs within the lipid membranes (Sharma and Sharma, 1997). Liposomes have been used for the encapsulation and release of various payloads, including chemotherapeutics (Barenholz, 2012), protein drugs (Tan et al., 2010), and nucleic acids (Balazs and Godbey, 2011). Drug release from liposomal carriers can be tuned by changing the composition of phospholipids (Gabizon et al., 1990) and incorporation of cholesterol (Coderch et al., 2000). Coencapsulation of drugs and sensitizers enabled drug release from liposomes that can be triggered by external stimuli such as light and ultrasound (Rwei et al., 2015; Zhan et al., 2015; Rwei et al., 2017).

Lipid vesicles consist of a hydrophobic core surrounded by a layer of surfactant (Jaspart et al., 2005). Various lipids can be used for the fabrication of solid lipid microparticles, including triglycerides, fatty acids, steroids, or a combination of these (Scalia et al., 2015). A hydrophobic payload is dispersed in the solid lipid matrix (Jaspart et al., 2007). Solid lipid microparticles can be well tolerated in the body since they are composed of biocompatible and degradable lipids. Naturally occurring surfactants such as phosphatidylcholine and bile acids are usually used to minimize potential safety concerns. Inflammation may occur in the surrounding tissues following subcutaneous administration of lipid particles (Reithmeier et al., 2001).

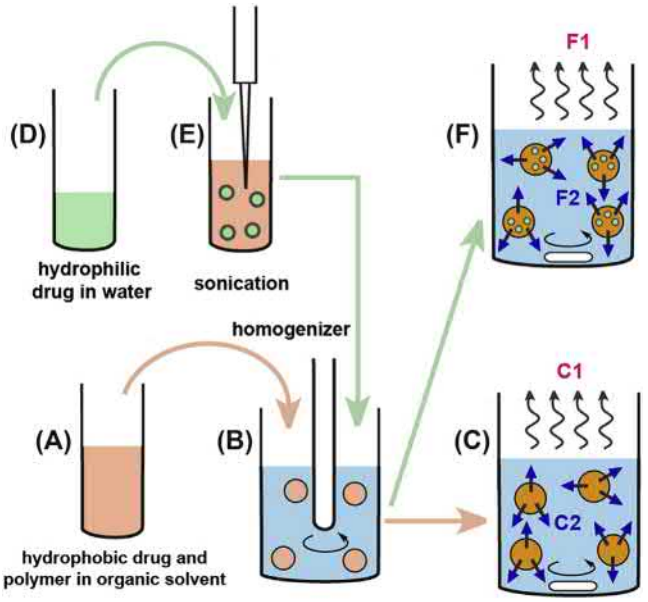
Microparticle Preparation

Many methods have been described for the fabrication of microscale particulate systems include single and double emulsion, coacervation, and spraying drying. Here we described some of the more commonly employed ones.

Single and double emulsion. Emulsification followed by solvent evaporation (or extraction into a second solvent) is one of the most commonly used techniques in microparticle preparation, particularly for drug encapsulation (Fig. 1.3.8A.2) (Lee et al., 2016). The polymer, along with a drug, is dissolved in solvent. The solution of drug and polymer is then dispersed (by homogenization or another form of mechanical agitation) in an immiscible liquid: e.g., an organic solvent, or "oil," in water (O/W emulsion). In this section, we will focus on the O/W emulsion, but an analogous approach disperses water in the oil [W/O emulsion (Xu et al., 2012)]. The O/W method is generally used for the microencapsulation of hydrophobic drugs, and sometimes for hydrophilic ones. (To encapsulate hydrophilic drugs using the O/W method, either a double emulsion [W/O/W] method is used, or solid forms of the hydrophilic drug are dispersed in the oil phase (Thomas et al., 2004).

The dispersion described above forms emulsion droplets. PLGA microparticles can be prepared by O/W emulsion. To prevent droplet coalescence, surfactants such as polyvinyl alcohol are used, and the emulsions are continuously stirred.

In an O/W system (e.g., PLGA and hydrophobic drug both dissolved in an organic solvent dispersed in water), microparticles harden as the volatile organic solvent diffuses out of the droplets. Solvent evaporation is often performed at atmospheric pressure, or can be accelerated by use of negative pressure and/or heating. The solvent can also be extracted



• **Figure 1.3.8A.2** Example of microsphere production by the emulsion system. (A–C) The single emulsion system, for encapsulating hydrophobic drugs. (A) A hydrophobic drug and polymer are dissolved in an organic solvent. (B) They are then poured into an aqueous solution of a surfactant [poly(vinyl alcohol)] under agitation, forming droplets (i.e., an emulsion) of organic solvent (with drug and polymer) dispersed in water (O/W). (C) The droplets in the emulsion are allowed to harden, by solvent evaporation (C1) or extraction (C2) under gentle agitation. (D–F) The double emulsion system, for coencapsulating hydrophilic drugs. (D) A hydrophilic drug is dissolved in an aqueous solution. (E) It is then mixed under agitation with the solution in (A), forming a primary emulsion (W/O) of aqueous droplets dispersed in organic solvent. This emulsion is then treated as in step (B), forming the secondary emulsion of droplets of organic solvent (with solutes) containing aqueous droplets (with solutes) as shown in (F); W/O/W. The droplets in the emulsion are allowed to harden by solvent evaporation (F1) or extraction (F2) under gentle agitation. O = oil, i.e., organic solvents immiscible with water; W = water, i.e., aqueous solvents.

by introducing a second liquid into the external phase, into which the first solvent is miscible, but the polymer and drug are not soluble. This process is termed solvent extraction. An example of this approach is placing isopropyl alcohol in the external aqueous phase surrounding an O/W emulsion; the methylene chloride in the internal organic phase is miscible in it and will be extracted, but PLGA is not and will remain in the nascent particle. With some drugs (e.g., relatively hydrophilic ones), acceleration of hardening can greatly improve drug loading by entrapping drugs before they can partition into the external aqueous phase. However, rapid solvent evaporation often results in more porous microparticles.

The outcome of particle production by emulsification is affected by a wide range of parameters, including the geometry of the system, the concentration of each ingredient, polymer molecular weight, solution viscosity, method and speed of solvent extraction, emulsifier type and concentration, osmolarity and pH of the external phase, and others. The effects of the method of mechanical agitation are particularly obvious. For example, the speed of homogenization is inversely related to the size of the resulting particles, and to the polydispersity of size (i.e., faster homogenization yields smaller but more uniform particles).

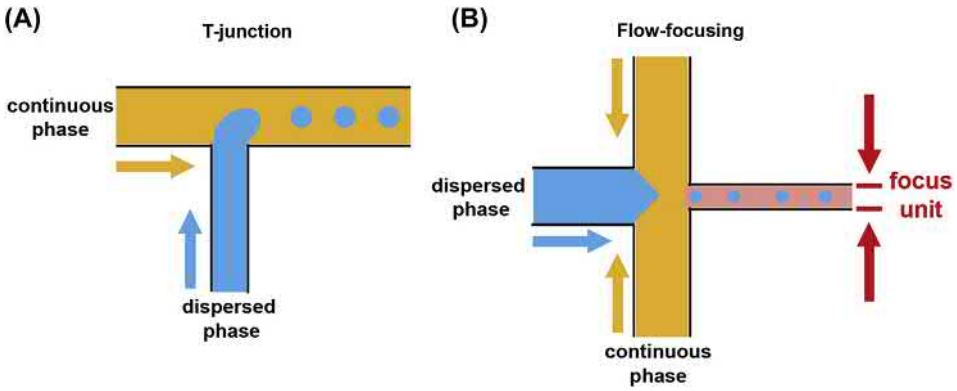
The double emulsion process or water-in-oil-in-water (W/O/W) method is often used for the encapsulation of hydrophilic drugs of all sizes. The therapeutic payload is dissolved in water, which is then dispersed in an organic solvent (oil) containing a polymer (and optionally hydrophobic drugs), forming a primary emulsion (Dorati et al., 2008). That emulsion is then dispersed in an aqueous phase, forming a secondary emulsion (W/O/W). The double emulsion system is otherwise analogous to the single emulsion system.

Microfluidic emulsion. Microparticles prepared by emulsification may be relatively polydisperse in size (Sansdrap and Moës, 1993). Microfluidic technologies offer precise control over the flow rate of fluid, which facilitates the continuous, reproducible, scalable production of microparticles with precise tunable compositions, structures, and polydispersities (Wang et al., 2013; Duncanson et al., 2012; Wang et al., 2017).

The generation of microparticles involves the formation of a dispersed phase (containing drug and polymer) in an immiscible continuous phase by a device with either a T-junction or a flow-focusing nozzle (Fig. 1.3.8A.3). The viscous shear force in the T-junction breaks up the immiscible two-phase mixture into droplets (Li et al., 2018). With flow-focusing, the dispersed phase is surrounded by the continuous phase before going through a focus unit with a diameter smaller than that of the channel providing the dispersed, which enhances the viscous shear forces and enables the formation of droplets (Li et al., 2018).

Coacervation phase separation. Coacervation relies on the changes in solubility of polymers, leading to phase separation and microparticle formation (Alvim and Grosso, 2010; Reverchon et al., 2008) (Fig. 1.3.8A.4). Polymers are dissolved in an organic solvent, in which drugs are dispersed in aqueous droplets (Fig. 1.3.8A.4A). A change of solution conditions [e.g., mixing with another component (Yeo et al., 2005) or changing the solvent system (Kaibara et al., 2000) so that the polymer(s) are no longer soluble] leads to the formation of polymer droplets (Fig. 1.3.8A.4B). These polymer droplets are adsorbed onto the surface of the aqueous (drug) droplets and coalesce into a coating (Fig. 1.3.8A.4C). Microparticles are obtained after rigidification of polymer droplets by washing, centrifugation, and lyophilization (Fig. 1.3.8A.4D). In a typical coacervation process for the encapsulation of proteins into PLGA microparticles (Nihant et al., 1995), the PLGA was first dissolved in methylene chloride. An aqueous solution of albumin was dispersed in the PLGA solution leading to the formation of albumin droplets. A polymer (silicone oil) immiscible with the PLGA solution was added to the dispersion, which caused the formation of PLGA droplets and its adsorption onto the surface of the albumin droplets. Albumin-loaded PLGA microparticles were obtained by washing with heptane, centrifugation, and lyophilization.

Coacervation has a relatively high loading efficiency. It can be operated at low temperature, which is particularly suitable for the encapsulation of sensitive payloads like



• **Figure 1.3.8A.3** Schematic illustration of chip designs for microfluidic devices. (B) Formation of polymer droplets (blue) by changing solution conditions (green). (C) Adsorption of polymer droplets onto the surface of drug droplets. (D) Rigidification of polymer droplets and formation of microparticles by washing, centrifugation, and lyophilization.

• **Figure 1.3.8A.5** Schematic illustration of microparticle production by spray drying. A mixture of drugs and excipients is sprayed through a nozzle into a chamber where hot air evaporates the solvent and leads to the formation of microspheres.

insulin (Black et al., 2014). Microencapsulation via coacervation phase separation has been used for the delivery of various payloads, including hydrophilic drugs (Thote et al., 2005), hydrophobic drugs (Dong and Bodmeier, 2006), and proteins (Jay and Saltzman, 2009).

Spray drying. This technique involves dispersion of drugs and/or excipients in a solvent system, which is then sprayed through a fine nozzle into a chamber (Fig. 1.3.8A.5) (Bakry et al., 2016). The hot air within the chamber causes the evaporation of the solvent, forming microparticles. Since the droplets are traveling through air during hardening, there is no external phase for drugs to escape to. Consequently, drug loading can be essentially whatever was put into the sprayed solution, and can be very high. Microparticles prepared by this method are usually 1–100 µm in diameter (Jain, 2000; Wagenaar and Müller, 1994).

Drug–polymer interactions, solution viscosity, and nozzle characteristics are important determinants of particle properties. Spray drying has been used with synthetic polymers such as PLGA, PLA, and PCL, natural polymers including gelatin and chitosan (Vehring, 2008), and other excipients (Edwards et al., 1997). Many parameters influence particle size, including nozzle radius, chamber temperature, air and solvent flow rate, and pressure. Mass loss due to particle aggregation and adhesion to the chamber walls can markedly curtail yield.

Characterization of Microparticles

There are a number of characterizations that are routinely done after manufacture of microparticles, The purpose is to verify that they are intact and of the expected size, shape,

and charge; to assess their drug loading, release, and degradation, etc. These studies are crucial to guide optimization and for quality control.

Morphology. Light microscopy can provide a quick qualitative assessment of the size and shape of particles, particularly if one of the eyepieces is equipped with a reticle. More detailed images of surface features (e.g., pores and defects) can be obtained by electron microscopy (EM) [i.e., scanning electron microscope (SEM) and transmission electron microscopy (TEM)]. Fig. 1.3.8A.6A shows a representative SEM image of PLGA microspheres, showing a spherical shape with a smooth surface (Zhao and Rodgers, 2006). EM also provides a qualitative appreciation of size distribution. Fluorescence microscopy, such as confocal laser scanning microscopy (CLSM) can also be used to visualize fluorescent dyes or drugs encapsulated in microparticles (Fig. 1.3.8A.6B) (Guo et al., 2016).

Size and polydispersity. Light scattering is the most commonly used method for measuring the size and polydispersity of particles (Lawrie et al., 2009). It measures particle size based on the intensity of the scattered light passing through a medium, which changes with many parameters including the size of particles in the medium (Goldburg, 1999). Light scattering is often confirmed by other techniques such as microscopy.

The Coulter counter is another tool for the measurement of size and concentration of particles (Henriquez et al., 2004). It has been used with nanoparticles, microparticles, cells, and viruses (Zhe et al., 2007). Particle size measurement is performed by allowing a suspension of microparticles to flow through a microchannel which separates two chambers containing electrolyte solutions. When particles pass through the channel, there is a transient change in the electrical resistance of the channel (DeBlois and Bean, 1970), which is correlated with the size, shape, surface charge, and concentration of the particles (Qin et al., 2011).

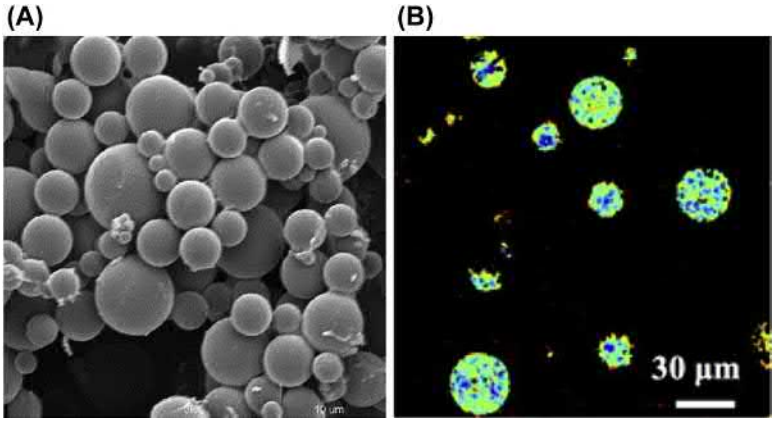
Surface charge. Surface properties of colloidal particles play a critical role in their physical stability as well as their interactions with cells (Zhang et al., 2008) and biomacromolecules (Singh et al., 2000). Zeta potential is a commonly used measure of the electrokinetic potential at the interface of a colloid particle and its surrounding medium (Bhattacharjee, 2016). Microparticles with a large absolute value of zeta potential are more stable in suspension and less likely to aggregate, due to the particles' mutual repulsion. Cationic particles are often suitable for delivery of nucleic acids (which are anionic) (Singh et al., 2000) For example, PLGA microparticles with positively charged surfaces can adsorb negatively charged plasmid DNA for gene delivery (Denis-Mize et al., 2000).

Other physiochemical properties. Infrared spectra (IR or FTIR) can be used to analyze interactions between the payload and microparticle matrix, such as hydrogen bonding (Huang et al., 2008). Atomic force microscopy (AFM) can provide information on particle shape, size, and morphology. AFM is often used to quantify a particle's elastic modulus (Moner-Girona et al., 2003), its adhesion to surfaces, and deformation (Vakarelski et al., 2001). AFM can measure the surface tension of colloidal particles, which is the surface energy per unit area (Cuenot et al., 2004). Colloidal particles with large surface tensions tend to aggregate in aqueous suspension. X-ray photoelectron spectroscopy (XPS) can provide information on the chemical composition of the particle surface, including the presence of biomolecules, dopants, and drugs.

Drug loading. Two parameters are commonly used in the evaluation of microencapsulation: drug encapsulation and encapsulation efficiency. The drug encapsulation is the ratio of the measured mass of encapsulated drug to the measured mass of drug and excipients. Encapsulation efficiency is a metric of how well the encapsulation process works, and is the ratio of the measured drug content of a given mass of particles to the theoretical content (i.e., the mass of drug used in creating the particles). Various methods have been used for the quantification of drugs, including UV absorption, liquid chromatography, and enzyme-linked immunosorbent assays.

$$\text{Drug Encapsulation } (\%) = \frac{\text{Mass of encapsulated drug}}{\text{Mass of microparticle}} \times 100$$

$$\text{Encapsulation efficiency } (\%) = \frac{\text{Mass of drug encapsulated}}{\text{Mass of drug used}}$$

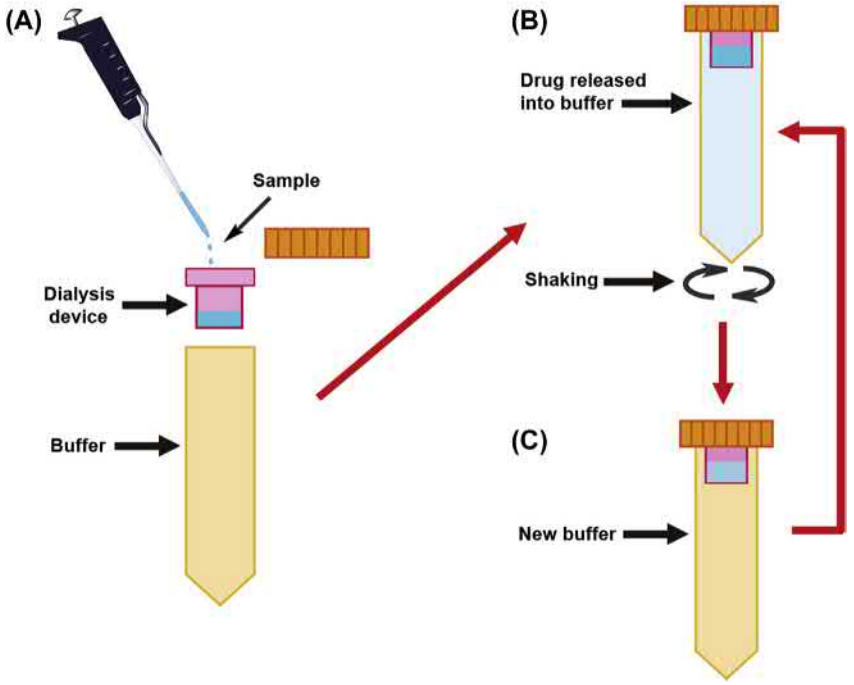


• **Figure 1.3.8A.6** Morphology of microparticles. (A) SEM image of PLGA microspheres (Zhao and Rodgers, 2006). (B) Confocal laser scanning microscopy image of rhodamine-loaded polyketal microparticles (Guo et al., 2016).

Release Kinetics. In polymeric drug-delivery systems, an initial rapid release is often observed, termed "burst release" (Huang and Brazel, 2001). In most cases, burst release results from drug located near the surface of microparticles (Mao et al., 2007) or drug diffusion to the surface during fabrication or storage, especially in porous systems (Yeo and Park, 2004). While a rapid initial release of encapsulated drugs may be desirable in certain circumstances, burst release may lead to excessive drug levels, causing toxicity which can be either systemic (Verrijk et al., 1992) or local (Padera et al., 2008). It is also potentially wasteful of drug, which might be better used—if released more slowly—to extend the duration of effect. Burst release of payload from microparticles can be reduced by using more hydrophobic polymers or materials (Huang and Brazel, 2001), polymers with higher molecular weight (Cohen et al., 1991), decreasing pore size (Wang et al., 2002), or increasing particle diameter (Berkland et al., 2002). The subsequent release kinetics can similarly be fine-tuned by altering key design parameters of microparticles such as material composition (Makadia and Siegel, 2011), size (Mitragotri and Lahann, 2009), morphology (Champion et al., 2007), and surface properties (Yoo et al., 2011). Drug release from microparticles can also be made inducible by stimuli in cellular compartments such as phagosome pH (Haining et al., 2004), or external stimuli such as heating (Lopes et al., 2013).

Release kinetics should be tested in a system that reflects the properties of the intended site of use in vivo, including temperature, pH, fluid turnover, shear forces, and other factors that may potentially impact the drug release behavior (D'souza and DeLuca, 2006). However, the correlation between in vitro release kinetics and in vivo findings is generally (although not always) poor. Another common method of assessing release kinetics is using "infinite sink" conditions, using a system where drug release is not impeded by accumulating drug levels in the external aqueous phase. (The latter is particularly important with hydrophobic drugs.) There are many ways to study release kinetics in this way. Particles may be suspended in a buffer solution, then spun down at predetermined intervals (Padera et al., 2008; McAlvin et al., 2013); the supernatant ("release medium") is removed for analysis then replaced. Alternatively, the particles may be placed in a dialysis bag then immersed in buffer (Zhou et al., 2016); the buffer outside the bag is removed for analysis at predetermined intervals (Fig. 1.3.8A.7). Preventing drug accumulation in the release media may involve relatively large volumes of buffer, or frequent replacement. Frequent sampling is particularly important early on in the release experiment, due to possible burst release. In studies in infinite sink conditions, the goal is not to mimic the rate of drug release in vivo, but to study the inherent ability of the particle to control drug release. Such studies can be useful for optimizing particles in vitro.

The technique used for quantification of drug concentrations in release media depends on the nature of the encapsulated payload. Commonly used methods include enzyme-linked immunosorbent assays (ELISAs), high-performance liquid chromatography (HPLC), UV spectrophotometry, and liquid chromatography-mass spectrometry (LC-MS).



• **Figure 1.3.8A.7** Schematic illustration of a release experiment. (A) A sample is placed into a dialysis device which is placed into buffer. (B) The system is agitated at an appropriate temperature. (C) At predetermined intervals, the dialysis buffer is removed for analysis and replaced, after which the process returns to (B).

Drug release kinetics are often represented graphically with time on the x-axis and drug release on the y-axis. The y-axis often represents cumulative release, i.e., each time point shows the total release of drug up to that point. The y-axis is also often the drug release at the particular time points studied. In a representative release of insulin from microparticles (Fig. 1.3.8A.8), burst release was observed in the first 2 days, followed by slower release over 14 days (Zhang et al., 2011).

Mathematical modeling can help predict drug release from a polymeric drug-delivery system (Siepmann and Göpferich, 2001). It may offer insights regarding potential approaches to release therapeutic levels of drugs for a prolonged duration as well as reduce systemic toxicities. Mathematical modeling of drug release from microparticles has been reviewed elsewhere (Brazel and Peppas, 2000; Narasimhan, 2001; Weiser and Saltzman, 2014).

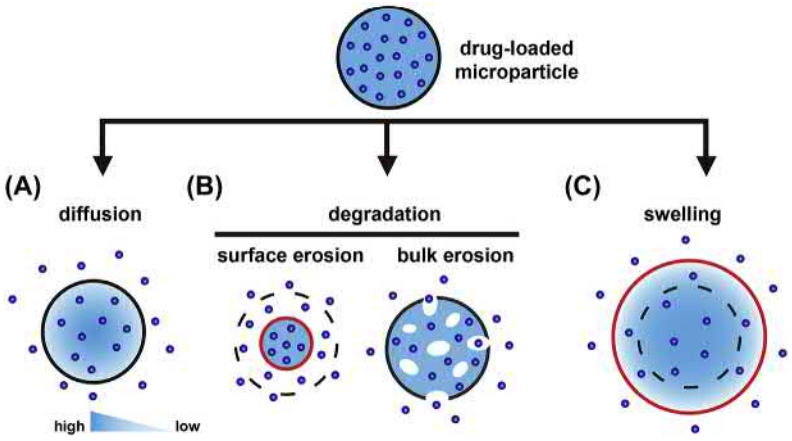
Drug Release Mechanisms

Drug release is a transport process in which a drug migrates from within the matrix or from the surface of drug carriers to the surrounding environment (Langer, 1990). Classic drug release mechanisms include diffusion, degradation, and swelling (Fig. 1.3.8A.9); release from microparticles can (and usually does) happen by more than one mechanism. Particle design parameters including composition, size, and geometry all play important roles in determining the drug release mechanism and kinetics.

Diffusion. Diffusional release is driven by the chemical potential gradient across the matrix of the drug-delivery system to the outside, and affected by the physicochemical properties of the microparticles, such as permeability/porosity, thickness, and electrochemical interactions if any between drug and particle. This is a prominent drug release mechanism in many drug-delivery depot systems (Fu and Kao, 2010).

Degradation. Polymers containing ester, amide, and anhydride bonds are most commonly used in the fabrication of biodegradable microparticles. "Degradation" refers to the cleavage of these chemical bonds by hydrolysis or enzymatic degradation in the body (Uhrich et al., 1999). Some excipients' degradation can be accelerated by environmental factors such as pH and enzymatic activity (see "Smart Polymers" section). Degradation leads to particle erosion, i.e., the depletion of materials (Batycky et al., 1997). There are two principal types of erosion of polymeric materials, surface and bulk erosion.

Surface erosion occurs when the degradation of polymeric materials is confined to the exterior surface of particles as a result of slow water penetration (Uhrich et al., 1999). Surface-eroding microparticles are usually composed of hydrophobic monomers prohibiting penetration of water molecules. Examples of surface-erodible systems include poly(anhydrides) and poly(ortho esters). Surface erosion



• **Figure 1.3.8A.9** Classic mechanisms of drug release from microparticles. (A) Diffusion driven by chemical potential gradient. (B) Degradation at the surface or throughout the matrix of microparticles. In surface erosion, the size of a microparticle decreases due to mass loss. (C) Swelling-driven drug release due to increased mesh size of the polymer network. In (B) and (C), dashed lines indicate the original boundary of microparticles and red lines indicate the boundary of microparticles after erosion or swelling.

leads to zero-order drug release, where the release rate is proportional to the surface area (Möckel and Lippold, 1993). Slow water penetration in surface-eroding materials may be desirable for the delivery of water-labile drugs.

Bulk erosion occurs when water molecules are able to easily penetrate into the bulk of the polymer, which results in homogeneous depletion of the entire matrix. Many biodegradable polymers used in the fabrication of microparticles are bulk-eroding systems, such as those based on poly(ester) polymers. For many biodegradable systems, the erosion of the polymer matrix occurs by a combination of bulk and surface erosion, the relative proportion depending on the chemical structure of the polymers (von Burkersroda et al., 2002).

Swelling. Swelling of particles can accelerate the release of entrapped payloads. Simple hydration of polymer chains may lead to the swelling of microparticles and accelerate release of payload (Keegan et al., 2012). Swelling is the basis of some stimulus-sensitive drug-delivery systems. Physical or chemical changes in the environment trigger the swelling, which allows release of entrapped drugs due to the increased mesh size of the polymer network. Most microparticles that release drugs primarily through swelling are hydrogels containing noncovalent cross-links such as alginate microgels (Lee et al., 2000). Hydrogels are three-dimensional networks of hydrophilic polymers that can be fabricated into various forms including microparticles (Hoare and Kohane, 2008). An example of triggered swelling is seen with poly(vinylpyridine) microparticles: the amine groups were protonated when the ambient pH deceased from 7.4 (physiological pH) to 4.5, causing electrostatic repulsion, which in turn caused swelling and release of the encapsulated antiseptic compound cetylpyridinium chloride (Bradley and Vincent, 2008). Temperature has also been used as the trigger for swelling: microgels made of the thermo-responsive polymer poly(acrylic acid)-*b*-poly(acrylamide) swelled by 60% when the ambient temperature increased from 37 to 45°C (Serrano-Ruiz et al., 2013).

Biomedical Applications of Microparticles

Drug Delivery

Microparticles have been predominantly investigated for drug-delivery applications. Microparticles have been used for the delivery of a wide range of drugs by different routes of administration, singly or in combination. The literature on the encapsulation of small-molecule (and other) drugs is very large, and has also been reviewed extensively (Edlund and Albertsson, 2002; Lam and Gambari, 2014; Ramazani et al., 2016). Here we focus on a few relatively specialized topics.

Encapsulation and Sustained Release of Biopharmaceuticals. Microencapsulation has been widely used for sustained release of nucleic acids (Guliyeva et al., 2006) and proteins (Putney and Burke, 1998). However, the encapsulation of biological pharmaceuticals like proteins and nucleic acids poses substantial challenges due to their large size (Radomsky et al., 1990), high viscosity (Yadav et al., 2010), and lability (Mitragotri et al., 2014) compared to small molecules. The preservation of their intrinsic structural complexity, crucial for their therapeutic potency and specificity, may also be difficult. Factors during formulation and storage such as organic solvents and high temperature may lead to denaturation and loss of activity (Sah, 1999). In addition, they are susceptible to enzymatic or hydrolytic degradation (Estey et al., 2006) following administration.

Improving the loading efficiency can be important for achieving long-term release of protein drugs. The loading capacity of proteins can be improved by changing the composition (Han et al., 2016), molecular weight (Blanco and Alonso, 1998), the mass ratio of polymers and proteins (Rafati et al., 1997), formulation method (Bilati et al., 2005), incorporation of surfactants (De Rosa et al., 2000) and formation of amorphous glasses using sugars or polyols (Weers et al., 2007). The release of peptide and protein drugs from microspheres can be tuned by changing key structural parameters such as particle size (Park et al., 2006), surface pore diameter (Kim et al., 2006), and others. Surface modification of microparticles such as PEGylation, which significantly decreases the uptake of drug-loaded microparticles by macrophages, has also been used to improve the sustained release of protein drugs (Simón-Yarza et al., 2013). The sustained release of microencapsulated proteins can vary from days to months (Ye et al., 2010), depending on the formulation. Further detail on the encapsulation of proteins and nucleic acids can be reviewed elsewhere (Mitragotri et al., 2014; Ye et al., 2010; Bhavsar and Amiji, 2007; Luo et al., 1999).

Local Injection. Most commonly, microparticles are delivered by injection at a specific site in the body, where they act as a depot, for local or systemic effect. They are very well-suited to situations where a therapeutic drug level is desired at a specific location, with minimal systemic drug distribution. This is well illustrated by microparticles used to prolong local anesthesia (Santamaria et al., 2017; McAlvin and Kohane, 2014). A variety of local anesthetics, with or without other compounds that enhance their performance, have been encapsulated in many different types of microscale vehicles composed of a range of materials. They are injected along the course of a peripheral nerve, where the resulting high drug concentration and sustained release provide local anesthesia that can last hours to days, much longer than could be safely achieved by free drug. Systemic drug distribution—and therefore toxicity—is minimal. Conceptually similar devices have been used to treat conditions in many other organs, such as the heart (Sy et al., 2008), brain (Kohane et al., 2002; Tamargo et al., 2002), eyes (Lavik et al., 2011), and others.

Microparticles can also be used to provide prolonged systemic drug delivery from a single injection, often with relatively zero-order release kinetics. Such formulations are useful for convenience and patient compliance (Kohane and Langer, 2005). Microparticles loaded with growth hormone

deposited in soft tissue can slowly release the drug for effect throughout the body (Johnson et al., 1996). Similarly, microparticles containing psychoactive medications can provide a prolonged effect (Lu et al., 2014; Ramstack et al., 1997).

Microparticles can also be delivered through the major portals of delivery into the body. They can be ingested or delivered by enema, for treatment of local conditions within the gut (Lamprecht et al., 2000) (e.g., inflammatory bowel disease), or for systemic disease (Cheng et al., 2006) (e.g., diabetes). They can be inhaled to treat local pulmonary disease [e.g., asthma (Edwards et al., 1997) and pulmonary hypertension (Evgenov et al., 2007)].

Oral Delivery. Oral administration remains the preferred route for the application of pharmaceutics due to its convenience (Sastry et al., 2000). Microencapsulation of labile biopharmaceuticals including proteins and nucleic acids has improved their bioavailability by decreasing chemical or enzymatic degradation inside the gastrointestinal tract (Mahato et al., 2003). Polysaccharide (e.g., chitosan)-based microparticles have been studied for the oral delivery of insulin (Zhang et al., 2011; Jose et al., 2012). Less than 3% of encapsulated insulin was released in 1.5 h after exposure to simulated gastric fluid containing pepsin at pH ~1.2, suggesting that microencapsulation preserves the chemical stability of encapsulated insulin. The blood glucose level of diabetic rats could be effectively reduced for over 60 h after oral administration of the insulin-loaded microspheres. Orally administered dextran microspheres have been used to improve the bioavailability of drugs delivered to the colon (Hovgaard and Brøndsted, 1995). The dextran matrix remains intact in the stomach and small intestine and degrades in the colon due to dextranase secreted by bacteria (Sinha and Kumria, 2001).

Pulmonary Delivery. Pulmonary administration is a noninvasive method of drug administration with fast absorption and direct targeting of the lungs (Abdelaziz et al., 2017). Microparticles have been used to deliver particles to the lung. This can be either to achieve systemic effect [e.g., insulin (Amidi et al., 2008)], or local delivery [e.g., bronchodilators (Ben-Jebria et al., 1999)]. Direct pulmonary delivery can achieve local effect while minimizing systemic effect (Edwards et al., 1997; Evgenov et al., 2007). Porous PLGA microspheres have been used for pulmonary delivery of protein drugs like insulin (Amidi et al., 2008), and small molecules like testosterone (Edwards et al., 1997) and doxorubicin (Fig. 1.3.8A.10) (Kim et al., 2012). The size of microparticles plays a key role in their retention in the lungs, and the level in the lungs (e.g., small airways) at which they are deposited (Adjei and Garren, 1990; Kutscher et al., 2010).

Ophthalmic Delivery. Microencapsulation has emerged as a promising approach to provide sustained released of drugs at a number of locations on or in the eye (Ludwig, 2005). Mucoadhesive ~10 μm PLGA microparticles can remain on the ocular surface for over 30 min, compared to ~5 min for a conventional eye drop formulation (Choy et al., 2008). Subconjunctival administration of 4 μm PLGA microparticles enabled release of celecoxib, which effectively inhibited diabetes-induced retinal oxidative damage for 14 days in rats (Ayalasomayajula and Kompella, 2005). Intravitreally injected ~10 μm PLGA microspheres released proteins for 7 weeks for the treatment of acute retinal ischemia in a pig model (Kyhn et al., 2009).

Vaccines and Immune Adjuvants. There has been considerable interest in particulate approaches to enhancing vaccines. Microparticles have been used in part because their relatively large size makes it only possible for them to be taken up by phagocytic cells such as antigen-presenting cells (APCs) (Haining et al., 2004). For example, 0.1–10 μm ovalbumin-loaded microparticles induced an antigen-specific immune response after being phagocytosed by dendritic cells (Dierendonck et al., 2014).

Another major challenge in the design of biomaterial-derived vaccines is the instability of encapsulated antigen and loss of immunogenicity. PLGA microspheres have been used for the encapsulation of vaccine antigens such as ovalbumin (OVA) with encapsulation efficiencies ranging from 4% to 13% (Uchida et al., 1994). A modified microencapsulation technique has been developed to increase protein antigen encapsulation efficiency and decrease exposure of antigens to organic solvents during formulation (Reinhold et al., 2012). PLGA microspheres loaded with trehalose and calcium phosphate ($CaHPO_4$) nanogels were formulated via a standard double emulsion and solvent evaporation technique (Fig. 1.3.8A.11A) (Bailey et al., 2017). Trehalose created a porous network inside the microsphere matrix and prevented $CaHPO_4$ gels from aggregating during lyophilization. The dried microspheres were incubated at 4°C in an aqueous solution of protein antigens, allowing the antigens to diffuse into the porous network created by the trehalose and bind to the calcium phosphate gel (Fig. 1.3.8A.11B). Pores were closed, keeping antigens inside by heating the aqueous solution above the glass-transition temperature of PLGA (Fig. 1.3.8A.11C). The encapsulation efficiency was 56%, compared to 10% with a conventional double emulsion method (Uchida et al., 1994). The obtained 7 μm PLGA microspheres enabled single-dose vaccination with sustained antigen release over 40 days (Bailey et al., 2017). Confocal microscopy confirmed that rhodamine-labeled microspheres were readily taken up by dendritic cells (Fig. 1.3.8A.11D), enabling the targeted delivery of antigens.

Radiotherapy

Radiotherapy uses high doses of radiation to kill cancer cells and shrink tumors (Delaney et al., 2005). However, external irradiation can have trouble reaching deep-seated cancers without damaging healthy tissues. Radioactive microparticles to be placed in situ have been developed to address these concerns. For example, 35 μm glass microspheres containing yttrium-90 have been applied by intratumoral injection in rabbits for tumor suppression (Yan et al., 1993). In situ radiotherapy provided localized β-irradiation with a

penetration depth of less than 3 mm, with minimal toxicity to surrounding normal tissues (Kawashita et al., 2003).

Other Applications

The use of particulate-delivery systems and microencapsulation technology has gone beyond pharmaceutics. Over the past several decades, the food and beverage industries have been using microencapsulation for controlled release of food ingredients. A simple example of encapsulation-enabled controlled release is the flavoring of chewing gums (Witzel and Patents, 1976). Flavor compounds were encapsulated into polysaccharide-based microspheres with sizes ranging from 1 to 100 μm, which were then deposited on the surface of a gum stick. Microencapsulation achieved release of sufficient flavoring ingredients to maintain an acceptable taste over 60 min (Witzel and Patents, 1976). Microencapsulation protects sensitive, reactive, or volatile food ingredients against heat, moisture, and pH during storage (Yeo et al., 2005). Microencapsulation may also turn liquid or gas ingredients into powders, enabling easier handling (Ho et al., 2014). For example, expansible thermoplastic

CASE STUDY: TRIAMCINOLONE ACETONIDE-ENCAPSULATED PLGA MICROSPHERES FOR MANAGEMENT OF OSTEOARTHRITIC PAIN OF THE KNEE

Osteoarthritis (OA) is a common chronic condition of the joints, characterized by intraarticular inflammation, deterioration of articular cartilage, and degenerative changes to periarticular and subchondral bone. OA occurs most often in large weight-bearing joints such as the knees and hips, but also occurs in the shoulders, lower back, neck, small joints of the fingers, and the bases of the thumb and big toe. About 13% of women and 10% of men aged 60 years and older have symptomatic OA of the knee, with rates likely to increase due to the aging of the population and the rate of obesity or overweight individuals in the general population.

During the early stages of knee OA, conservative management including weight loss, the use of ambulatory aids, simple analgesics, and nonsteroidal antiinflammatory drugs is the first line of treatment; however, as the disease progresses and the joints becomes increasingly painful, the effectiveness of these treatment options becomes limited. Intraarticular administration of immediate-release corticosteroid or hyaluronic acid has been clinically used to relieve symptoms of knee OA. However, the duration of pain reduction from intraarticular corticosteroid injections is less than 1 week, which is insufficient for chronic knee osteoarthritis.

Triamcinolone acetonide (TCA) is an FDA-approved short-acting corticosteroid for the treatment of various disease conditions including osteoarthritis. A PLGA microsphere-based formulation (Zilretta) has been developed to provide extended release of TCA. It is prepared as TCA-loaded microspheres with a drug loading of 25% (w/w) to provide more persistent pain relief than currently available immediate-release formulations of TCA. The excipient is biodegradable PLGA polymer. In a nearly 500-patient phase three study, Zilretta significantly lowered pain intensity scores compared to placebo 3 months following a single dose intraarticular administration. Compared to conventional immediate-release formulations, microencapsulation provides the following benefits: (1) extended drug release; (2) potent therapeutic response through targeted local delivery; (3) minimal systemic exposure; (4) long–lasting local pain relief from a single injection; and (5) safety profile with treatment–related side effects comparable to placebo. In 2017, Zilretta was approved by FDA for the treatment for patients with OA-related knee pain.

polymers synthesized with alkenyl aromatic monomers have been used for the preparation of microparticles 3–50 μm in diameter for the encapsulation of volatile fluid foaming agents for applications such as coffee foam (Morehouse Jr et al., 1971). Changes in physiological conditions such as pH have been used for triggered release of food ingredients from microparticles (Zhang et al., 2015). Microparticles have been applied in cosmetics (Takezaki et al., 2015) as in the preparation of perfume by encapsulation of volatile fragrances (Tekin et al., 2013). Microencapsulation has also been used in the development of agricultural products (Gimeno, 1996). Microparticle-based pesticide-delivery systems have been designed for sustained release of encapsulated pesticides, resulting in improved handling safety and increased time intervals between applications of pesticides (Tsuji, 2001; Delin, 2000).

Concluding Remarks

Microparticles have many desirable properties for biomedical applications. They are excellent depot systems for sustained release of a wide range of therapeutic compounds. The formulation methods are readily tunable to allow variation in a range of particle parameters, resulting in the potential for release over a range of time frames, or stimulus-responsive release. Microparticles can be administered by a variety of routes and are generally small enough to be injectable.

Chapter Exercises

1. Which of the following cell types is least likely to take up microparticles?
   A. Dendritic cells
   B. Macrophages
   C. Endothelial cells
2. Which of the following routes of administration is not commonly used for drug-loaded microparticles?
   A. Oral delivery
   B. Intravenous injection
   C. Pulmonary delivery
   D. Local injection
3. Which is the principal mechanism underlying drug release from poly(ortho ester) microparticles?
   A. Surface erosion
   B. Bulk erosion
   C. Diffusion
   D. Swelling
4. Why do microparticles usually exhibit more prolonged release of drugs compared to nanoparticles?
5. What is burst release? What are the potential consequences of burst release? What parameters of polymers and microparticles may affect burst release?
6. Discuss strategies to improve microencapsulation efficiency of proteins. What factors in the microencapsulation process may lead to the loss of biological activity of proteins?
7. A new hydrophobic drug which absorbs light at 580 nm has been developed. PLGA microspheres are used for the encapsulation of this drug by a conventional o/w emulsion and solvent evaporation method. Twenty mg of drug and 200 mg of PLGA polymer were dissolved in methylene chloride and the final volume was made to 2 mL. The absorption of polymer and drug solution at 580 nm was 0.8. The solution was then emulsified in 10 mL PBS buffer with a surfactant, using a homogenizer. Microspheres underwent solvent evaporation, washing and freeze-drying. To quantify drug encapsulation, 50 mg of the 210 mg of drug-loaded PLGA microspheres obtained were redissolved in methylene chloride and the final volume was made to 5 mL. The absorption of the redissolved solution at 580 nm was 0.065. What were the drug encapsulation and encapsulation efficiency in this example?

Chapter Objectives

- To provide an overview of nanoparticles (NPs)
- To outline various types of NPs and their preparation as well as characterization methods
- To highlight the intelligent design of NPs in overcoming multiple biological barriers
- To elucidate the numerous applications of NPs toward diagnosis and disease treatment

Introduction

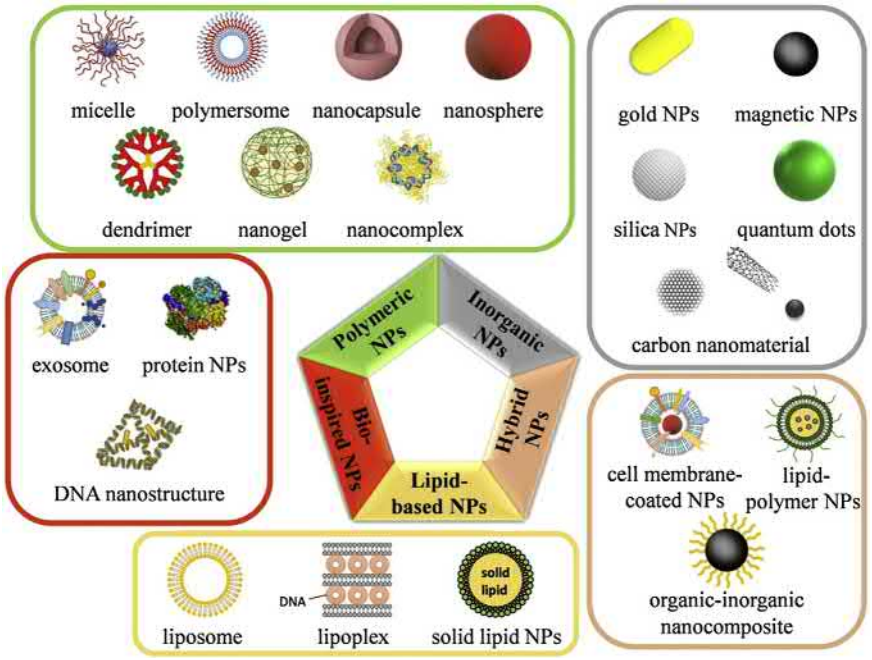
NPs are colloidal solid particles with the size range of 1–1000 nm. In the field of nanomedicine and nanodiagnosis, NPs are more preferentially referred to as particles of 5–~100 nm that are favorable for overcoming various systemic barriers. NPs have demonstrated extensive utilities for biomedical applications because of their unique physiochemical properties including changes in biochemical, magnetic, optical, and electronic properties at cellular, atomic, and molecular levels due to their high surface-to-volume ratio. Biomaterials-based NPs have received particular attention because they hold the promise to revolutionize medical treatment with more potent, less toxic, and smart therapeutics. For the purpose of drug delivery, NPs can encapsulate or covalently conjugate hydrophobic drugs to greatly enhance their aqueous solubility. They can also encapsulate hydrophilic drugs or biomacromolecules (such as proteins, peptides, or nucleic acids) to enhance their stability in vivo, prolong blood circulation time, and facilitate transmembrane delivery. The nanoscale diameter of NPs allows targeting to tumors via the enhanced permeability and retention (EPR) effect, and can dramatically reduce the nonspecific toxicity of chemodrugs. In addition, NPs with large surface area, improved circulation time, and high stability offer a platform for highly specific and sensitive molecular imaging, by delivering the imaging probe or contrast agent to the target tissues or cells. Various ligands or antibodies can be grafted onto NP surfaces to increase the targeting efficiency and specificity. Alternatively, certain NPs, especially inorganic NPs with desired optical properties, have intrinsic imaging or therapeutic properties. These NPs, such as gold NPs or superparamagnetic iron-oxide NPs, often allow multimodal imaging due to production of the imaging contrast by themselves, and can mediate photothermal therapy due to photon-to-heat conversion.

Categories of NPs

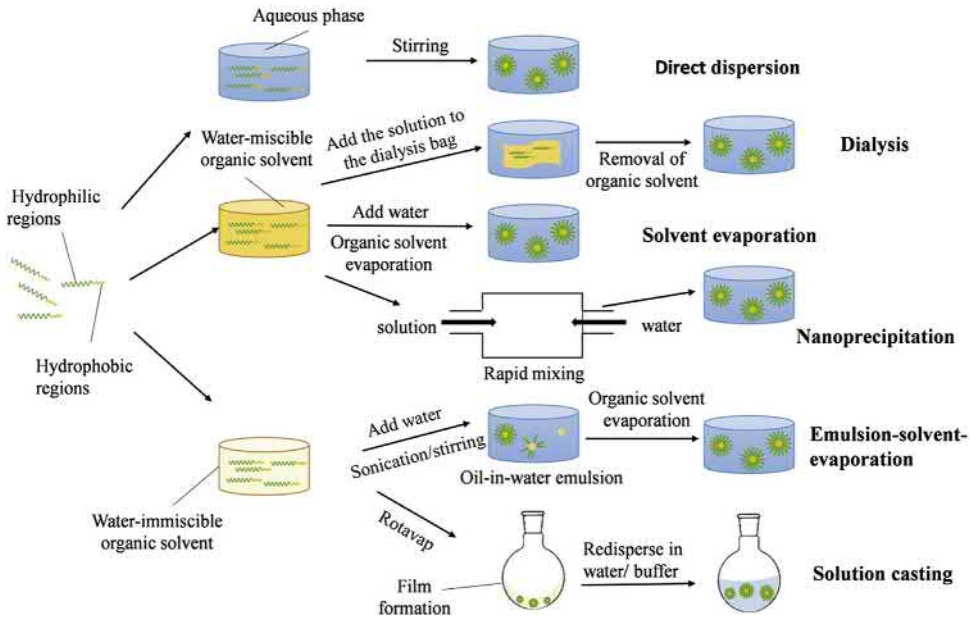
Depending on the type of fabricated materials, NPs can be classified into five major categories, including polymeric NPs, lipid-based NPs, inorganic NPs, bio-inspired NPs, and hybrid NPs (Fig. 1.3.8B.1).

Polymeric NPs

Polymeric micelles. Polymeric micelles (PMs) typically possess a core/shell structure with sizes of 20–200 nm. PMs are formed via the self-assembly of amphiphilic copolymers, driven by the hydrophobic interactions of the hydrophobic blocks of amphiphilic copolymers, generating a hydrophobic core surrounded by a hydrophilic shell (Kataoka et al., 2001). This thermodynamically driven process occurs when the copolymer concentration is higher than the critical micellar concentration (CMC), an important indicator of micelle stability that is affected by the hydrophilic–lipophilic balance (HLB). In general, with the same hydrophilic portion, a longer hydrophobic chain correlates to a lower CMC, and thus better micelle stability. The CMC can be determined by fluorescence spectroscopy, surface tension measurement,



• **Figure 1.3.8B.1** Categories of NPs.



• **Figure 1.3.8B.2** Methods for the preparation of polymeric micelles (Cagel et al., 2017).

UV-vis spectroscopy, and dynamic light scattering (DLS). A preferred technique to determine the CMC involves the use of fluorogenic dyes, such as pyrene, due to its high sensitivity. When PMs are formed, pyrene is preferentially partitioned into the hydrophobic core and thus a CMC value can be determined. Commonly used amphiphilic copolymers to prepare micelles include poly(ethylene oxide)-poly(propylene oxide)-poly(ethylene oxide) (PEO-PPO-PEO), poly(ethylene glycol)-poly(lactic acid) (PEG-PLA), PEG-poly(lactic-*co*-glycolic acid) (PEG-PLGA), and PEG-poly(ε-caprolactone) (PEG-PCL), approved by the FDA for biomedical applications. In addition, other biodegradable copolymers with hydrophobic segments covalently bonded to PEG have also been used to build PMs. These hydrophobic segments include polyanhydrides, such as poly(sebacic anhydride) (PSA), and hydrophobic poly(L-amino acid) and derivatives. Hydrophobic drugs can be encapsulated into the hydrophobic core of PMs via hydrophobic interactions.

There are various methods for micelle preparation such as direct dispersion, nanoprecipitation, emulsion-solvent evaporation, solvent evaporation, dialysis, and film formation. The dispersion method involves direct dispersion of the polymer in an aqueous solution, which is usually employed for intermediate hydrophobic polymers (Fig. 1.3.8B.2).

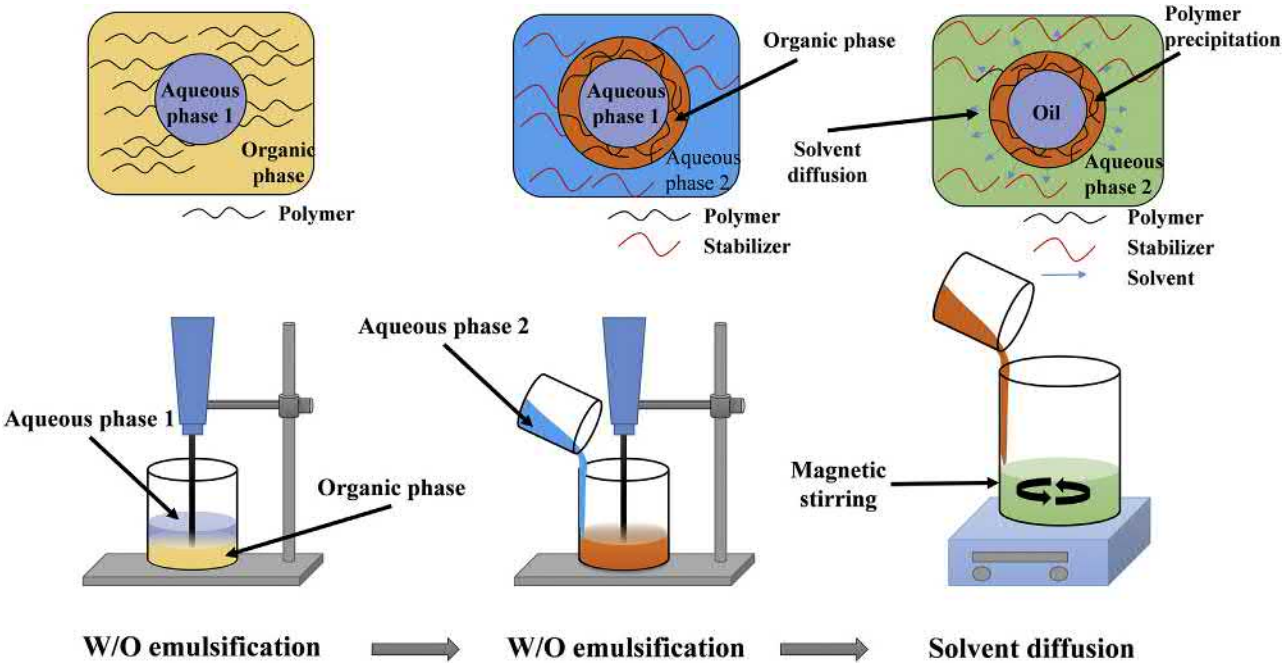
The advantages of this method are simplicity, short processing time, and avoidance of organic solvent. However, only a few drugs could be encapsulated using this method. The nanoprecipitation method involves copolymer dissolution in a water-miscible organic solvent, and the organic solution is afterward added dropwise to an aqueous solution under vigorous stirring. Subsequently, the organic solvent is removed by evaporation. In the method of emulsion-solvent evaporation, copolymers are dissolved in a water-immiscible organic solvent. After the solvent is emulsified in an aqueous solution, the solvent is removed by evaporation. The solvent evaporation method is similar to the emulsion-solvent evaporation method, except that the organic solvent is miscible with water. The organic solvent is removed through evaporation, and the change in solvent quality from organic to aqueous is gradual, which allows the polymer and drug to aggregate into micelles rather than precipitate from the solution in bulk. The solvent of choice is usually acetone, due to its high water miscibility and low vapor pressure, which simplifies the solvent removal. The dialysis method involves the use of water-miscible organic solvent to dissolve copolymers with low water solubility. The micelles are assembled when the organic phase is removed by dialysis against water, and the hydrophobic core could encapsulate poorly water-soluble drugs. Another method is based on the formation of a thin film. The organic phase containing copolymers and hydrophobic drugs are evaporated using a rotary evaporator to form a thin film. The micelles are formed when the thin film is rehydrated with an aqueous phase (Cagel et al., 2017).

Nevertheless, micelle-based nanomedicines will suffer from premature disintegration upon dilution in the bloodstream. Core-cross-linked or shell-cross-linked PMs have thus evolved to overcome this critical issue. Either the core or the shell of micelles can be cross-linked via covalent bonding, hydrogen bonding, or π–π stacking, and the obtained PMs have no CMC values to completely resist dilution-induced disassembly. By incorporating stimuli-responsive domains in the cross-linker, the cross-linked PMs allow stable drug retention yet tailored release kinetics.

In addition to noncharged polymeric micelles, polyion complex (PIC) micelles with sizes lower than 100 nm are developed from a pair of oppositely charged block copolymers through electrostatic interactions. For example, upon mixing aqueous solutions of PEG-poly(L-lysine) (PEG-PLys) and PEG-poly(aspartic acid) (PEG-PAsp), PIC micelles with an extremely narrow size distribution are formed without exchanging solvent. This behavior could be explained by the segregation of the PIC structure from the aqueous polyion exterior to form the core of the micelles.

Nanospheres. Polymeric nanospheres are defined as matrix-type, solid colloidal particles based on hydrophobic polymers stabilized via surfactants assembled on the nanosphere surfaces. Generally, these particles are larger than micelles with diameters between 100 and 200 nm. The hydrophobic surfaces of nanospheres are highly susceptible to opsonization and clearance by the reticuloendothelial system (RES). There are two methods to prepare nanospheres. One method involves either emulsion polymerization in the case of poly(methylmethacrylate) and poly(ethylcyanoacrylate) or interfacial polymerization for poly(alkylcyanoacrylate). The monomers are usually dissolved in the aqueous phase containing stabilizers (such as PVA) or surfactants (such as Span 80), and polymerization is initiated upon contact of the monomers present in continuous phase with an initiator molecule that can be an ion, a free radical, or by high-energy radiation. Polymerization leads to the formation and precipitation of solid nanospheres. Another method is based on emulsification/solvent evaporation and nanoprecipitation. Polymers are dissolved in water-miscible organic solvent, and then added to the aqueous phase. Upon contact with the aqueous phase, the organic solvent immediately diffuses out, resulting in the formation of nanospheres. Alternatively, the organic phase is emulsified in an aqueous phase containing surfactant or stabilizer using high-energy homogenization or sonication. Subsequently, the organic phase is evaporated under vacuum, leading to the formation of nanospheres.

Nanocapsules. Nanocapsules are defined as nano-vesicular systems consisting of an inner liquid core surrounded by a polymeric membrane. Frequently, the core is an oily liquid, and the surrounding polymer is a single layer of polymer. Polyesters such as PLA, PLGA, and PCL, have been widely used to construct nanocapsules. Generally, there are six classical methods to prepare nanocapsules, including nanoprecipitation, emulsion-diffusion, double emulsification, emulsion-coacervation, polymer-coating, and layer-by-layer assembly (Mora-Huertas et al., 2010). The nanoprecipitation method, also known as solvent displacement or interfacial deposition, produces nanocapsules as a colloidal suspension when the organic phase containing polymers is added slowly to the aqueous phase under stirring. For the emulsion-diffusion method, the procedure requires three phases, organic, aqueous, and dilution. The organic solvent should be partially water-miscible and the aqueous phase should be solvent-saturated, while the dilution phase is usually water. The organic phase is emulsified under vigorous agitation in the aqueous phase. Addition of dilution solvent into the system leads to the diffusion of solvent into the external phase, resulting in nanocapsule formation. The double emulsification method, also called "emulsion of emulsion," often involves water-oil-water emulsion, that requires two surfactants, a hydrophobic one to stabilize the interface of the w/o internal emulsion and a hydrophilic one to stabilize the external interface of the oil globules (Fig. 1.3.8B.3). The emulsion-coacervation method is based on the formation of a coacervate phase that causes polymer precipitation from the continuous emulsion phase to form a film on the template. This method is suitable for naturally occurring polymers, such as sodium alginate and gelatin. Polymer is dissolved in an aqueous phase and o/w emulsion is formed by mechanical stirring or ultrasound. Subsequently, a coacervation process is performed by using either



• **Figure 1.3.8B.3** Preparation of nanocapsules by the double emulsion method (Mora-Huertas et al., 2010).

electrolytes with a sodium alginate-calcium chloride system, or by addition of a water-miscible nonsolvent or a dehydration agent with a gelatin-isopropanol-sodium sulfate system. The polymer-coating method is based on depositing a thin layer of polymer on the nanoparticle surface during the final stage of conventional methods such as nanoprecipitation and double emulsification to allow simultaneous layer formation. Nanocapsules obtained by the layer-by-layer assembly process are called polyelectrolyte capsules with well-defined chemical and structural properties. This technique requires a colloidal template on which a polymer layer is adsorbed via electrostatic attraction. This procedure is repeated using a second polymer with opposite charge.

With regard to drug encapsulation efficiency, nanoprecipitation, emulsion-diffusion, and layer-by-layer methods exhibit excellent encapsulation efficiencies (80% or more). In the case of the layer-by-layer method, the solid drug serves as the template to ensure high encapsulation efficiency. However, for the nanoprecipitation and emulsion-diffusion methods, various factors including the chemical nature and polarity of the drug may influence the encapsulation efficiency. Hydrophilic drugs can reach maximum values of 10%, while lipophilic compounds can reach higher than 70%. Regarding the double emulsification method, encapsulation efficiency ranges from 65% to 75%, depending on both the polymers and the surfactants used. For the emulsion-coacervation method, its encapsulation efficiency is obviously low in comparison to other nanoencapsulation methods. Although nanocapsules are considered as stable systems due to Brownian motion, they can be subject to instability due to polymer degradation, migration of the active substance from the inner liquid, and microbiological contamination of aqueous systems.

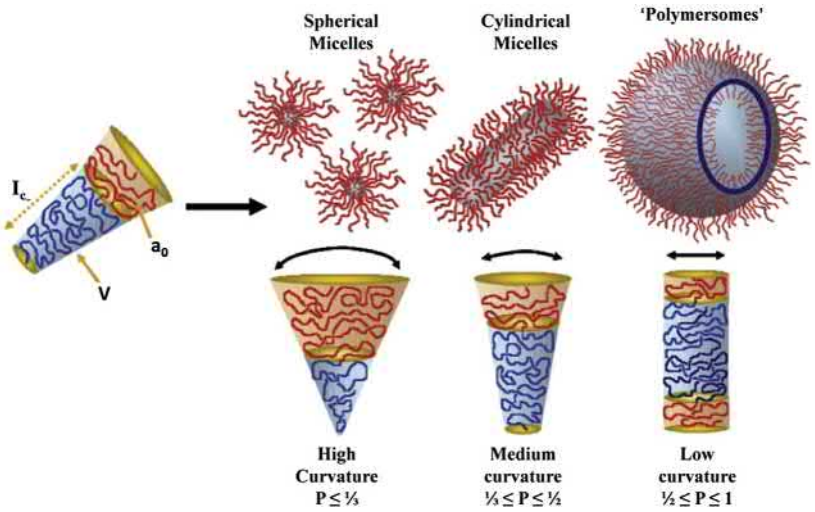
Polymersomes. Polymersomes self-assembled from block or graft amphiphilic copolymers afford similar properties to liposomes yet higher stability. Regarding the specific self-assembled nanostructure of amphiphilic block copolymers, a dimensionless "packing parameter," p, defined in the following equation, is developed to indicate the most likely morphology.

$$p = v/a_o l_c$$

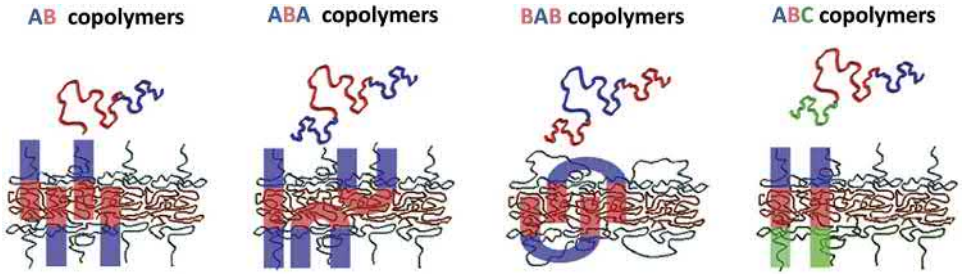
where v is the volume of the hydrophobic chain, a_o is the optimal area of the head group, and l_c is the length of the hydrophobic tail.

Generally, spherical micelles are favored at $p \leq 1/3$; cylindrical micelles are obtained at $1/3 \leq p \leq 1/2$; and polymersomes are formed at $1/2 \leq p \leq 1$ (Fig. 1.3.8B.4) (Blanazs et al., 2009).

Typical polymersomes are hollow spheres that contain an aqueous solution in the core surrounded by a bilayer membrane. The bilayer membrane is composed of hydrated hydrophilic coronas both at the inside and outside of the hydrophobic middle part of the membrane separating and protecting the fluidic core from the outside medium. Water-soluble drugs could be encapsulated in the core of polymersomes, and hydrophobic drugs are integrated within the hydrophobic membrane. In general, the composition and molecular weight of synthetic amphiphilic polymers can be varied, offering polymersomes with different membrane thicknesses and permeability. Usually, polymersomes from amphiphilic copolymers with high molecular weight have relatively thick (3–4 nm) and robust membranes (Lee and Feijen, 2012). The possible bilayer assemblies in the aqueous environment are schematically illustrated in Fig. 1.3.8B.5 for AB diblock, and ABA, BAB, and ABC triblock



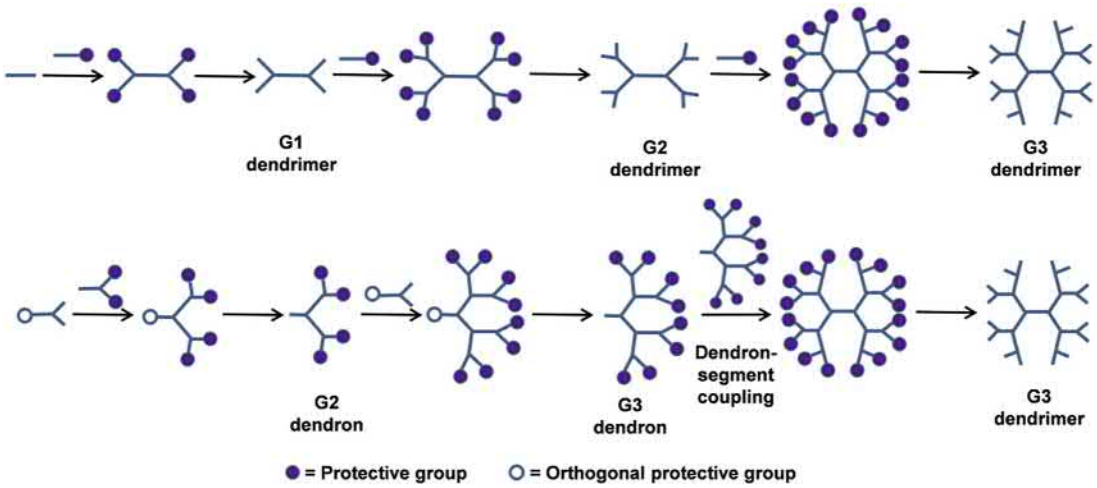
• **Figure 1.3.8B.4** The self-assembled nanostructures of block copolymers. (Reproduced from Blanazs, A., Armes, S. P., Ryan, A. J., 2009. Self-assembled block copolymer aggregates: from micelles to vesicles and their biological applications. Macromol. Rapid Commun. 30, 267–277.)



• **Figure 1.3.8B.5** Membrane conformation of polymersomes formed by diblock and triblock copolymers. (Reproduced from Lee, J. S., Feijen, J., 2012, Polymersomes for drug delivery: design, formation and characterization. J. Control. Release 161, 473–483.)

copolymers, where A and C are different hydrophilic blocks and B is the hydrophobic block. The geometric shapes of the amphiphiles in the aqueous environment are driven by complementary hydrophobic–hydrophobic interactions between the polymer chains. For AB and BAB copolymers, there is only one molecular conformation that can result in bilayer membrane formation (cylindrical shape for AB and curved shape for BAB). The hydrophobic chains are entangled in the middle of the membrane to minimize the interfacial area with water and the hydrophilic block is positioned to the outside of the membranes. In the case of ABA copolymer, there are two possible conformations. The hydrophobic block can either form a curved loop so that both hydrophilic chains are faced toward the outside of the membrane or they can stretch to form a cylindrical shape with the two hydrophilic blocks at the opposite sides of the membrane. Additionally, ABC copolymers can self-assemble into polymersomes with asymmetric membranes. Due to the difference in MW, charge, and solubility of the hydrophilic blocks, polymer chains with relatively larger fraction are preferentially positioned to the outer surface of the polymersomes (Blanazs et al., 2009).

Solvent-switching and polymer rehydration are two major techniques to prepare polymersomes. For the solvent-switching method, also called the phase inversion method, polymersomes are formed by first dissolving amphiphilic copolymers in an organic solvent, followed by hydration of the solution either through slow addition of water into the organic phase or injection of the organic solution into water. This procedure causes the hydrophobic blocks to become insoluble, thus triggering copolymer self-assembly into polymersomes due to increasing interfacial tension between the hydrophobic blocks and water. In this method, the size and size distribution of the polymersomes can be varied by selecting different organic solvents. The polymer rehydration method involves the hydration of amphiphilic block copolymer films to induce self-assembly. Polymers are first dissolved in an organic solvent followed by evaporation of the organic solvent to form a thin film. Then, water is added to hydrate the film, and the successive processes of water permeation through defects in the polymer layers driven by hydration forces, inflation of polymer layers, and formation of bulges finally yield polymersomes upon separation from the surface. Polymersomes produced by this method have a broad size distribution, and desired polymersomes are obtained by sequential extrusion through filters with different pore sizes under high pressure. In general, polymersomes are more stable in the blood circulation



• **Figure 1.3.8B.6** Synthesis of dendrimer. (Top) Divergent strategy; (bottom) convergent strategy (Boas and Heegaard, 2004).

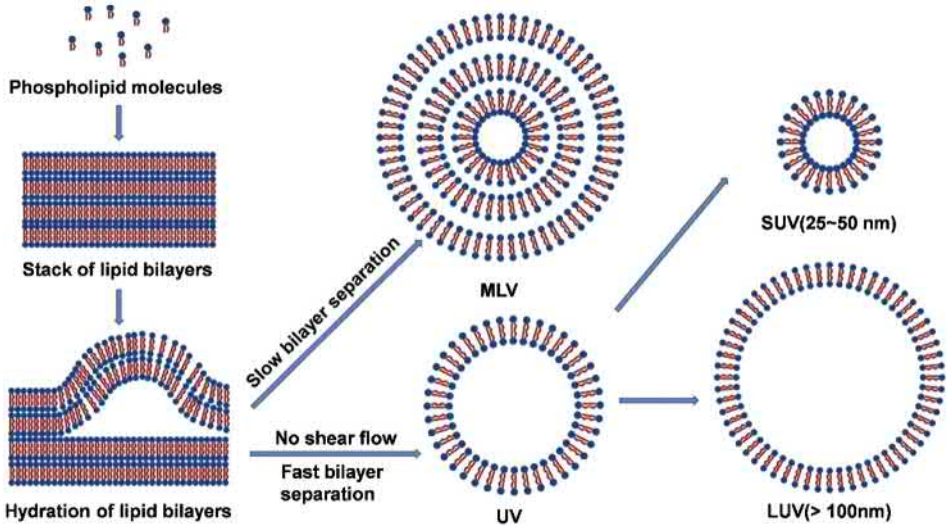
than liposomes. Hydrophilic, hydrophobic, or amphiphilic compounds can be loaded in either the aqueous core or the bilayer membrane of polymersomes, which makes them highly attractive for drug delivery, bio-imaging, and diagnosis.

Nanogels. Nanogels are nanoscale three-dimensional polymer networks with a high capacity to hold water, without dissolving into the aqueous medium. Nanogels with high loading capacity for drug cargoes and unique physical properties offer distinct advantages over other nanomaterials for biomedical applications. Their size, charge, porosity, amphiphilicity, softness, and degradability can be fine-tuned by flexible design. Nanogels can be prepared by physical or chemical cross-linking. Amphiphilic polysaccharides were first used to create physically cross-linked nanogels via hydrophobic interactions in water. However, physically cross-linked nanogels tend to be more fragile because they are stabilized by relatively weak interactions such as hydrophobic or ionic interactions. Meanwhile, the control over the particle size is another critical challenge, which is affected by the polymer concentrations, temperature, pH, and ionic strength. Chemically cross-linked nanogels are therefore developed via covalent bond formation during the polymerization of monomers or cross-linking of polymer precursors via thiol-disulfide exchange, amide cross-linking, click chemistry, Schiff-base reactions, photo-induced cross-linking, and enzyme-mediated cross-linking.

Dendrimers. Dendrimers are unimolecular NPs with a well-defined, homogeneous, and monodisperse architecture consisting of three distinct domains: (1) a core at the center of the dendrimer consisting of an atom or a molecule having at least two identical chemical functions; (2) branches, emanating from the core, constituted of repeating units having at least one branch junction, whose repetition is organized in a geometrical progression that results in a series of radially concentric layers called "generations"; and (3) multiple terminal functional groups, located on the surface of the dendritic architecture. The nomenclature dendrimer is derived from a Greek term *dendron* that means "tree." Divergent and convergent methods are most frequently used for dendrimer synthesis (Fig. 1.3.8B.6). The divergent approach comprises two steps, the activation of functional surface groups and the addition of branching monomer units. In this approach, the core is reacted with two or more equivalents of reagent containing at least two protecting/branching sites, followed by removal of the protecting groups, leading to the formation of a first-generation dendrimer. This process is repeated several times until dendrimers with specific generations and sizes are formed. One advantage of this approach is the ability to modify the surface of dendrimer molecules by changing the end groups at the outermost layer, while the main constraint is that only one type of functional group is placed on the outermost generation.

The convergent growth method would overcome this issue, and involves two stages, reiterative coupling of protected/deprotected branch to produce a focal point functionalized dendron, followed by a divergent core anchoring step to produce various multidendron dendrimers. Precise control over molecular weight and production of dendrimers with functionalities in precise positions and numbers are unique advantages of this method. However, difficulty in synthesizing dendrimers in large quantities is a significant limitation. Dendrimers with uniform and well-defined molecular structure, size, and shape are of prominent interest in biomedical applications because of their ability to cross cell membranes as well as reduce premature clearance from the body. Amine-terminated polyamidoamine (PAMAM) and polypropyleneimine (PPI) dendrimers display concentration-dependent toxicity and hemolysis, which, nevertheless, can be overcome by partial or complete modification of their periphery with negatively charged or neutral groups.

Nanocomplexes. Nanocomplexes are functional supramolecular nanocomposites formed from the self-assembly



• **Figure 1.3.8B.7** Preparation of different liposomes. (Reproduced from Yingchoncharoen, P., Kalinowski, D. S., Richardson, D. R., 2016. Lipid-based drug delivery systems in cancer therapy: what is available and what is yet to come. Pharmacol. Rev. 68, 701–787.)

of polymers and biomacromolecular drug cargoes, such as protein and nucleic acids, via specific intra- and intermolecular interactions. Cationic polymers can condense negatively charged nucleic acids to form nanocomplexes, called polyplexes. Polyplex formation is usually kinetically controlled; it is performed at ionic strengths where the polycation/polyanion association is rapid and almost irreversible. The sequence of addition of components during the complexation procedure (involving either the addition of a polymer solution to the DNA solution, or vice versa) influences the resulting polyplex size, as well as the transfection efficiency. Besides nucleic acid-based nanocomplexes, proteins can serve to form nanocomposites with various materials by self-assembly via electrostatic interactions, hydrogen bonding, hydrophobic interactions, or salt bridging. In addition, proteins can be fabricated into fluoroamphiphilic nanocomplexes via the fluorination effect.

Lipid-Based NPs

Liposomes. Liposomes are a class of nano- or micrometer-sized phospholipid vesicles composed of one or multiple lipid bilayers that envelope the inner aqueous cores. The polar head groups of phospholipids are oriented in the pathway of the interior and exterior aqueous phases. The liposome size can vary from very small (25 nm) to large (2.5 μm). On the basis of their size and number of bilayers, liposomes can be classified into two categories, multilamellar vesicles (MLVs) with sizes of 0.05–10 μm and unilamellar vesicles (ULVs) with sizes ranging from 25 nm to several hundred nm. ULVs can also be classified into large unilamellar vesicles (LUVs) and small unilamellar vesicles (SUVs) (Fig. 1.3.8B.7). Hydrophilic drugs can be encapsulated in the aqueous core and hydrophobic drugs are entrapped in the lipid bilayer, making them ideal candidates for drug delivery. Major methods to prepare liposomes include thin-film hydration, solvent injection, reverse-phase evaporation, detergent depletion, and microfluidics.

As a common technique for liposome preparation, thin-film hydration (also called the Bangham method) involves dissolution of the lipid in an organic solvent, evaporation of the solvent, and dispersion of the lipid film in aqueous media. However, the encapsulation efficiency of water-soluble drugs is often low (5%–15%). Moreover, this method produces large and heterogeneous MLVs that require additional sonication or extrusion to produce homogeneous small ULVs. Another technique is solvent injection. A lipid solution (diethyl ether or ethanol) is injected to an aqueous solution or a huge excess of buffer, and liposomes are obtained after removal of organic solvent. The major disadvantage of this technique is the heterogeneous population and difficulty to remove organic solvent. The reverse-phase evaporation method is based on the creation of inverted micelles. The inverted micelles are shaped upon sonication of a mixture of a buffered aqueous phase, which contains the water-soluble drug cargoes and an organic phase containing amphiphilic molecules. The slow elimination of the organic solvent leads to conversion of inverted micelles into viscous state and finally gel forms. At a critical point in this process, the gel state collapses, and some of the inverted micelles were disturbed. The excess of phospholipids in the environment donates to the formation of a complete bilayer around the residual micelles, which results in the liposomes. The detergent-depletion method involves the hydration of a lipid film with a detergent solution and leads to the formation of large MLVs. However, this method usually suffers from a long preparation time and poor trapping efficiency. The microfluidic-based method for liposome preparation allows strict control over lipid hydration, thus enabling precise control over liposome size and size distribution by controlling the flow rate and mixing conditions.

Solid lipid NPs (SLNs). SLNs, also known as lipospheres or solid lipid nanospheres, consist of lipid matrix that remain

in the solid state at room and body temperature coated with a monolayer of phospholipid and exhibit a size range of 50–1000 nm. Compared with liposomes, SLNs feature easy preparation, low cost, and amenability to scale up. Various techniques have been developed to prepare SLNs, including high-pressure homogenization, microemulsion, and precipitation via solvent evaporation. High-pressure homogenization further involves hot and cold homogenization. For hot homogenization, the drug is firstly dissolved in the lipid at the temperature 5–10°C above its melting point. The mixture is dispersed in an aqueous surfactant solution at the same temperature to form a pre-emulsion. After homogenization, the hot oil-in-water (o/w) nanoemulsion is allowed to cool down to recrystallize the lipid and form SLNs. For temperature-sensitive drugs, cold homogenization is required. The mixture of melted lipid and drug is cooled down to form the solid lipid which is ground to form microparticles (50–100 μm). The microparticles are further dispersed in a cold surfactant solution, homogenized at room temperature or lower, and cut into SLNs by the cavitation forces produced by the high-pressure homogenizer.

With regard to the microemulsion method, water, cosurfactants, and surfactants at the same temperature are mixed under mild stirring. Subsequently, the microemulsion is dispersed in cold water (2–3°C) under mild stirring and small particles are formed upon precipitation. This method allows preparation of SLNs on a large scale. The precipitation method by solvent evaporation is similar to PMs. Lipid is dissolved in organic solvent, emulsified in an aqueous phase, and then organic solvent is evaporated, leading to precipitation of the lipid to form SLNs. The main challenge of this method is the difficulty in removing organic solvent.

Lipoplexes. Cationic lipids can condense negatively charged nucleic acids at particular weight ratios to form nanocomplexes, termed lipoplexes. The lipid can fuse with cell membranes and endolysosomal membranes to potentiate intracellular gene delivery. The concentration, temperature, environment, and kinetics of mixing could affect the characteristics and transfection potential of lipoplexes. X-ray diffraction (XRD) studies have demonstrated the existence of different lipoplex structures. One is a multilamellar structure, with DNA monolayers sandwiched between cationic membranes, and the other is an inverted hexagonal structure, also called the inverted "honeycomb" phase, with DNA encapsulated within cationic lipid monolayer tubes. Similar to the gene complexes, cationic lipids can also assemble with negatively charged proteins/peptides to form lipopolyplexes.

Inorganic NPs

Gold NPs. Gold nanoparticles (GNPs) have unique chemical and physical properties for diagnosis and drug delivery. First, the gold core is essentially inert with low toxicity. Second, monodispersed GNPs are easy to synthesize, with sizes ranging from 1 to 150 nm. Via thiol linkages, GNPs can be facilely functionalized. Moreover, their photophysical properties can be used to trigger drug release at a remote place. GNPs can be prepared via various methods based on the reduction of gold salts in the presence of appropriate stabilizers, such as ligands, surfactants, and polymers. However, the most robust GNPs are stabilized by thiolates using a strong Au–S bond. A variety of monolayer-protected clusters (MPCs) can be formed rapidly and in scalable manner using the one-pot protocol developed by Schiffrin et al. in 1994 (Brust et al., 1994). In particular $AuCl_4^-$ salts are reduced with $NaBH_4$ in the presence of the thiol capping ligand. The core size of the particles can be varied from 1.5 nm to ~6 nm by varying the thiol-gold stoichiometry. Tunable size and functionality make GNPs a useful scaffold for efficient recognition and delivery of biomolecules. GNPs also have several advantages in diagnosis over quantum dots and organic dyes due to their better contrast for imaging, and surface-enhanced and distance- and refractive index-dependent spectroscopic properties. Moreover, GNPs can cause local heating to eradicate tumors when they are irradiated with light in the "water window" (800–1200 nm), which enables so-called photothermal therapy.

Magnetic NPs. Magnetic nanoparticles (MNPs) are being actively investigated as magnetic resonance imaging (MRI) contrast agents and nanocarriers for targeted drug delivery. Colloidal iron oxide nanoparticles, such as superparamagnetic iron oxides (SPIO) and ultrasmall superparamagnetic iron oxides (USPIO), are the most extensively investigated MNPs for biomedical applications. Typically composed of nanocrystalline magnetite (Fe_3O_4) or maghemite (γ-Fe_2O_3) protected with a polymeric coating, these ferrite NPs possess a spinel crystal structure with oxygen ions forming a close-packed cubic lattice and iron ions located at interstices. Efficient synthesis approaches including co-precipitation, thermal decomposition, hydrothermal synthesis, microemulsion, and sonochemical synthesis have been developed to produce the shape-controlled, stable, biocompatible, and monodispersed iron oxide NPs. In addition, electrochemical synthesis, laser pyrolysis techniques, microorganism or bacterial synthesis are also used to fabricate MNPs. The most conventional method for obtaining Fe_3O_4 or γ-Fe_2O_3 is by co-precipitation. This method consists of mixing ferric and ferrous ions in highly basic solutions at room temperature or at an elevated temperature. The size and shape of the iron oxide NPs depend on the type of salt used, the ferric and ferrous ions ratio, the reaction temperature, pH value, ionic strength, and other reaction parameters (e.g., stirring rate, dropping speed of basic solution). However, this method generates particles with a wide particle size distribution, which sometimes requires secondary size selection.

Silica NPs. Silica NPs are widely utilized for bioimaging and drug delivery due to their easy synthesis, uniform morphology, high surface area-to-volume ratio, controlled size, easy surface functionalization, and biocompatibility. In addition, silica NPs with size <5 nm show significant optical properties due to the quantum confinement effect. Generally, there are two types of silica NPs, the solid core/shell silica NPs and mesoporous silica NPs (MSNs).

The solid NPs can be used to deliver imaging probes doped into the core. MSNs contain mesopores with high surface area (600–1000 m^2/g) and pore volume (0.6–1.0 mL/g), and thus allow high drug loading and controllable release. The most well-known MSNs include MCM-41, MCM-48, and SBA-15, with different pore sizes (2–10 nm) and structures (2D hexagonal and 3D cubic).

There are two general routes for the synthesis of silica NPs, reverse microemulsion, and the Stöber method. The reverse microemulsion is an isotropic and thermodynamically stable single-phase system. Water nanodroplets formed in the bulk oil phase act as nanoreactors for the formation of discrete NPs. The Stöber method involves the hydrolysis of tetraalkyl silicates in a mixture of alcohol and water using ammonia as a catalyst. The synthesis of MSNs typically relies on the cooperative self-assembly of oligomeric silica species and supramolecular surfactant assemblies that act as structure-directing agents. MSNs are obtained after removal of the structure-directing agent, which leads to opening of the pores. By tuning the synthesis conditions and/or by variation of the reactants, elongated MSNs with tunable aspect ratios can be synthesized.

Quantum dots. Quantum dots (QDs) are semiconductor NPs with sizes ranging from 2 to 10 nm, often made from hundreds to thousands of atoms of group II and VI elements (e.g., CdSe and CdTe) or group III and V elements (e.g., InP and InAs). Physical size smaller than the exciton Bohr radius results in a three-dimensional quantum confinement of charge carriers within the QD and limits the number of possible energy states that an electron can occupy, thus giving NPs novel properties including unique photophysical properties and versatile surface chemistry that are not achievable in bulk materials. However, QDs are water-insoluble, limiting their biological applications. To address this issue, one approach involves replacing the hydrophobic trioctyl phosphine oxide (TOPO) coating with bifunctional ligands, which presents both a surface-anchoring group (e.g., thiol) and a hydrophilic end group (e.g., carboxyl or hydroxyl). An alternative approach is to retain the native TOPO coating and encapsulate the hydrophobic QDs with amphiphilic molecules such as polymers, or phospholipids. By decorating QDs with biomolecules that mediate specific interactions with living systems, QDs are effectively used for bioimaging, detection, and drug delivery. To this end, QDs can be conjugated with biomolecules via covalent bonding or coordination with metal atoms of the QD core/shell.

Nanocarbons. Nanocarbons, including carbon nanodots (CNDs), carbon nanotubes (CNTs), and graphene oxide, have been widely developed. Carbon dots (C-dots) contain many carboxylic acid moieties at their surface, thus imparting them with excellent water solubility and the suitability for subsequent functionalization. Approaches for synthesizing CNDs include top-down and bottom-up methods. Top-down methods consist of arc discharge, laser ablation, and electrochemical oxidation, where the CNDs are formed or "broken off" from a larger carbon structure. Bottom-up approaches consist of combustion/thermal, supported synthetic, or microwave methods during which the CNDs are formed from molecular precursors. Typically, their surfaces are oxidized by nitric acid (HNO_3) and further purified by using centrifugation, dialysis, etc.

Graphene is a 2D single layer of carbon atoms with a hexagonal packed structure. The highly reactive surface of graphene makes it difficult to be suspended in solution, which can be overcome by oxidizing graphene into graphene oxide (GO). The oxidized portion of the surface offers functional groups for further conjugation and the unmodified part of the surface is capable of loading drugs through hydrophobic interactions and π–π stacking.

CNTs are rolled-up seamless cylinders of graphene sheets, exhibiting unparalleled physical, mechanical, and chemical properties. Depending on the number of graphene layers, CNTs are classified into single-walled carbon nanotubes (SWCNTs) or multiwalled carbon nanotubes (MWCNTs). SWCNTs are one-dimensional (1D) nanomaterials with diameters of 1–2 nm and lengths ranging from 50 nm to 1 cm, and they may behave distinctly from spherical NPs in biological environments. MWCNTs are formed by multiple layers of graphene and have much larger diameters (10–100 nm). Surface functionalization of CNTs can be covalent or noncovalent. Covalent modification includes oxidation reaction using nitric acid to introduce carboxyl at the end of CNTs or at the defects on the sidewalls. Cycloaddition reaction via photochemical reaction of CNTs with azides is also commonly utilized. However, intrinsic physical properties of CNTs such as photoluminescence and Raman scattering are often destroyed after chemical reactions. In contrast, noncovalent functionalization of CNTs can be carried out by coating CNTs with amphiphilic surfactant molecules or polymers. The polyaromatic graphitic surface of CNTs is accessible to the binding of aromatic molecules via π–π stacking. Moreover, various amphiphiles have been used to suspend CNTs in aqueous solutions, with hydrophobic domains attached to the nanotube surface via van der Waals forces and hydrophobic effects, and polar heads for water solubility.

Bio-Inspired NPs

Exosomes. Exosomes are inherent carriers of genetic and proteomic information, and are believed to be a central form of cell–cell communication. This makes them attractive as delivery vehicles. Exosomes are formed intracellularly via endocytic invagination within the endosomal network. Early endosomes then undergo a series of alterations to become late endosomes or multivesicular bodies (MVBs), and the fusion of MVBs with plasma membrane results in the release of exosomes into extracellular space. Exosomes have a characteristic lipid bilayer with an average thickness of ~5 nm.

To date, five major exosome isolation techniques including differential ultracentrifugation-based techniques, size-based techniques, immunoaffinity capture-based techniques, exosome precipitation, and microfluidics-based techniques have been developed (Li et al., 2017). Ultracentrifugation-based exosome isolation is a gold standard method, wherein particulate constituents in a heterogeneous mixture can be

sedimented under the condition of centrifugation according to their density, size, and shape. More dense and/or larger particles settle out first. A variation of ultracentrifugation is density gradient ultracentrifugation including isopycnic ultracentrifugation and moving-zone ultracentrifugation. Ultrafiltration is a popular size-based exosome isolation technique, wherein the separation of suspended particles is primarily dependent on their size or molecular weight. Therefore, exosomes can be isolated using membrane filters with defined molecular weight or size exclusion limit. Ultrafiltration is faster than ultracentrifugation and does not require special equipment. However, the mechanical force may result in the deformation and breakage of large vesicles. Immunoaffinity capture involves immunoaffinitive interactions between antigens on exosomes and their antibodies. With respect to the precipitation method, exosomes can be settled out from biological fluids by altering their solubility or dispersibility. Generally, samples are incubated with a precipitation solution containing PEG (8000 Da), which tie up water molecules and force less soluble components out of the solution. The precipitate containing exosomes is isolated by means of either low-speed centrifugation or filtration. With the aid of microfluidics devices, exosomes can also be isolated with significantly reduced sample volume, reagent consumption, and isolation time (Li et al., 2017).

Protein NPs. Proteins have been used to construct NPs due to their biodegradability, nonantigenicity, abundant renewable sources, emulsification, gelation, foaming and water-binding capacity, and extraordinary binding capacity of various drugs. Additionally, protein NPs undergo less opsonization by the reticuloendothelial system (RES) through an aqueous steric barrier. Moreover, protein NPs can be easily prepared and scaled up, and they are amenable to surface modification due to abundant functional groups (i.e., carboxylic and amino groups) on the NP surface. Generally, animal proteins including gelatin, collagen, albumin, silk proteins, elastin, and milk proteins, and plant proteins including zein, gliadin, soy proteins, and lectins are widely used to construct protein NPs.

The techniques to prepare protein NPs include desolvation, coacervation-phase separation, emulsification-solvent evaporation, reverse-phase evaporation, nanoprecipitation, nano spray drying, and liquid–liquid dispersion (Elzoghby et al., 2012). For example, paclitaxel-loaded gelatin NPs are prepared by a coacervation-phase separation method. An aqueous solution of sodium sulfate is added slowly to gelatin solution containing Tween 20 followed by addition of isopropanol containing paclitaxel. The liquid–liquid dispersion method is used to fabricate zein NPs. Zein and drugs are dissolved in 70% ethanol, followed by shearing the solution into deionized water. Zein becomes insoluble when the ethanol concentration in the emulsified droplets decreases below a certain level, and precipitates to form NPs. However, proteins as natural polymers are heterogeneous mixtures of different sizes with a wide range of molecular weights, which will cause heterogeneous size distribution with batch-to-batch variation. Recombinant protein technology can be used to overcome this drawback, such as recombinant human serum albumin (HSA) and recombinant gelatin.

DNA nanostructure. The unique programmability of DNA enables the design of uniform nanostructures with well-defined geometries and topologies. DNA nanostructures are designed by precise self-recognition of A–T and C–G pairings. The superior biocompatibility is attributed to the degradability of DNA by DNase in tissues. Meanwhile, though free DNA is cell membrane-impermeable, a DNA nanostructure could readily enter cells via endocytosis. Single-stranded DNA could self-assemble into small building block materials called tiles. DNA tiles with "sticky ends" are able to further self-assemble into larger arrays with distinct geometries based on Watson-Crick base pairing (Pei et al., 2014). Various DNA nanostructures can be obtained, such as cubes, networks, arrays, or arbitrary shapes on a DNA canvas.

Generally, the process of DNA self-assembly can be divided into four categories. (1) The quick mix approach, wherein a set of DNA strands designed with unique sticky ends associate at definite positions to form the entire architecture. (2) Hierarchical self-assembly, wherein DNA strands are mixed in a particular order to minimize the unique set of strands required to generate individually formed multitile DNA structure. (3) Algorithmic self-assembly, wherein the DNA tiles are programmed with built-in instructions following algorithmic rules. (4) Nucleated self-assembly, wherein a longer strand is used as a nucleation site to attach the associated strands to generate a complex pattern. More recently, DNA origami has been developed, which is based on folding a long single-stranded DNA (ss-DNA, also called a scaffold strand) into a customized shape with a set of short synthetic ss-DNA strands (also called staple strands). DNA origami nanostructures could be further used as modular elements to form supernanostructures, making it possible to design complex nanostructures with one, two, and three dimensions. Moreover, rolling circle amplification (RCA), a polymerase chain reaction-based method, has also attracted considerable attention in assembling DNA nanostructure, which amplifies repeated single-stranded DNA from a circular single-strand template.

Hybrid NPs

Cell membrane-coated NPs. Cell membrane-coated NPs are characterized by a synthetic nanoparticulate core cloaked with a layer of natural cell membrane, which inherently mimics the properties of the source cells such as long circulation and disease-specific targeting. For example, red blood cells' (RBC) membrane coating prolongs the blood circulation of NPs. Platelet membrane coating renders an entire array of platelet surface markers, such as collagen-binding proteins and immunomodulatory proteins CD47, therefore allowing binding to human type IV collagen and reducing macrophage uptake. White blood cells' (WBC) membrane coating enables site-specific targeting to the vasculature of tumors or inflammatory tissues. Cancer cell membrane-coated NPs feature self-targeting and antigenic displays which could be used for immune modulation. Stem cell

membrane-coated NPs also feature tumor-targeting due to the tumor tropism of stem cells.

The cell membrane coating technology was first reported in 2011 (Hu et al., 2011). By transferring the outermost layer of a cell directly onto the surface of NPs, the complexity of the membrane, with all of its lipids, proteins, and carbohydrates, can be faithfully preserved. Cell membrane-coated NPs can be fabricated using several different methods. The extrusion method was firstly adopted, wherein the nanoparticulate cores and purified membrane were coextruded through a porous membrane. This method is adapted from the synthesis of liposomes, and the mechanical force provided by the extrusion is believed to disrupt the membrane structure and enable it to reform around the nanoparticulate cores. Another method is based on sonication. The cell membrane and NPs are subjected to disruptive forces provided by ultrasonic energy, resulting in the spontaneous formation of a core–shell nanostructure with less material loss. Recently, a microfluidic system that combines rapid mixing with electroporation has been employed for membrane coating. By fine-tuning the pulse voltage, pulse duration, and flow velocity, high-quality particles with complete coatings and exceptional stability are fabricated. Besides coating of NPs with purified membranes, an alternative approach is based on the in situ packaging of NPs using live cells. Cells are first incubated with NPs to allow internalization, and after incubation in serum-free media, the cells secrete vesicles containing the exogenous NPs.

Organic–inorganic nanocomposites. Organic–inorganic nanocomposites, also known as polymeric nanocomposites, are often obtained by grafting polymers onto inorganic NPs or by adding modified NPs into polymer matrices. The produced composite materials are intended to combine the unique optical, magnetic, and electronic properties of inorganic NPs and in the meantime enable desired colloidal stability as well as biological activity. Inorganic NPs have a strong tendency to aggregate in the polymer matrix and thus cause insufficient dispersion, and therefore it is essential that the NP surface is modified by polymer surfactant molecules or other modifiers. Commonly used methods for surface modification of inorganic NPs include chemical treatment, grafting of synthetic polymer, and ligand exchange. Various types of inorganic NPs, such as metals (e.g., Al, Fe, Au, and Ag), metal oxides (e.g., ZnO, Al_2O_3, $CaCO_3$, and TiO_2), nonmetal oxides (e.g., SiO_2), and others (e.g., SiC), have been incorporated into polymeric nanocomposites.

The conventional and simple method for the preparation of polymeric nanocomposites is direct mixing of NPs with the polymer matrix, which can be done by solution blending, emulsion blending, or melt blending. Solution blending is a liquid-state powder processing method, which is widely used when the polymer and inorganic NPs are dissolved in solution. Emulsion blending, also known as suspension blending, is similar to solution blending, but requires the use of an emulsion or suspension solution instead of a simple solution, which is an effective method for polymers difficult to dissolve. Regarding melt blending, NPs are dispersed in the polymer melt and the polymeric nanocomposites are obtained by extrusion. Sol–gel processing is another method for the synthesis of polymeric nanocomposites. The sol–gel processing of NPs inside a polymer dissolved in aqueous solutions leads to the formation of interpenetrating networks between inorganic and organic moieties at mild temperature. The network improves the compatibility between components and builds a strong interfacial interaction between the two phases. In situ fabrication of polymeric nanocomposites is another simple and efficient method, wherein the NPs are generated from their respective precursors in the presence of the polymer matrix. After the nanocomposites are formed, the undesired or unbound chemical products are removed. Another in situ fabrication approach consists of the simultaneous formation of both the polymer matrix and the inorganic NPs. In this method, precursors of the NPs are dispersed in the polymerizable monomers, and the inorganic NPs and the polymer matrix are generated simultaneously. The in situ formed metal surface can catalyze or initiate the polymerization via electron transfer from the metal surface atoms to the monomers. Thus, the degree of dispersion of the inorganic component is an important parameter, which may affect the formation of inorganic NPs and in turn the degree of polymerization.

Lipid–polymer NPs (LPNs). LPNs are a class of core–shell NPs consisting of three components, a polymer core, an inner lipid layer enveloping the polymer core, and an outer lipid-PEG layer. The LPNs combine the characteristics of both polymeric NPs and liposomes, and feature high structural stability, membrane fusion capability, biocompatibility, and bioavailability. Generally, the preparation of LPNs can be realized via a two-step or one-step method. In the two-step method, polymeric NPs and lipid vesicles are mixed together, and the lipid vesicles are adsorbed on the NPs via electrostatic interactions. Alternatively, polymeric NPs can be added to a dried thin lipid film. For both of these approaches, LPNs are produced by either vortexing or ultrasonication of the mixture. Afterward, the LPNs are separated from the nonadsorbed lipid by centrifugation. By passing through a porous membrane, monodisperse LPNs are obtained in the determined size range. Other methods such as spray drying and soft lithography particle molding have also been developed to prepare LPNs via mixing of polymeric NPs and lipids. The soft lithography particle molding technique, also called particle replication in nonwetting templates (PRINT), is a promising technique for scalable fabrication of particles with definite shape and size. In this technique, the polymer is dissolved in an organic solvent and cast onto a polyethylene terephthalate (PET) sheet which is heated to allow flow of the polymer into the mold and then solidifying at room temperature. The NPs are thus formed, and harvested using a poly(vinyl alcohol) (PVA)-coated PET sheet. The NPs are released from the sheet by dissolving PVA in an aqueous solution of lipids, thus forming the LPNs. Based on this technique, a variety of shapes can be prepared. The main disadvantage of the

two-step method is that polymeric NPs and lipid vesicles have to be separately prepared in advance.

In comparison, the one-step method that only involves the mixing of polymer and lipid solutions followed by nanoprecipitation or emulsion is more effective. In the nanoprecipitation approach, polymer is dissolved in a water-miscible organic solvent, while the lipid and/or the lipid-PEG are dissolved in water and heated. The organic solution is added dropwise into the aqueous solution under continuous stirring, leading to formation of NPs and self-assembly of the lipids on the surface via hydrophobic interactions. The emulsion approach is divided into single and double emulsification. For single emulsification, polymer dissolved in a water-immiscible solvent is added to an aqueous solution containing lipids with continuous stirring or ultrasonication to form an oil-in-water (o/w) emulsion. After removal of the oil phase by evaporation, LPNs are formed via self-assembly. The single emulsification approach is suitable for encapsulating cargoes soluble in the water-immiscible solvent. In contrast, double emulsification is employed when the encapsulated substance is insoluble in any organic solvent. In this case, the substance is dissolved in aqueous phase, and emulsified in an oil phase containing the polymer and lipid. The w/o emulsion is further emulsified for the second time in aqueous phase containing lipid-PEG to form w/o/w emulsion. The LPNs are obtained after evaporation of the oil phase.

Characterization of NPs

Physicochemical properties of NPs, such as size, surface properties, and morphology, are major determinants of their behavior in biological systems. By modulating these physicochemical properties, researchers can obtain NPs with tailored structures to meet their purposes of application. In addition, the biocompatibility of NPs is another crucial property consideration for biomedical applications. In this section, the common methods to characterize the size, surface charge, morphology, and biocompatibility of NPs are introduced.

Size

Various characterization methods of NP size have been developed. First, size can be determined by direct visualization via microscopy techniques such as scanning electron microscopy (SEM), transmission electron microscopy (TEM), and atomic force microscopy (AFM). Among them, SEM and TEM can directly observe the size and shape of NPs. The thickness of the particles can be estimated, and the size distribution can be analyzed in combination with statistics. In addition, the microstructure inside NPs can be analyzed after slicing the samples. The SEM resolution is lower than TEM, but the preparation of the sample is simpler, and nonconductive samples need to be sprayed with Pt or Au. The size measured by both SEM and TEM is aggregate size, and due to the small number of samples it may not be representative and the results may not be statistical. Therefore, it is necessary to fully disperse the NPs during sample preparation. For AFM, the reaction of the probe to the forces that the sample imposes on it can be used to form an image of the three-dimensional shape of NPs at high resolution. AFM can not only measure the size and shape of the sample at a near-atomic resolution, but can also measure the force between surface atoms, the surface elasticity, plasticity, hardness, friction, and other properties. However, AFM can only observe a small number of samples and takes a long time, which is the main obstacle.

Dynamic light scattering (DLS) is the most widely used characterization method for determining NP size. This method obtains particle size information by utilizing time variation of scattered light from suspended particles under Brownian motion to obtain their hydrodynamic size distribution. DLS can accurately measure NP size below 5 μm. However, DLS results are susceptible to interference. Sample preparation is crucial, and should be clear, homogeneous, and without haze. A higher concentration of NPs results in multiscattering, where the scattered light from one particle interacts with other particles before reaching the detector and loses intensity, which will result in a size estimate that is too low. Overdiluted samples cannot generate enough scattered light for analysis. As a result, it is necessary to run DLS experiments on serial dilutions. NP shape and size distribution have a great influence on the DLS measurement results. Irregular particle shape and wide particle size distribution may cause more errors.

X-ray diffraction (XRD) and light Raman scattering (LRS) can be used to calculate crystal size. When NP size is smaller than 100 nm, it can be calculated from the diffraction peak width of XRD. LRS can measure the average diameter of nanocrystalline grains. In addition, NP size can be calculated by the specific surface area and density.

In practical applications, the size characterization method is selected according to the particle size range and morphology. It is recommended to use two or more characterization methods to verify each other.

Surface Charge

Until now, there is no satisfactory technique to directly determine the surface charge of NPs in liquid. Common practice is to determine the electric potential of NPs at a location away from the particle surface, somewhere in the diffuse layer, which is called the slipping or shear plane. The potential measured is called the zeta potential (ζ-potential), which is related to the movement of NPs in liquid. Zeta potential is usually used to represent the surface charge of NPs, and is closely related to NP suspension stability. In the solution state, the absolute value of the zeta potential is larger and the repulsive force between particles is larger, and thus the system is more stable. On the contrary, if the absolute value of zeta potential is small, NPs tend to aggregate. Zeta potential can be affected by pH, the electrolyte type, as well as concentration.

There are three existing methods to measure zeta potential, electrophoretic light scattering (ELS), acoustic, and electroacoustic. The acoustic method yields only average values with low sensitivity provided that the solid concentration is known. ELS, characterized with desired sensitivity, accuracy, and versatility, is the most widely used method. Its principle is that under the action of an electric field, the charged particles will move along a set direction. By irradiation with the laser, the velocity of the particles can be calculated and, from that, the zeta potential can be calculated. Recently, commercial instruments have been widely used for measuring zeta potential. Zetasizer Nano series (Malvern, UK) can effectively eliminate electroosmosis and analyze samples in nonaqueous dispersions.

Morphology

Morphology of NPs can be observed by microscopy, such as SEM, TEM, and AFM. Several factors can be used to describe the morphology, including circularity, aspect ratio, elongation, convexity, and fractal dimension. Diffraction technology such as powder XRD, small angle X-ray scattering (SAXS), small angle neutron scattering (SANS), and electron diffraction (ED) can also be used to characterize NP morphology. XRD determines the atomic and molecular structure of a crystal. The principle of XRD is that the crystalline structure causes incident X-rays to diffract into many specific directions. By measuring the angles and intensities of these diffracted beams, a three-dimensional picture of the density of electrons within the crystal can be produced. From that, the mean positions of the atoms in the crystal can be determined, as well as their chemical bonds, crystallographic disorder, and other information. SAXS is suitable for characterizing the structure of NPs at lower resolutions and the crystalline sample is not required. In addition, techniques such as nuclear magnetic resonance (NMR) can be used for morphology characterization.

Biocompatibility

Biocompatibility of NPs refers to the ability of NPs to perform their desired function without eliciting any undesirable local or systemic effects. When NPs enter the body, there may be a series of interactions between NPs and cells or the extracellular environment, which could eventually cause the NPs to be contained, removed, degraded, metabolized, or undergo toxicological reactions leading to tissue damage. To ensure the safe use of NPs for biomedical applications, the biocompatibility must be studied and clearly characterized. In fact, a thorough evaluation of the biocompatibility of NPs is central and possibly a first key step for the safe delivery of drugs.

In Vitro Toxicity

Cell viability test. The cell viability test is an in vitro method to detect the cytotoxicity of NPs, and is usually based on the measurement of metabolic activity. The most common method to measure metabolic activity of cells involves the utilization of tetrazolium reagent chemistries (e.g., MTT, MTS, XTT, WST). For example, MTT can be reduced by viable cells into an intensely colored formazan precipitate that is subsequently solubilized followed by absorbance measurement. Detection of ATP is another viability assay that has become the gold standard for high-throughput screening. The process of cell death results in a loss of ability to synthesize new ATP along with a rapid depletion of cytoplasmic ATP by endogenous ATPases, which makes ATP a valid marker of viable cells. Protease activities (such as caspase-3) can also be used as a marker of cell viability.

Oxidative stress test. Oxidative stress (OS) caused by the presence of reactive oxygen species (ROS) is an important cause of NP toxicity. ROS can cause damage to biomolecules including DNA, RNA, proteins, and lipids, and the OS levels can be evaluated using the following assays. Direct ROS measurement is the most common method, which involves the use of fluorescent probes and electron paramagnetic resonance. However, ROS are extremely unstable and difficult to measure directly. Therefore, indirect approaches such as measurement of proteins, DNA, RNA, lipids, or other biomolecules levels are utilized. An alternative approach is to measure the levels of antioxidant enzymes and other redox molecules which serve to counterbalance ROS generated in the cells.

Cellular stress response test. NPs can cause nonfatal damage or changes in cell behavior that are mainly due to changes in protein and gene expression, regulation of phagocytic capacity, and inflammatory response. Changes in protein and gene expression relevant to inflammatory responses can be determined by PCR, immunoblotting, and total protein analysis (e.g., BCA method, Bradford method).

Hemocompatibility

Hemocompatibility refers to the properties that allow NPs to maintain contact with flowing blood without causing adverse reactions, releasing leachable components, or triggering adverse reactions. Regardless of the administration method used, NPs may be translocated to the blood circulation, which makes hemocompatibility of critical importance. Generally, erythrocyte composure (hemolysis and hemagglutination), thrombogenicity, cytokine assays, and complement activation (protein adsorption) are the major parameters during hemocompatibility assessment.

In Vivo Toxicity

Acute toxicity. Acute toxicity testing of NPs is designed to determine the serious toxicological effects produced within a certain period of time after single or multiple administrations. It serves to determine the doses that should be used in subsequent studies, and it renders another opportunity to find out what effects the NPs have in clinical chemistry, and also gives an early indication of possible target organs. Acute toxicology testing may have multistage exposures, with escalating doses to find the maximum tolerance dose (MDT). In general, these studies include 3–4 animals per sex per

group for nonrodent species, and 5–10 rodents per sex per group. Most studies include clinical observations and pathology determinations. LD_{50}, also known as the median lethal dose, is an important parameter for acute toxicity testing, which represents the dose required to kill half of the tested animals within a specified test duration.

Subacute/subchronic/chronic toxicity. The objective of these tests is to define the toxic effect of NPs over a period of repeated administrations. It is performed by giving NPs at multiple doses with certain intervals that will produce animal intolerance. Additionally, these studies may identify the minimal doses harmful to animals. Importantly, such long-term toxicity testing is designed to serve clinical trials and clinical medications. Therefore, attention should be paid to predicting the possible clinical adverse reactions of NPs, judging the target organs or target tissues when they are repeatedly administered, and estimating the range of clinical doses. In addition, the choice of experimental animal species and strains should enhance the predictability of the studies for human subjects. When choosing the species and strain of animals, the therapeutic target and the similarity of its distribution in the experimental animals to that in humans are important. The similarity of the pathophysiological mechanisms in the target organ should also be taken into consideration.

Genotoxicity and carcinogenicity. The genotoxicity and carcinogenicity of NPs are mainly attributed to factors such as direct interaction of NPs with the genetic material, indirect damage due to ROS generation, release of toxic ions, interaction with cytoplasmic/nuclear proteins, binding with the mitotic spindle or its components, increased oxidative stress, disturbance of cell cycle checkpoint functions, and inhibition of antioxidant defense. The genotoxicity of the NPs can be assessed using the prokaryotic system, either in in vitro cell cultures or in in vivo models. The bacterial reverse mutation assay (Ames test) is used for initial screening for genotoxicity. Subsequently, the ability of NPs to induce DNA damage is assessed in multiple cell lines using different assays such as the comet assay, gene mutation assay, micronucleus assay, and chromosomal aberration assay. The genotoxic potential of NPs is finally confirmed using animal models. Carcinogenicity tests are intended to identify the carcinogenicity risk in experimental animals and predict carcinogenic potential in clinical medication. Long-term exposure of animals, such as 2-year chronic administration in mice and rats, is required to express any carcinogenic potential.

Drug Delivery Applications of NPs

Drug Loading

Drug delivery using nanocarriers has various advantages, such as increasing drug solubility, prolonging blood circulation, enhancing tumor distribution, and decreasing systemic toxicity. Drugs can be loaded into NPs via covalent bonding and noncovalent encapsulation.

Covalent Bonding (Prodrug)

Drugs can be conjugated to NPs via covalent bonding, which affords advantages such as high drug-loading efficiency, stability of covalent bonds during circulation, and minimal side toxicity in nondiseased tissues. The covalent bonds need to be cleaved in tumor tissues/cells, thus realizing drug release and recovery of drug activity. Polymer–drug conjugates which can self-assemble into NPs have been widely developed. Polymers including block copolymers, dendritic polymers, and comb-like copolymers have a large number of active functional groups, and anticancer drugs can be coupled onto side chains to achieve high drug loading.

The most widely used polymers include poly(ethylene glycol) (PEG)-based block copolymers, poly(amino acid)s, polypeptides, and polysaccharides. For example, NPs self-assembled from PEG-b-PCPTM have been developed for camptothecin (CPT) delivery, in which PCPTM is a polymerized block of a CPT prodrug monomer with a reduction-responsive drug release manner. Drugs can also serve to control the polymerization for preparing polymer–drug conjugates. For example, paclitaxel (PTX) with multiple hydroxyl groups can be used to initiate the controlled polymerization of lactide for the formulation of polymeric NPs (Tong and Cheng, 2008).

Besides polymer–drug conjugates, drugs can also be connected to each other to form drug–drug conjugates. For example, PTX can be connected via a thioketal linker to form ROS-responsive PTX dimer. Camptothecin (CPT) can also be connected to form the dimeric CPT derivative, which can prevent the π–π interaction among drug monomers, thus prohibiting the drug aggregation in the aqueous solution to achieve ultra-high drug loading in NPs.

Different from polymer–drug conjugates and drug–drug conjugates, one drug molecule can be coupled to another nondrug small molecule, and the prodrugs themselves can self-assemble into NPs. These drug conjugates mainly include four categories: (1) lipid–drug conjugates (e.g., squalenoylations, cholesteryl, and palmityl prodrugs of anticancer agents); (2) low-molecular-weight oligo(ethylene glycol) (OEG)–drug conjugates; (3) amphiphilic peptidic prodrugs; and (4) tocopherol succinate–drug conjugates. An advantage of a low-molecular-weight prodrug delivery system lies in their smaller particle size and higher drug-loading capacity. However, they also have limitations, such as short circulation time in the blood due to lack of a dense shield layer (e.g., long-chain PEG) and poor structural stability owing to the relatively higher CMC. Therefore, NPs self-assembled from low-molecular-weight conjugates are usually stabilized by using an amphiphilic block copolymer containing a long PEG chain to achieve both long blood circulation time and high structural stability.

Noncovalent Encapsulation

Prodrug design features precise control over chemical composition, which unfortunately can be associated with tedious synthesis that would result in high cost and difficulty in quality control as well as scale up. As an alternative, drugs can be

noncovalently encapsulated into various NPs, which allows easy manipulation and scale up. Common noncovalent interactions include hydrophobic interaction, π–π interaction, hydrogen bonding, electrostatic force, van der Waals force, coordination bonding, and physical combination.

Hydrophobic interaction. Hydrophobic interaction (10–60 kJ/mol) is most widely utilized for drug encapsulation, in particular in micelles. Hydrophobic chemodrugs are efficiently encapsulated in the hydrophobic core of micelles via hydrophobic interactions. Various factors, such as the chemical characteristics of the drug, the hydrophobic nature of the copolymers, and the miscibility of both, affect the strength of the hydrophobic interaction and accordingly the entrapment efficiency, drug-loading capacity, and stability of the drug-loaded micelles.

π–π interaction. π–π interaction, although featuring relatively low bonding energy (8–9 kJ/mol), plays an important role in improving the loading capacity of aromatic drugs in NPs bearing aromatic rings. For example, nanographene with polyaromatic surfaces features efficient loading of aromatic drug molecules (i.e., DOX, hypocrellin B, chlorin e6, and epirubicin hydrochloride) via π–π stacking.

Hydrogen bonding. Hydrogen bonds with relatively high bonding strength (10–40 kJ/mol) can be introduced between NPs and drug molecules to enhance the drug-loading capacity. For example, NPs can be modified with thymine and cyanuric acid to enhance the loading of methotrexate (MTX) by forming three-point hydrogen bonds.

Electrostatic force. Electrostatic interaction (~500 kJ/mol) is totally nondirectional and by far the strongest physical interaction. It can be attractive or repulsive, and can function over distances much longer than those of covalent bonds. Electrostatic interaction plays an important role for drug loading, since many active substances carry charged groups. For instance, the charged drug can be efficiently encapsulated inside the liposomes by forming an insoluble ion complex through a strong electrostatic interaction between drug and particular ions such as ammonium sulfate, manganese, citrate, and phosphate. Drug can also be efficiently encapsulated in liposomes based on the direct electrostatic interactions between the drug and lipid.

van der Waals force. van der Waals force (~1 kJ/mol) includes three distinct types of forces, induction, orientation, and dispersion forces. The dispersion force is solely involved in the interactions between nonpolar molecules (i.e., hydrocarbons), and plays a dominant role in the drug–NP interactions when hydrocarbons are used as hydrophobic regions. Usually, the nonpolar groups (i.e., cholesterol and aliphatic hydrocarbons) are grafted to the hydrophilic polymer (i.e., polyvinyl alcohol, PEG, polysaccharide, and peptides) to allow them to form micelles.

Coordination bonding. Coordination bonding, also known as donor–acceptor interaction, is a common molecular force between electron donors and acceptors. The donor–acceptor bond energy is usually weaker than covalent bonds, whereas it is stronger than hydrophobic interactions. Ultra-high drug loading (50%) and quantitative loading efficiency (>99%) can be achieved for DOX using micelles, by incorporating the coordination effect between the pendant phenylboronic acid (electron-acceptor unit) on micelles and DOX (donor acceptor) (Lv et al., 2018).

Physical combination. Drug can be physically loaded into NPs via embedding. Mesoporous materials, especially mesoporous silica NPs, are commonly used to physically encapsulate drugs that can diffuse into channels or empty cores of these materials. To prevent the preleakage of drug cargoes, the mesoporous NPs are often surface-decorated with gating materials, and the gates can be opened under specific conditions to allow selective cargo release.

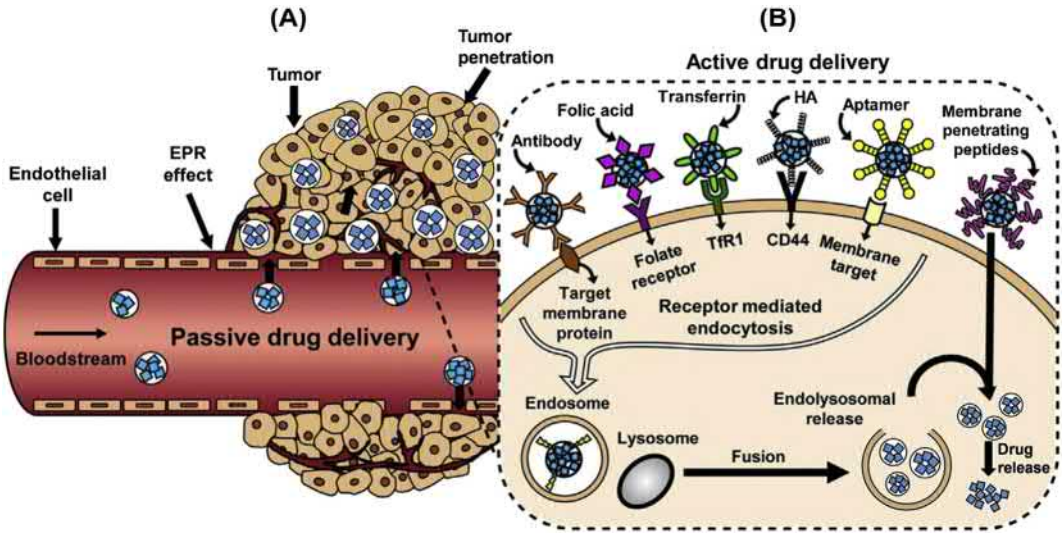
Systemic Barriers Against Drug Delivery

NP delivery to tumors is impeded by multiple systemic barriers, including clearance by renal filtration and the reticuloendothelial system (RES), extravasation through the enlarged endothelial gaps in tumors, the dense stroma in the tumor microenvironment that impedes penetration of NPs, cellular membranes blocking internalization of NPs, and release of the drug cargoes to induce a pharmacological effect (Fig. 1.3.8B.8).

Circulation. Short circulation time can greatly limit the performance of chemodrugs. The RES interaction can scavenge NPs from the blood circulation, especially positively charged NPs, because phagocytic cells such as macrophages will engulf particles bearing recognized opsonins (negatively charged serum proteins) that have adsorbed to NPs via electrostatic interaction. Factors affecting opsonization and the RES interaction include size, surface composition, zeta potential, and the shape of NPs. Interaction of NPs with the RES will shorten the blood circulation time, and accordingly reduce tumor accumulation.

Tumor accumulation. The tumor blood vessels are dense, immature, chaotically branched, and dilated. Limited perfusion becomes a barrier against extravasation of NPs from the bloodstream into the tumor tissues. Typical tumor vascular characteristics, such as irregular leakage, poor perfusion, and compressed blood vessels, limit the accumulation and distribution of NPs.

Tumor penetration. NPs that have successfully extravasated into tumor tissues face another barrier consisting of high interstitial fluid pressure (IFP), dense stromal tissue, and complex interactions with macrophages, fibroblasts, and tumor cells, which collectively impedes the penetration of NPs into deep tumor tissues. The lack of lymphatic vessels and the vascular hyperpermeability inside tumors results in interstitial hypertension. High IFP in tumors disrupts normal convective flow, and NPs that rely on convective flow cannot efficiently transport into the deep tumor compartment. In addition, tumors are often rich in stromal tissues. Fibroblasts in tumors are unregulated, continuously proliferate, and do not senesce. The dense extracellular matrix (ECM) produced by the activated fibroblast impedes the convective and diffusive transport of NPs.



• **Figure 1.3.8B.8** Critical steps in nanomedicine-mediated delivery of chemodrugs into cancer cells, including circulation in blood compartments, accumulation and penetration in tumors, cellular internalization, and intracellular drug release. (Reproduced from Bar-Zeev, M., Livney, Y. D., Assaraf, Y. G., 2017, Targeted nanomedicine for cancer therapeutics: towards precision medicine overcoming drug resistance. Drug Resist. Updates 31, 15–30.)

Cellular internalization and efflux. Phagocytosis and endocytosis are two major internalization mechanisms by which cells take up NPs. Endocytosis can be further divided into caveolae- or clathrin-mediated endocytosis, as well as clathrin-independent or caveolae-independent endocytosis. Different mechanisms of endocytosis put forward different requirements for NP design. For example, in clathrin-mediated endocytosis, endosomal escape must occur before fusion with the lysosome to prevent cargo degradation. For NPs entering the lysosomal compartments, the released drug must be resistant to the lysosomal environment and be able to escape into the cytosol. Besides internalization, the efflux system also plays a pivotal role in eliminating chemodrugs. The ATP-binding cassette transports (such as P-glycoprotein) work in concert with drug-metabolizing enzymes to pump out drugs and their metabolites, thus provoking multidrug resistance (MDR).

On-demand drug release. The drug cargoes need to be released effectively and selectively in tumor tissues/cells to realize their anticancer efficacy and reduce undesired toxicity to normal tissues/cells. Excessive stability of NPs will impair the drug release efficiency. For example, Doxil (a liposomal formulation of DOX) delivers 10–15 times more DOX to the tumor compared to standard therapy, but slow release results in low bioavailability (40%–50%). Additionally, the excessively slow drug release may cause drug resistance, due to the insufficient drug concentration to potently kill cancer cells. On the other hand, excessive instability can also be a persistent challenge. In the application of Genexol and NK105, the taxanes rapidly partition out of the polymeric micelles and bind with serum proteins during blood circulation. Excessive instability can also cause additional toxicity, because the prematurely released drugs would distribute in normal organs.

Approaches to Overcome Systemic Barriers

Long-Circulating NPs

In order to prolong the circulation time, hydrophilic stealth polymers such as PEG, poly(acrylic acid), and polysaccharides have been used as surface coating materials. PEGylation is the most commonly used strategy, because PEGylated NPs experience reduced opsonization by blood proteins and clearance by RES. Due to its hydrophilic nature, PEG chains grafted on the NP surface generate a hydrated cloud with a large excluded volume that sterically precludes NPs from interacting with neighboring NPs and blood components. The surface charge shielding effect of PEG on positively charged NPs is also an important factor to prolong circulation, because positively charged NPs will not only increase the adsorption of opsonins, leading to their recognition by macrophages, followed by phagocytosis and elimination, but also increase electrostatic interactions with the vascular wall to increase the clearance rate. In addition, the large conformational freedom provided by the flexibility of PEG renders interpenetration of foreign matters into the PEG corona thermodynamically unfavorable. Thus, PEG coatings on NPs prevent aggregation, opsonization, and phagocytosis, thereby prolonging the blood circulation time. The first PEGylated polymeric NPs based on poly(lactic-co-glycolic acid) (PLGA) were developed in 1994 by Ruxandra Gref et al. (Gref et al., 1994).

However, PEGylation also has some shortcomings. First, PEG impedes the interaction with target cells because of its superhydrophilicity that is rejected by the phospholipid bilayer of the cell membrane. Second, PEG possesses accelerated blood clearance effect, because repeated administration of PEG may result in anti-PEG IgG in the human body. After being connected with neutralizing antibodies

secreted by B cells, the PEG-modified NPs that are repeatedly administered will be recognized and cleared by phagocytes, resulting in a significantly shortened half-life.

Various strategies have been developed to overcome these shortcomings. Sheddable PEGylation is a commonly used approach, which removes the PEG coating from NPs at the target site. For example, PEG could be conjugated to the liposomal surface via a matrix metalloproteinase-2 (MMP-2) cleavable peptide. MMP-2 overexpressed in the ECM of tumor tissues can cleave the peptide and remove PEG to promote cancer cell internalization. Besides PEG, other materials have also been investigated for NP surface decoration. Polyvinyl pyrrolidone (PVP) is a common example used for the modification of metal NPs or upconversion NPs to enhance their solubility. Recently, zwitterion as an alternative to PEG has demonstrated good performance. Besides endowing the NPs with good solubility, decreased immunogenicity, and excellent mucus-penetrating ability, the zwitterion provides monolayer-type coverage with minimal thickness, while the PEG appears to yield a more three-dimensional coating.

In addition to covalent modification, the noncovalent surface coating strategy is also used. For example, negatively charged hyaluronic acid can be coated onto positively charged NPs via electrostatic interaction, thus neutralizing the positive surface charge of NPs to prolong blood circulation. Recently, cell membrane-coated NPs have attracted tremendous attention due to their desired capabilities to prolong the systemic circulation. Among them, erythrocyte membrane displays the strongest long-circulation property, and thus erythrocyte membrane-coated NPs can bypass macrophage uptake and systemic clearance.

Suitable NP morphology design contributes to extension of the circulation time. The importance of NP shape was first demonstrated by Dennis Discher in 2007, with the persistent circulation of soft filamentous or worm-like micelles for ~1 week in mice or rats (Geng et al., 2007). NPs in cylindrical shape display a longer circulation time than those with a spherical shape, and this prolonged circulation effect stems from the interplay between surface properties, nanoparticle core rigidity, length or aspect ratio, and shape. Phagocytosis by macrophages exhibits a strong dependence on NP morphology, as NPs with higher aspect ratios are less likely to undergo phagocytosis than spherical ones of the same volume. The reason is that the interactions between long cylindrical micelles and cell surfaces are easily disrupted under strong hydrodynamic shear forces that minimize the opportunity for cell uptake. In contrast, spherical NPs are less influenced by shear and are able to interact more strongly with cell surfaces to enhance cellular uptake. In addition, nonspherical NPs show a deviating hydrodynamic behavior in comparison to spherical ones, which allows them to align with the blood flow and contributes to the extension of circulation time. Apart from this, nonspherical NPs exhibit more complex motions with tumbling and rolling, which can be exploited to the action of drifting laterally toward the vessel walls under flow without the need for lateral external forces. Thus, they can exit the main vasculature more easily than quasihemispherical and spherical NPs in the bloodstream. Other NP shapes such as disks and lamellae can also prolong the circulation time.

Targeted Drug Delivery

Targeted delivery of chemodrugs has always been an important direction of modern pharmacy. Most chemodrugs have great toxic and side effects because they kill not only cancer cells but also normal cells. Targeted drug delivery can reduce cytotoxicity, promote entry into tumor tissues and cells, and overcome MDR.

Passive targeting (EPR effect). Unlike the compact and well-structured microvascular endothelial spaces in normal tissues, the vasculature in solid tumor is characterized by poor structural integrity, wide vessel wall spaces, and abundant blood vessels. Such leaky vasculature thus promotes the transport of NPs from the blood circulation into tumor tissues. Additionally, solid tumors lack lymphatic reflux, thus impeding the clearance of NPs from the interstitial space of tumor tissues. Such a phenomenon is called the EPR effect, and EPR effect-enhanced tumoral accumulation of NPs is defined as passive targeting.

The EPR effect is mainly based on leaky blood vessels within tumors, with transvascular endothelium gaps ranging between 100 and 780 nm in diameter. The size and shape of NPs can significantly affect their passive targeting to the tumor tissue. The sizes should be larger than 4–5 nm to avoid quick kidney filtration while being less than 200 nm to extravasate the leaky vasculature. NPs in the size range of 20–200 nm tend to penetrate inside the interstitial space due to the poorly aligned defective endothelial cells. The biodistribution pattern of NPs is also highly dependent on their shape. Nonspherical NPs exhibit different in vivo behaviors. For example, filomicelles have limited accumulation in healthy organs or tissues because of the hydrodynamic flow effect, but they are able to move around obstacles and reptate into tumors through small leaky vasculatures, while spherical NPs of the same volume must deform to pass through small tubular pores into tumors. Surface charge is another important factor. Positively charged NPs can bind to the luminal surface of vascular walls and be cleared rapidly from the blood circulation, as the blood vessels have a negatively charged surface. In contrast, negatively charged NPs show higher accumulation in the liver due to charge-selective filtration.

Several strategies have been applied to improve EPR-mediated passive targeting, which includes the use of inflammatory cytokines and vasomodulators to permeabilize blood vessels and increase blood flow. Several vasomodulators such as histamine, serotonin, bradykinin, and tumor necrosis factor-alpha (TNF-α) have been coupled with nano-delivery systems to enhance vascular permeability in tumors. Nitric oxide (NO), as a potent endothelium-derived vasomodulator, is also utilized to enhance vascular permeability, thus inducing vasodilation and increasing blood flow. Nitroglycerin (NG) is a pharmacological agent, which

dilates blood vessels and increases blood flow by releasing NO, by modulating denitrase and nitrite reductases. NG has been employed to enhance drug delivery, and works particularly well in tumors characterized by clogging problems. The use of angiotensin-II (AT-II) is an alternative approach to enhance blood flow and promote vascular permeability in tumors, because it induces blood vessel constriction in healthy tissues and raises the systemic blood pressure. Using anticoagulants can also achieve the goal of enhancing blood flow. Vascular disruption is another strategy to enhance the EPR effect. Several vascular disrupting agents (VDAs) have been evaluated over the years, including combretastatin A4 phosphate (CA4P), a tubulin-binding agent which induces vessel disruption by inhibiting tubulin polymerization. Another well-known VDA is the flavonoid acetic acid-based agent 5,6-dimethylxanthenone-4-acetic acid (DMXAA), which increases NO and serotonin production, leading to endothelial damage.

Active targeting. Active targeting of tumors is an approach utilizing a high-affinity targeting ligand for selective recognition of a specific receptor or antigen overexpressed on the surface of cancer cells to achieve targeted drug delivery. To accomplish this goal, the surface of the NPs is typically functionalized with a targeting ligand/antibody, followed by receptor-mediated endocytosis. Active targeting enhances drug specificity and accumulation to the tumor tissues/cells. Therefore, it enhances the cytotoxic activity of anticancer drugs against tumor cells while avoiding adverse effects on healthy tissues.

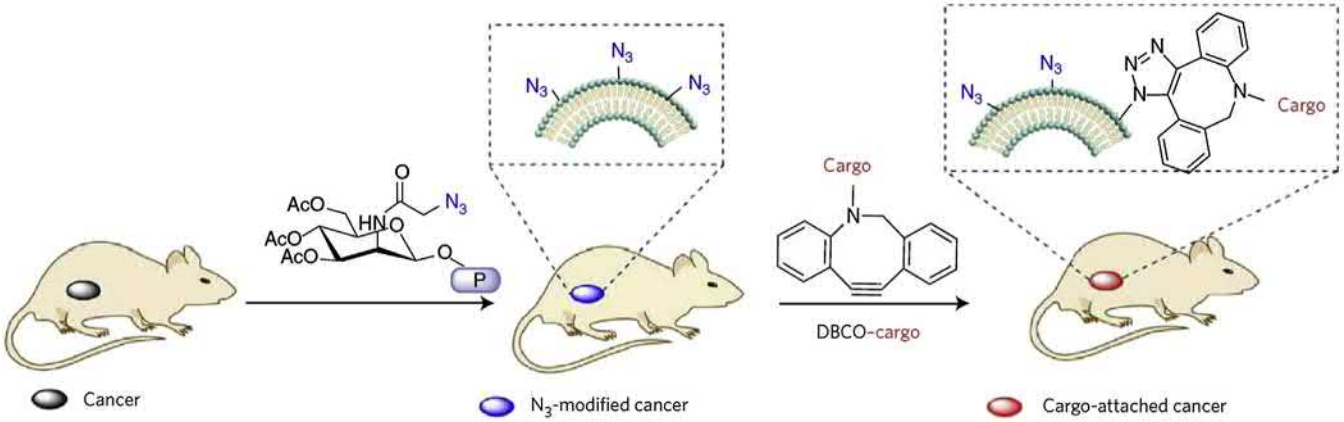
Commonly used cancer-targeting moieties include antibodies and ligands that can respectively bind to overexpressed antigens and receptors on cancer cell membranes. For instance, folic acid receptors, CD44, transferrin receptors, HER2, PSMA, and EGFR are overexpressed on cancer cells, and thus folic acid, hyaluronic acid, transferrin, and antibodies against HER2, PSMA, and EGFR are widely used as active targeting domains toward cancer cells. Peptides can also serve as cancer cell targeting ligands, among which the "cilengitide-like" cyclopentapeptides (i.e., cRGDfK, cRGDyK, and cRGDfC) that target overexpressed integrins on cancer cells are widely utilized. Additionally, aptamers, short single-stranded oligonucleotides (DNA or RNA) or peptides with specific tertiary structures, have emerged as effective targeting ligands to tumors. Compared with DNA aptamers, RNA aptamers have smaller physical size and more flexible 3D structures, making it easier to be conjugated with NPs and to penetrate target cells. Multiple antibody/ligand-based targeted drug-delivery NPs are under clinical trial, including MM-302 (HER2-targeting liposome), BIND-014 (PSMA-targeting polymeric NPs), and MBP-426 (TfR-targeting liposome).

The active targeting mechanism heavily relies on the overexpression of specific biomarkers on cancer cells. However, the number of cancer-specific antigens/receptors on different cancer cells is heterogeneous and often not high enough. Some cancer types, such as the triple negative breast cancer (TNBC), lack any specific receptors, thus preventing traditional antibody/ligand-based active targeting. To overcome such issues, two major strategies have been exploited to manually manipulate cell-surface receptors. The first strategy is to directly amplify the expression of existing cell-surface protein receptors using a gene transfection method. However, this strategy is of limited translational applicability given the stringent technical requirements, nonselectivity over cell types, and potential detrimental effects on the treated cells.

A different strategy, instead of directly increasing the amount of cell-surface protein receptors, is to introduce unique chemical functional groups onto the cell surface as an alternative to protein receptors. These externally introduced chemical functional groups can mimic the receptor function of cell-surface proteins, which can be utilized for cell binding via efficient chemical reactions. Among them, an unprecedented targeting technology called active tissue targeting via anchored click chemistry (ATTACK), is based on unnatural sugar-mediated cancer-selective labeling followed by reagent-free click chemistry. In this technique, Ac_4ManAz as a mannose derivative bearing an azide group was reversibly caged, and its metabolic activity could be recovered selectively in cancer cells after decaging, thus labeling the cancer cells with abundant azide groups to enable further targeting of DBCO-modified NPs via the DBCO-azide bioorthogonal chemistry (Fig. 1.3.8B.9) (Wang et al., 2017). Besides ATTACK, there are other methods to introduce artificial targets onto cancer cell membranes, such as inserting targets into cell membranes via lipids.

Tumor Penetration

There are two major approaches to promote the tumor penetration of NPs, manipulation of the tumor microenvironment and transformation of the NP structures. The former approach is often realized via IFP reduction and stromal depletion. Reducing IFP to restore a normalized flow pattern can enhance convective transport and intratumoral penetration of NPs. Using antiangiogenic drugs which target VEGF (i.e., bevacizumab and cediranib) can normalize tumor vasculature and thus decrease IFP. Tumor-associated fibroblasts have also been identified as good targets to alleviate high IFP, reduce tumorigenic stimuli, debulk the tumor, and restore perfusion and drug delivery. For example, prostaglandin inhibitors such as Imatinib can reduce IFP and improve tumor penetration of NPs, because prostaglandins can interact with fibroblasts to increase contractile forces and therefore decrease IFP. In addition, debulking the ECM or stromal cells can also reduce IFP. Treatment of ECM with ECM-degrading enzymes (i.e., hyaluronidase and collagenase), or debulking tumor cells with drugs (i.e., PTX) can reduce IFP and greatly enhance tumor penetration of NPs. Several stromal depletion approaches are being tested in clinical trials, including Abraxane (PTX-albumin NPs) and Hedgehog inhibitors. In the clinical evaluation of a combination with gemcitabine, Abraxane reduced pancreatic ECM, possibly due to increased interactions with stromal cells via an SPARC (secreted protein acidic and



• **Figure 1.3.8B.9** Schematic illustration of ATTACK technology, in vivo selective labeling of cancer cells with azido groups and subsequent cancer targeting via efficient click chemistry. (Reproduced from Wang, H., Wang, R. B., Cai, K. M., He, H., Liu, Y., Yen, J., et al., 2017. Selective in vivo metabolic cell-labeling-mediated cancer targeting. Nat. Chem. Biol. 13, 415.)

rich is cysteine)-mediated mechanism. The latter approach could be achieved via size shrinkage of NPs. In general, NPs with sizes of 50–100 nm are suitable for prolonged blood circulation and efficient tumor accumulation via the EPR effect. However, the tumor-associated fibroblasts and dense ECM are major barriers to the deep interstitial penetration of large NPs. On the other hand, NPs with sizes below 10 nm are characterized by better intratumoral penetrating efficiency but possibly a reduced EPR effect. Thus, ideal NPs should be relatively large (50–100 nm) during blood circulation to achieve effective EPR-dependent tumor accumulation, but once inside the tumors, they ought to be small enough for enhanced penetration. These systems are usually composed of a mothership nanocarrier with larger size (approximately 50 nm) and 10 nm-sized babyship nanocarriers encapsulated in the NPs or conjugated on the surface. The mothership NPs are stable during systemic delivery and concentrate in tumor tissues via the EPR effect. Subsequently, the babyship NPs are released by the acidic pH or overexpressed enzymes in the tumors, thus triggering deep tumor penetration.

Stimuli-Responsive Drug Delivery

One of the most important requirements for NP-mediated drug delivery is that the cargos need to be released effectively and selectively in the target disease site. Stimuli-responsive delivery systems serve as a promising modality to meet the demand of precision delivery, because they can release the payloads upon exposure to endogenous or exogenous triggers such as chemical, physical, or biological stimuli. These drug delivery systems enable target-activated release of the drug to potentiate the pharmacological activity while minimizing systemic toxicity. Significant inherent differences between the tumor microenvironment and normal tissues can be exploited for designing internal stimuli-responsive NPs, while exogenous stimuli such as light or heat can also be utilized to trigger transformation of the NPs (Meng et al., 2009).

Internal stimuli in tumors mainly include acidic pH, high intracellular GSH concentration, high levels of reactive oxygen species (ROS), high APT levels, overexpressed enzymes, and hypoxia. In particular, the pH condition in the extracellular compartment of tumors is more acidic (pH 6.5–7.2) than in the normal neighboring tissues (pH ~7.4), whereas endolysosomes typically exhibit even more acidic pH values (pH 4.5–6.5). The GSH and ATP concentrations are notably different between extracellular (~10 mM and <0.4 mM) and intracellular (~2 μM and 1–10 mM) compartments. The endogenous ROS are maintained at a low level in normal cells by the intracellular reduction–oxidation balance, while ROS levels are much higher in tumor cells. Tumor tissues or cells also express a higher amount of specific enzymes, which include extracellular [i.e., matrix metalloproteinase (MMP), hyaluronidase, phospholipase, and alkaline phosphatase] and intracellular (i.e., cysteine caspase, cathepsin, furin, telomerase, and azoreductase) enzymes. Solid tumors often undergo hypoxia because of the uncontrollable tumor cell proliferation and irregular vascular system.

By responding to these stimuli, NPs can change their morphology, solubility, or assembly state to allow drug release. For example, NPs with pH-labile or ROS-responsive linkages can change their hydrophilicity/hydrophobicity to enable dissociation of NPs. Alternatively, reversibly cross-linked polymersomes containing GSH-cleavable disulfides can undergo decross-linking by GSH, thus triggering on-demand drug release in tumor cells (Chen et al., 2010; Zou et al., 2016a,b). Nanoparticulate prodrugs can also mediate drug release via cleavage of the stimuli-cleavable linkers (such as redox-responsive disulfide, pH-responsive ketal, ROS-responsive thioketal, and hypoxia-responsive azobenzene). NPs that can respond to extracellular stimuli (such as slightly acidic condition or extracellular enzymes) are often constructed to undergo PEG removal or charge reversal in the extracellular compartment, thus exposing the membrane-penetrating domains to enhance tumor cell uptake. In the case that internal stimuli

are of an insufficient level to trigger effective transformation of NPs, their concentration could be artificially elevated. For instance, photodynamic therapy is often coupled with ROS-responsive NPs to artificially generate ROS in tumors cells, which not only triggers drug release but also kills cancer cells via ROS-mediated cell apoptosis/necrosis.

Compared with internal triggers, external triggers such as light, heat, and magnetic field show unique advantages such as spatiotemporal precision, relative safety, and minimal cross-reaction with cellular signaling networks. Ultraviolet (UV) light (<400 nm)-responsive NPs are widely developed for drug delivery, while the low penetration depth of UV light greatly restricts their in vivo utility. As such, NPs responsive to near-infrared (NIR) light (700–1000 nm) with better penetration and safety have been developed. Alternatively, upconversion materials are incorporated into UV-responsive NPs, which can change NIR light into UV light to realize NIR light responsiveness. The disadvantage of this approach is the heat damage caused by high-power-density light irradiation. To overcome this dilemma, indirect photo-responsive NPs utilizing an internal trigger as "mediator" have been proposed and explored. Particularly, thermal-responsive NPs can be coupled with photothermal materials to enable light-to-heat transfer and thereafter heat-responsive drug release. Similarly, light-triggered NPs can also be fabricated via the combination of ROS (or hypoxia)-responsive NPs with photodynamic therapy that generates a tremendous amount of ROS or local hypoxia in tumor tissues/cells (Zhou et al., 2018).

Besides light-responsive NPs, thermo-responsive NPs can also change their macroscopic properties and thus enable drug release by changing the interaction force between polymer molecules and solvent molecules upon temperature alteration. For instance, the principle of the thermo-responsive NPs (e.g., nanogels) is based on their solubility behavior that changes in response to temperature alterations. Most often, the thermo-responsive behavior is obtained by utilizing the LCST (low critical solution temperature) of polymers. The solubility of thermo-responsive NPs is increased by decreasing the temperature below the LCST. Subsequently, a volume phase transition and swelling of the nanogels occur by means of the formation of hydrogen bonds. Such polymeric NPs are called "negative thermo-sensitive" polymers. The problem with these NPs is that heating may damage normal cells around the tumor. Furthermore, magnetic NPs have been widely developed and combined with flexible polymeric materials to achieve magneto-responsive drug delivery. By integration with thermo-responsive materials, the localized heating caused by magnetic particles under an alternating current magnetic field can be used to realize controlled drug release. Alternatively, the magnetic material integrated with flexible polymers is able to deform by stretching, compressing, or bending to release the drug upon exposure to the magnetic field.

Clinical Development

The application of nanotechnology in drug delivery has developed rapidly in the past few decades, and many nanodrugs have been approved or are in clinical trials (Table 1.3.8B.1). The first anticancer nanodrug, Abraxane, was approved by the FDA in 2005. By 2018, 38 nanodrugs had been approved by FDA, and more than 60 nanodrugs were in clinical trials. Liposomes, as the first class of therapeutic NPs to receive clinical approval for cancer treatment, have tremendously developed in the past decades. Nowadays, various stimuli-responsive or active-targeting liposomes have been developed. Other nanodrug delivery systems such as polymeric micelles or even inorganic NPs are also being gradually applied in clinical practice.

Nucleic Acid Delivery Applications of NPs

Since the discovery of DNA in the 1950s, nucleic acids have not only revolutionized our capability to understand the fundamental basis of life, but also have encouraged us to develop novel nucleic acid-based therapeutics. Gene therapy has drawn tremendous attention as a promising modality for the treatment of numerous gene-associated diseases, which is implemented via the introduction of nucleic acids into the pathological cells to correct, replace, or silence defective genes. Therapeutic nucleic acids mainly include plasmid DNA, messenger RNA (mRNA), oligodeoxynucleotides (ODNs), small interference RNA (siRNA), micro-RNA (miRNA), and ribozymes. The majority of nucleic acids function within cells at either transcriptional or posttranscriptional states, and thus transmembrane delivery of nucleic acids is essential for their biological function. Viral vectors, although highly efficient in terms of gene transfection, often suffer from safety concerns such as carcinogenicity, immunogenicity, and insertional mutagenesis. In contrast, nanoscale non-viral vectors possess desired biocompatibility and minimal mutagenesis, and thus serve as an alternatives to viral vectors for gene delivery.

Intracellular Barriers Against Nucleic Acid Delivery

After injection of a nucleic acid delivery system into the body, it will face multiple systemic barriers before reaching the target site to initiate gene transfection. Extracellular barriers, such as circulation in the blood, tissue distribution, and disease targeting, have been summarized in the section on drug delivery. Intracellular barriers against gene delivery mainly include cell membranes, endolysosomal entrapment, intracellular gene release, and nuclear transport (Fig. 1.3.8B.10).

Cell membrane and endocytosis. Nucleic acids are hydrophilic and negatively charged macromolecules, and are thus expelled by cell membranes that adopt lipophilic and negatively charged structures. Therefore, cationic materials are normally used to condense nucleic acids into nanocomplexes to facilitate cellular internalization. To date, the majority of nanocomplexes are internalized via endocytosis.

TABLE 1.3.8B.1 Representative Examples of Clinical-Stage NPs for Anticancer Drug Delivery

Nano-Platform		Generic Name	Active Ingredients	Status
Polymeric NPs	Nontargeted polymeric NPs	Genexol PM	Paclitaxel	Approved in Korea
		NK 105	Paclitaxel	Phase III
		SMANCS	Neocarzinostatin	Approved in Japan
	PSMA-targeting polymeric NPs	BIND-014	Docetaxel	Phase II
Inorganic NPs	Iron oxide NPs	NanoTherm	NA	Approved in Europe
	Hafnium oxide NPs	NBTXR3	NA	Phase II/III
	Colloidal gold NPs	CYT-6091	TNF	Phase I
Lipid-based NPs	Liposome	DaunoXome	DNR	Approved by FDA
		Marqibo	Vincristine sulfate	
		Myocet	DOX	Approved in Europe
		Mepact	MTP-PE	
		Tecemotide	MUC1 antigen	Phase III
		CPX-351/Vyxeos	AraC and DNR	
	Thermo-responsive liposome	ThermoDox	DOX	
	PEGylated liposome	Doxil	DOX	Approved by FDA
		Onivyde/MM-398	Irinotecan	
	HER2-targeting liposome	MM-302	DOX	Phase II/III
Bio-inspired NPs	Albumin NPs	Abraxane	Paclitaxel	Approved by FDA

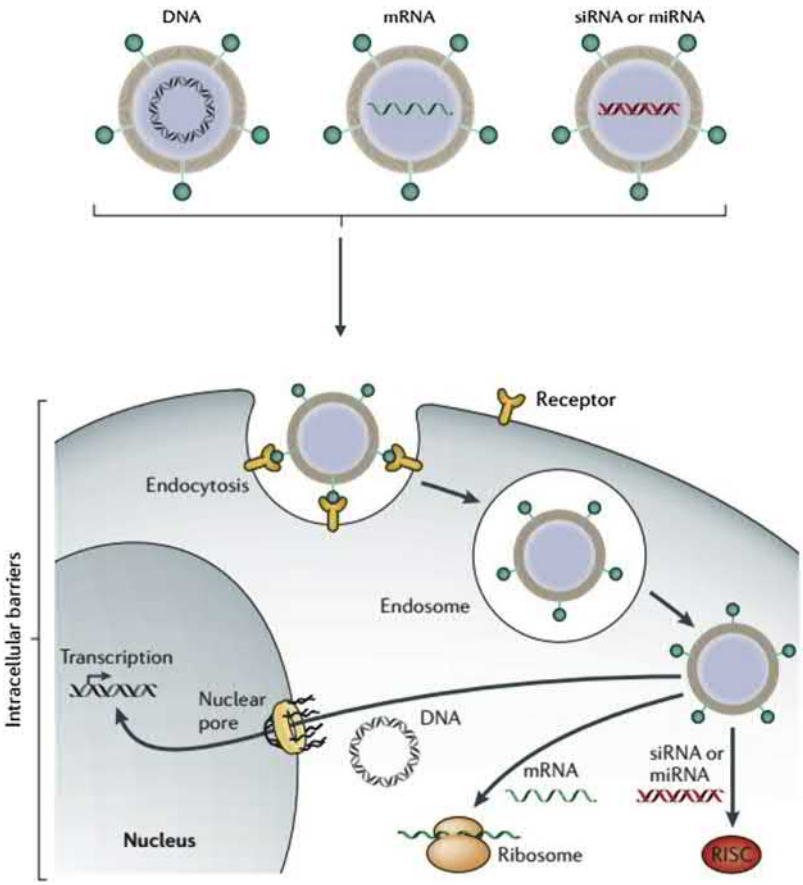
Endocytosis is an energy-dependent process that mainly includes clathrin-mediated endocytosis (CME), caveolae, and macropinocytosis. Many factors determine the endocytosis pathway, including both cell lines and complex properties, such as chemical structure, presence of ligands, size, and surface charge. Nanocomplexes internalized via CME will be trapped in acidic and digestive endosomes and lysosomes, unless the nanocomplexes can enable particular mechanisms to escape the endosomes. Therefore, the CME pathway is ineffective toward gene transfection. In contrast, caveolae take part in a nonacidic and nondigestive process, wherein the nanocomplexes experience association with the cell membrane, encapsulation within caveolae, uptake by caveosomes, and direct transport to the Golgi or endoplasmic reticulum to facilitate nuclear transport. Thus, caveolae are an effective pathway for gene transfection. Macropinocytosis, which involves a large volume of extracellular fluid and vesicles (~200 nm–5 μm) via the cell membrane, is a prevalent pathway for dendritic cells and antigen-presenting cells. The innate leaky property of macropinosomes allows the nanocomplexes to easily transport into the cytosol to enhance gene transfection.

Endolysosomal entrapment. After CME, nanocomplexes are usually transported to the late endosomes, which are rapidly acidified to pH 5-6 by the activation of ATPase proton-pump enzyme in the endosomal membrane. Afterward, complexes are trafficked to lysosomes, which further acidify to pH 4.5 and with abundant digestive enzymes. The acidic environment of lysosomes accelerates substrate denaturation and aids lysosomal hydrolases, leading to the degradation of nucleic acids that fail to escape from these acidic vesicles. Therefore, endosomal/lysosomal entrapment is a main bottleneck step for successful nucleic acid delivery.

Intracellular gene release. Another important barrier that should be overcome is the kinetics of nucleic acid release from the NPs. Nanocarriers with higher cationic charge density afford stronger nucleic acid condensation capacities and will facilitate cellular internalization via electrostatic interactions with cell membranes. However, the excessively strong binding affinity toward nucleic acids will impede intracellular release. While the negatively charged components in the cytoplasm such as polysaccharides or proteins can competitively replace the nucleic acid from the nanocomplexes, its efficiency is low. Therefore, a proper balance between gene condensation and gene release needs to be achieved for NPs to synchronize the multiple transfection processes such as cellular internalization and intracellular release, thus synergistically contributing to effective gene transfection.



• **Figure 1.3.8B.10** Intracellular barriers to successful delivery of nucleic acids. (Reproduced from Yin, H., Kanasty, R. L., Eltoukhy, A. A., Vegas, A. J., Dorkin. J. R., Anderson, D. G,. 2014, Non-viral vectors for gene-based therapy. Nat. Rev. Genet. 15, 541–555.)

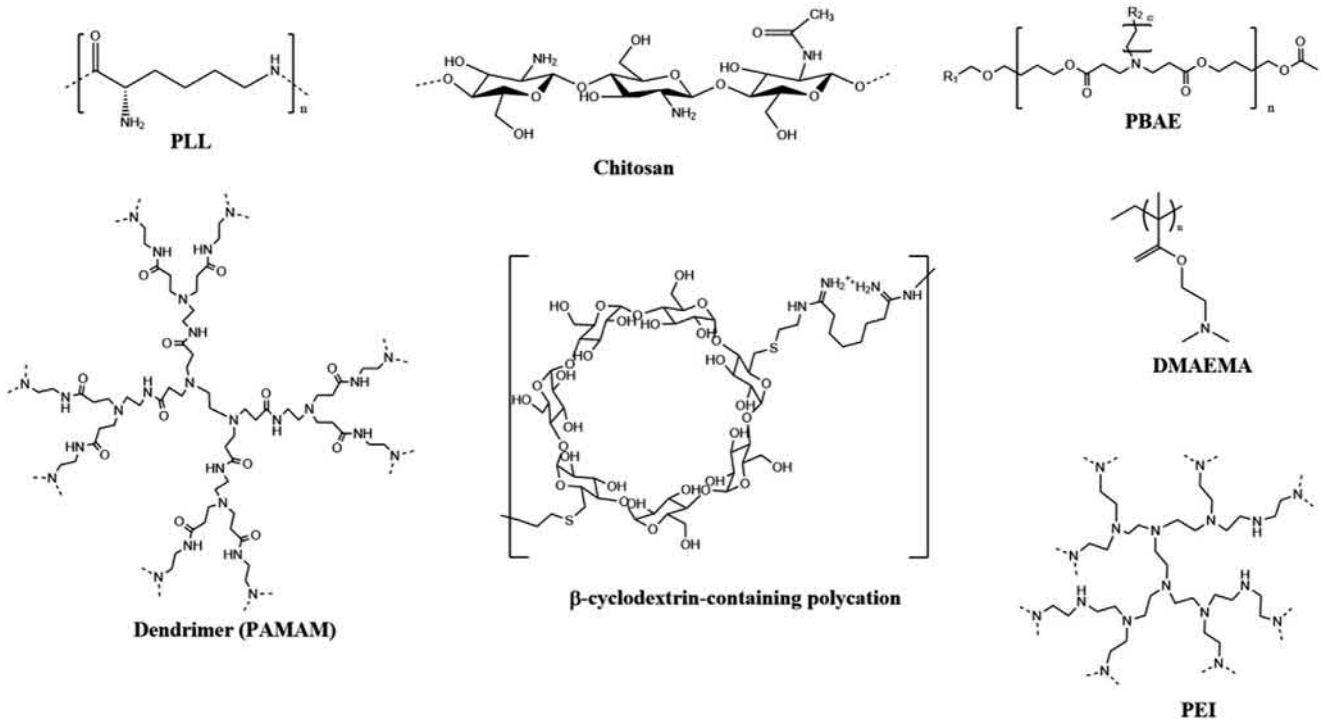
Nuclear transport. For DNA delivery, nuclei transport is another critical barrier because DNA needs to be transcribed in the cell nuclei. The nucleus is coated with a double-bilayer membrane with tightly regulated pores that allow the passage of small particles (≤10 nm) freely into or out of the nuclei, while large macromolecules or NPs enter the nuclei with difficulty via the nuclear pore complex (NPC). Evidence has proven that it is easier to achieve nuclear transport in proliferating cells. During cell division, the nuclear membrane disintegrates for a short time, allowing transport of exogenous nucleic acids into the nuclei. To this end, for nondividing cells or slowly dividing cells, nuclear transport of DNA is difficult, thus conferring low transfection efficiency.

Strategies to Overcome Intracellular Barriers

Nucleic Acid Condensation and Cellular Internalization

Nucleic acids are often condensed by cationic materials, exemplified by cationic polymers (polycations) and lipids, to form positively charged and nano-scale complexes, thus favoring the cellular internalization.

Polycations. Commonly utilized polycations include poly(L-lysine) (PLL), polyethylenimine (PEI), poly(β-amino ester) (PBAE), cationic dendrimer, 2-dimethyl(aminoethyl) methacrylate (pDMAEM), cyclodextrin, or carbohydrate-based polymers such as chitosan (Fig. 1.3.8B.11). Cationic groups, including primary, secondary, tertiary, and quaternary amines, as well as other positively charged groups such as amidines, are incorporated into the polymer backbone or side chain to facilitate binding with nucleic acids. Protonation of amines can increase the net positive charge of cationic polymers, and thus cationic polymers often exhibit a pH-dependent interaction with nucleic acids in which higher charge-density polyamines show stronger binding affinity. Based on the flexible chemistries of polycations, they can provide various functions used for efficient gene delivery and feature biocompatibility, easy manufacturing, and controllable formulation. The molecular weight and chain length of a polymer also have a significant impact on its nucleic acid condensation capability and cellular uptake level. Polycations with higher molecular weight (MW) usually afford higher nucleic acid condensation capability, cellular uptake level, and transfection efficiency, while polycations with lower MW have less cytotoxicity and better DNA unpackaging. The excessively strong binding affinity endowed by high-MW polycations will impede the intracellular release of gene cargos and induce stronger posttransfection cytotoxicity, which impairs the transfection efficiency.

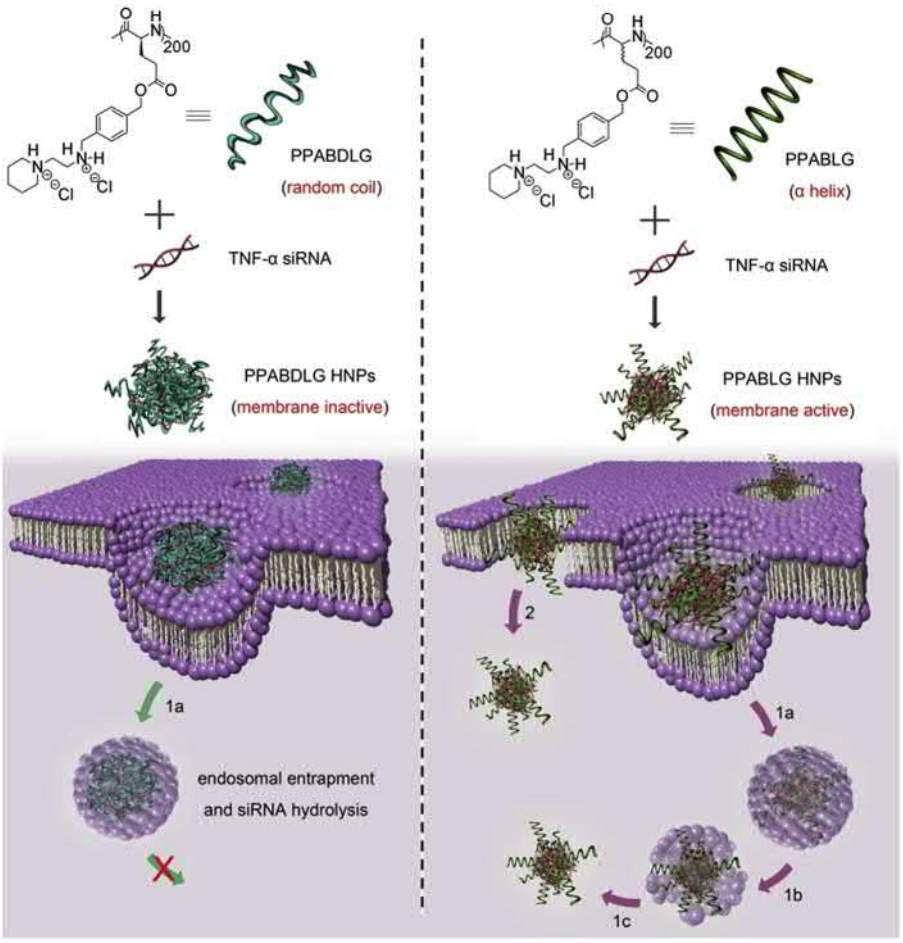


• **Figure 1.3.8B.11** Chemical structures of commonly used polycations for the construction of gene delivery NPs.

Tremendous efforts have been devoted to enhancing transfection efficiency while reducing the toxicity of polycations. The salt bridge is an effective method to improve gene condensation, which is formed between positively charged groups of polycations (such as guanidines or Zn-DPA) and the phosphate groups of nucleic acids. Hydrophobic modification of polycations has also received much attention. Mounting evidence shows that the incorporation of hydrophobic domains, especially aromatic motifs, can enhance gene delivery efficiency, due to the hydrophobic interactions with lipophilic cell membranes that enhance cellular uptake. To achieve a proper balance between cationic charge and hydrophobicity, large library screening is often performed. For instance, a library of PBAEs with different backbone structures, side chain functionality, and terminal groups has been prepared via the Michael addition reaction between different diacrylates and amine-containing molecules (Lynn and Langer, 2000). Alternatively, fluorinated polycations are both hydrophobic and lipophobic, and have a high phase-separation tendency in polar and nonpolar conditions, which can enhance the affinity between polycations and cell membrane as well as endo/lysosomal membrane, accelerating the entry of complexes into cells and escape from endo/lysosomes. Moreover, the fluorinated polycations have low surface energy and tend to connect with others at low concentrations, which allows the formulation of complexes at low nitrogen to phosphorus (N/P) ratios to minimize the toxicity (Wang et al., 2014).

The topological structure of complexes alters how the cells interact with material surfaces, affects cell migration, and modulates endocytosis, and thus manipulation of the topological structure of polycations can potentially enhance the membrane affinity and transfection efficiency. Polycations with branched, dendritic, or brush topologies often exhibit higher affinity with nucleic acids and cell membranes due to their multivalent structure, and accordingly lead to higher transfection efficiency. One important example is branched PEI and branched PBAE, which demonstrate notably higher transfection efficiencies than their linear counterparts. Similar to the NPs used for anticancer drug delivery, incorporation of targeting ligands/antibodies onto the surface of nanocomplexes can enhance the affinity with specific cell membranes, thus enhancing the intracellular delivery efficiency of gene cargoes.

Cationic lipids. The use of cationic lipids for nucleic acid delivery was first introduced by Felgner in 1987. The lipid structure has significant influence on the interaction with DNA or RNA, and thus has a strong relationship with gene delivery efficiency. Based on their high transfection efficiency, cationic lipids have been widely used for nonviral gene delivery. A typical liposomal formulation needs a mixture of cationic lipid and neutral lipid, wherein cationic lipids, such as DOTMA, DOSPA, DOTAP, DMRIE, and DC-cholesterol, play a key role in gene binding and transfection. The structure of cationic lipids consists of a cationic head group, a hydrophobic tail, and a linker region. Alternatively, neutral lipids, such as phospholipids DSPC, DOPE, and cholesterol serve as "helper lipids" to enhance complex stability and transfection efficiency. Particularly, Lipofectamine 2000, as a commercial product, has been widely used for gene transfection. However, lipid-based gene delivery demonstrates crucial drawbacks, including cytotoxicity, poor in vivo stability, and low condensation efficiency.



• **Figure 1.3.8B.12** Schematic illustration of the formation of stable helix in polypeptides and their transmembrane gene-delivery mechanisms. (Reproduced from He, H., Zheng, N., Song, Z. Y., Kim, K. H., Yao, C., Zhang, R. J., et al., 2016. Suppression of hepatic inflammation via systemic siRNA delivery by membrane-disruptive and endosomolytic helical polypeptide hybrid nanoparticles. ACS Nano 10, 1859–1870.)

Currently, a combinatorial series of lipid-like materials called "lipidoids" has been developed, and they have been widely used as carriers for delivering nucleic acids. These lipidoids are synthesized by reacting amines with lipophilic acrylates, acrylamides, and epoxide, which generate a large library of materials followed by screening to identify the top-performing candidate (Akinc et al., 2008). These lipidoids have various advantages for nucleic acid delivery, such as low cost, facile synthesis, and structural diversity of the starting materials.

Cell-penetrating peptides (*CPPs*). Cell-penetrating peptides, such as HIV-Tat, oligoarginine, Pep-1, MPG, TP10, and melittin, are sequence-specific oligopeptides with distinguished membrane-penetrating properties. As such, they have been utilized for the transmembrane delivery of nucleic acids. CPPs often adopt an inherent helical structure or form a helix during membrane penetration, which strengthens the interactions with cell membranes to facilitate cellular internalization. However, because of their short length and lack of sufficient cationic charges, CPPs have difficulty effectively delivering genes by themselves. To address this dilemma, cationic polypeptides with long backbones and stable helical structures have been developed by elongating the separation distance between backbone and charged side groups, which reduced the side-chain charge repulsion to stabilize the helix (Fig. 1.3.8B.12). Such helical polypeptides possess strong membrane penetration capability via the "pore formation" mechanism, outperforming classical CPPs such as Arg9 and HIV-Tat by 1–2 orders of magnitude (Tang et al., 2013). Because of their sufficient backbone length, these polypeptides demonstrate potent transfection efficiencies for both DNA and siRNA, notably outperforming commercial reagents such as PEI and Lipofectamine 2000 (Tang et al., 2013; He et al., 2016).

Endosomal Escape

"Proton sponge" effect. Polymers with high buffering ability, such as PEI and polyamidoamine (PAMAM) dendrimers, possess secondary and tertiary amines in their structures with pKa values between physiological and lysosomal pH. These polymers absorb protons in the endolysosomes, and in order to maintain the endolysosomal pH, the ATPase enzymes pump protons from the cytosol into endosomes

along with passive entry of chloride ions. The increased ion concentration in the endolysosomes induces water diffusion into the endolysosomes to maintain the balance of ion concentration, which finally induces osmotic swelling and rupture of the endosomal membrane. This mechanism is called the "proton sponge" effect.

Fusion with endosomal membranes. Lipoplexes coated with a lipid membrane can fuse with the endosomal membrane, resulting in the release of nucleic acid into the cytosol. The charge of cationic liposomes ensures close interaction with and destabilization of the endosomal membrane, leading to fusion and release of the nucleic acid. The cationic liposomes incorporated with fusogenic "helper" lipids, such as DOPE, further facilitate endosomal fusion and escape via conformational change upon acidification and enhancing a nonlamellar lipid phase change. Incorporation of cholesterol in cationic liposomes can also enhance fusogenicity in a pH-dependent way at the plasma membrane.

CPPs. Most CPPs have a similar mechanism of membrane activity, which is mediated by endosomal pH. Acidic environment in the endosome causes conformational transition of CPPs from a random coil to α-helix, which interacts with endosomal membrane phospholipids and induces pore formation. HIV-Tat is a commonly used CPP and derives from the transcriptional activator protein of human immunodeficiency virus type 1 (HIV-1), which significantly enhances complex-mediated gene delivery. Enlightened by the CPPs, various new peptides with endosomal membrane-destabilizing activity have been developed. Although these peptides have a random coil conformation in the neutral environment, the structure is converted to an amphiphilic α-helical conformation in endosomes, resulting in the endosomal membrane disruption.

Photochemical disruption. Photosensitizers can produce reactive oxygen species (ROS) upon light irradiation, which disrupts the endolysosomal membranes to facilitate endosomal escape, the so-called photochemical internalization (PCI) effect. Many studies have demonstrated that the incorporation of photosensitizers with nucleic acid carriers can notably improve gene transfection efficiency as a result of PCI-facilitated endosomal escape. However, ROS will also destabilize the nucleic acid cargoes via oxidation, and thus photosensitizers need to be encapsulated in the gene carrier in a separate compartment from the gene cargo, avoiding direct contact between generated ROS and genes. Alternatively, the photosensitizer can be localized on the NP shells, which is removed from the NPs before light irradiation and thus avoids ROS-induced gene damage.

Stimuli-Responsive NPs for Intracellular Gene Release

One major approach to trigger on-demand gene release is to use intracellularly degradable carriers. These carriers have potent DNA/RNA binding affinity to facilitate cellular internalization, but can degrade into small segments inside the cells to release cargoes instantaneously. Various cationic polyesters have been developed as degradable gene carriers due to hydrolysis of the ester bonds by the esterases rich in the cytoplasm. Among them poly [α-(4-aminobutyl)-L-glycolic acid] (PAGA), a biodegradable analogue of polylysine, demonstrates lower cytotoxicity and higher transfection efficiency than polylysine. Another important cationic polyester is PBAE, which possesses ester bonds in its backbone. However, hydrolysis of the ester bonds occurs on the time scale of several hours to a few days, and is largely affected by the polymer structure as well as the cellular condition. As such, it is difficult to precisely control when and where gene release will occur. As a structural-mimicking analogue of PBAE, a poly(amido amine) has been developed which contains stable amide bonds instead of hydrolysable ester bond in the backbone. To enable controlled and fast degradation of these materials inside cells, trigger-cleavable domains are introduced into the backbone, such as disulfide, thioketal, ketal, or nitrobenzyl linkers that can be cleaved by intracellular redox, ROS, acidic pH, or external UV light, respectively. Similarly, cross-linking of low-MW oligocations with cleavable linkers to synthesize high-MW polymers is also a commonly utilized approach. For example, low-MW PEI can be cross-linked by disulfide-, ketal-, thioketal-, or nitrobenzyl-containing linkers to achieve high-MW PEI. Using these approaches, the inconsistency between nucleic acid condensation and intracellular gene release are harmonized. Additionally, the posttransfection material toxicity can also be reduced as a result of polymer degradation.

Charge reversal is another efficient method to facilitate intracellular nucleic acid release. Upon internal or external triggers, the responsive polycations transform to neutral or negatively charged materials, thus repelling the gene cargoes to potentiate transfection (Yin et al., 2013).

Nuclear Transport

Many proteins are naturally targeted to the nucleus by nuclear localization signals (NLSs), which are short amino acid sequences recognized by importins. NLSs are often rich in arginine or lysine, and widely used NLSs include SV40 large T-antigen (PKKKRKV) and the bipartite NLSs. NPs conjugated with NLSs can improve nuclear entry in both dividing and nondividing cells. Therefore, the incorporation of NLSs in nucleic acid delivery NPs through electrostatic complexation or covalent conjugation holds great promise for the nuclear transport of DNA cargoes that have to be transcribed in the nuclei.

Clinical Development

Gene therapy is a promising strategy for the treatment of many gene-associated human diseases by altering gene expression, such as cancer, hemophilia, hypercholesterolemia, neurodegenerative diseases, and autoimmune diseases (Table 1.3.8B.2). Despite some clinical trials of NPs for gene delivery showing promising results, the wide use of gene therapy for disease treatment still faces great challenges. The primary factor is the delivery, including fast degradation and clearance in circulation, nonspecific uptake, inability for endosomal escape, and cytotoxicity.

TABLE 1.3.8B.2 NP-Based Gene Therapy Under Clinical Evaluation

Delivery System	Product	Sponsor	Disease	Administration	Phase	Status	Gov Identifier
PEI-based NPs	BC-819/PEI	BioCancell	BC	Local	2	Active	NCT00595088

NPs have been used as gene delivery systems to overcome the delivery barriers based on their desirable properties such as safety, nonimmunogenicity, controllability, and low cost. The first NP-based siRNA delivery system called CALAA-01, has been studied in a phase 1 clinical trial against cancer, and shows potent antiproliferative activity to many cancer cells (Davis et al., 2010). Many other NP-based gene delivery systems have also been widely studied for clinical trials, such as PEI-, lipid-, and PLGA-based NPs. Most of these contain polycations or cationic lipids for condensing nucleic acids, PEG for stabilization, and targeting ligands for binding to the receptors on the target cells.

Diagnostic/Theranostic Applications of NPs

In Vitro Diagnosis

In vitro diagnosis is an essential component of clinical care that performs a diagnostic test on biological samples (blood, urine, tissue, etc.). In vitro diagnosis tests have received great attention due to their unique features in the medical area. For example, these tests do not directly interact with the human body, making them accessible without invasive surgeries and possible biological safety problems for patients. Moreover, an in vitro diagnosis test can quickly provide valuable information on the health status of patients and

can even enable early diagnosis, thus leading to the easier treatment of severe diseases.

Although much progress has been made in the biotechnology field, only limited in vitro diagnostic systems have been successfully translated into clinical use. Therefore, the pursuit of simple but efficient tools is highly desirable. In addition, the increasing requirement for in vitro diagnosis with enhanced properties is pushing the exploitation of highly sensitive and easily processed sensors. In recent years, with the rapid development of nanoscience and nanotechnology, advances have been made in the design of in vitro diagnostic tools using NPs. NPs large surface areas can carry various kinds of functional molecules (such as organic dye, DNA, and enzyme), allowing the detection of analytes with very low concentrations. Moreover, the surface groups of NPs can be easily functionalized using physical or chemical linkages, thus enabling analysis for real-time and direct detection of multiple targets. Up to now, a variety of NPs, such as polymeric NPs, gold NPs, carbon nanotubes, silica nanostructures, QDs, and magnetic NPs, have been utilized for constructing high-sensitivity in vitro diagnostic systems. These highly sensitive analytical systems can detect biomarkers at pico-, femto-, atto-, and even zepto-molar levels, which would open a new era of early diagnosis and certainly provide more valuable information for better treatment of diseases.

Detection of glucose. Diabetes is a major cause of death and disability around the world. Frequent measurement of blood glucose levels is a requisite for the confirmation of effective treatment. As a result, the development of highly sensitive, low-cost, and reliable glucose biosensors is in great demand. While glucose oxidase (GOx)-based glucose biosensors have been popularly utilized over the past several decades, they have disadvantages such as complicated enzyme immobilization, critical operating conditions, and chemical instability. Another important glucose detection method is amperometric nonenzymatic sensing based on the direct electrochemical oxidation of glucose, which addresses the problem of insufficient long-term stability usually encountered with enzymatic glucose sensors. In recent years, the regulation of glucose biosensors at a molecular level has become possible using various functional NPs. The conducting NPs can greatly enhance the electron communication between enzymes and electrodes. Amperometric glucose biosensors based on various NPs (carbon NPs, nanostructured metal oxides, etc.) have been extensively studied.

Detection of prostate-specific antigen (*PSA*). Early detection of cancer enables more timely treatment and would significantly improve therapeutic outcomes. One promising method for the early detection of cancer is to detect a specific biomarker in the blood or other body fluids that are closely related with the occurrence of cancer. These cancer biomarkers may be carbohydrates, nucleic acids, or proteins (e.g., surface glycoproteins, secreted proteins). Analyzing the levels of particular cancer biomarkers from a patient could achieve the detection of cancer at early stages, identification of tumor recurrence, prediction of a patient's risk for cancer, as well as monitoring of therapeutic efficacy. As one of the most widely measured biomarkers for prostate cancer, PSA is a serine protease generated by the prostate epithelium to maintain liquefaction of seminal fluid. Generally, PSA tests are performed at specialized laboratories using large automated instruments, which require sample transportation that leads to increased waiting time and medical cost. Nanotechnology has been frequently utilized to address these concerns, since the unique characteristics of certain classes of NP probes endow the potential to produce rapid, inexpensive, and high-throughput assays with high sensitivity and selectivity. The resultant nanoparticulate sensor usually comprises two distinct components: (1) a recognition segment, usually high-affinity intact antibodies, to recognize and bind PSA; and (2) a transducing element that converts the interactions of biomolecules (e.g., antibody and antigen) into a quantifiable signal, such as fluorescence, surface plasmon resonance, electrochemical signal, etc.

Detection of circulating tumor cells (CTCs). With the progression of cancer, metastasis happens and drastically diminishes the prognosis of patients. Metastatic cancer formation occurs through the spread of cancer cells from the primary tumor site to the bloodstream and lymphatic system, and to new sites at distal organs and tissues to form secondary tumors. CTCs are a key component in this prognosis process, and thus the early detection of CTCs in the blood offers an efficient way to predict metastatic risk. To realize this, the correlation of CTC presence with cancer patient prognosis needs to be established.

Current technology to detect CTCs depends on the immunomagnetic separation of cells based upon their expression of cell surface antigens, such as epithelial cell adhesion molecule (EpCAM). Although this methodology has been successfully commercialized, it is often restricted by the need to recognize the antigens on the cell surface and can result in the failure to distinguish CTCs whose protein expression level is too low for isolation. It has been reported that several kinds of NPs are especially suitable for the design of nanoparticulate probes that could detect small populations of CTCs through the production of a fluorescent output (Shen et al., 2017). For instance, QDs modified with moieties that bind and recognize CTC surface markers demonstrate competitive advantages over organic dyes, such as high quantum yields, size-dependent emission tunability, improved photostability, and longer fluorescence lifetimes. The continuing progresses in the use of NP probes for CTC detection significantly strengthens the existing methods to detect CTCs, and may produce potential impacts for cancer patient prognosis in the clinic.

In Vivo Imaging

In contrast to in vitro diagnosis mentioned above, "in vivo" tests are generally conducted. Noninvasive in vivo imaging, including magnetic resonance imaging (MRI),

ultrasonography (US), X-ray computed tomography (CT), positron emission tomography (PET), optical imaging (OI), single-photon emission computed tomography (SPECT), and photoacoustic imaging (PAI), is an essential tool for the diagnosis of many diseases, such as cancer, cardiovascular diseases, and infectious diseases. A fundamental goal of in vivo imaging is to determine and localize specific molecular targets, pathways, as well as physiology in the disease state. In the imaging techniques based on contrast agents, diseases are generally identified by the accumulation of an agent at the site of pathological changes. Hence, these agents should be able to produce a signal recognized by an imaging modality. Customarily, the agents are mostly small molecules and sometimes may be linked to peptides, proteins, oligonucleotides, or antibodies. These small-molecule imaging agents are usually injected systemically and designed to accumulate at disease sites based on the difference in the fundamental biology between the diseased and normal tissues.

Although small-molecule imaging agents can make a trip easily within the body and often are able to enter cells, their small size will inevitably result in high nonspecific uptake, which is one of their greatest weakness. Other drawbacks include the increased time and expense of synthesizing the agents, the difficulty of incorporating a signaling segment without significantly changing the property of the original molecule, the low payload, and the minimal circulation half-life. The size of NPs is advantageous for in vivo imaging because it is sufficiently large to carry much more contrast than small molecules, while keeping the ability to systemically travel through the body. In other words, NPs fill in a critical gap between small molecular and larger imaging agents. Moreover, NPs provide the ability to selectively enter cancer sites other than small-molecule agents or larger agents due to the EPR effect. NPs designed for in vivo imaging require a suitable reporter moiety for the imaging application and a biocompatible coating that serves not only to control the toxicological and pharmacological properties of NPs but also serves as the functional linkage between the reporter and other molecules (e.g., targeting ligands, other imaging agents, and even therapeutic agents). On the other hand, multimodal imaging techniques using NPs are also being exploited to overcome the respective limitations of an individual imaging modality and to provide more precise physiological and anatomical data for diagnosis and treatment.

Magnetic resonance imaging (MRI). MRI is a noninvasive and nonionizing imaging technique based on the principle of NMR. In a strong magnetic field, the hydrogen nuclei absorb resonant radiofrequency pulses, and then the excited nuclei return to the initial state by emitting the absorbed energy. MR contrast is thus generated by the different relaxation characteristics of the hydrogen atoms in tissues that are influenced by the nearby magnetic materials. MRI offers information that can hardly be accessed by other imaging methods since its sufficient penetration depths enable imaging throughout the entire human body, and the spatial resolution is usually down to 10 μm. Over the last 2 decades, various NPs or composites have been investigated as MRI contrast agents, and several formulations have been approved for clinical use. These contrast agents are mostly formed by transition and lanthanide metals, iron oxide NPs, and more recently ferrite NPs. A new generation of T1 contrast agents is developed by Gd complexes embedded in various NPs, such as porous silica NPs, dendrimers, perfluorocarbon NPs, and nanotubes. Iron oxide NPs with varying diameters can be used for MRI of different organs. For example, superparamagnetic iron oxide NPs with overall diameters greater than 50 nm can be used for imaging of liver, spleen, and bone marrow; ultra-small superparamagnetic iron oxide NPs with diameters smaller than 50 nm have been used for lymph node imaging. In addition, iron oxide NPs modified with bioactive moieties have been used for targeted imaging. The most notable restrictions associated with such MR contrast agents are the current detection limits and the lack of tissue specificity. The successful overcoming of these issues would inevitably accelerate the clinical translation of NP-based MRI to in vivo applications.

Optical imaging (OI). OI is a noninvasive and highly sensitive imaging method that can detect a concentration of up to 10^{-9}–10^{-12} M. OI applies nonionizing radiation ranging from ultraviolet to infrared light that offers desired safety. A key advantage of OI is the accessibility to interactions between tissue and light plus the corresponding photo-physicochemical processes at the molecular level. The lower risk for patients and faster analysis procedure of OI enables long-term or repetitive observations of disease progression. In terms of cancer study, OI is mainly applied for the localization and metastases of tumors, as well as the monitoring of progression or regression of pathological sites. A critical issue for the OI technique is to maximize the penetration depth, which comes at the price of decreasing spatial resolution, and minimizing background signal, while retaining resolution and signal intensity. Multifunctional NPs have been widely utilized to manipulate and greatly amplify these optical signals. Many of these NPs provide an improvement in sensitivity and can even achieve the same imaging results using tiny amounts of material. Currently, several kinds of NPs have been used for OI application, such as quantum dots (CdSe, Ag_2S, etc.), carbon nanomaterials (carbon dots, single-walled carbon nanotubes, graphene, and nanodiamonds), as well as upconversion nanomaterials. Moreover, some other NPs (e.g., polymer-, silicon-, and lipid-based nanomaterials) have also been applied in OI, yet the vast majority are made fluorescent through incorporating organic fluorescent dyes either covalently linked to the surface or incorporated inside the NPs.

X-ray computed tomography (CT). CT is a radiography imaging technology that constructs 3D images of a body structure, which can easily distinguish between electron-dense structures (e.g., bone) and relatively electron-poor moieties (e.g., soft tissues). However, its soft-tissue contrast is quite poor and extrinsic contrast agents are thus needed to generate high contrast. The current small molecule-based CT contrast agents, especially the most commonly used iodinated compounds, usually require a relatively higher

dosage (molar concentration range) than other imaging modalities, such as MRI (millimolar concentration range) and OI (nanomolar concentration range). NPs can make intriguing CT contrast agents since they can carry a high-contrast payload, circulate for a long period of time, and can easily be prepared with electron-dense contrast materials. Such denser materials (e.g., gold over iodine) with higher absorption coefficients can achieve better contrast structures. Some other typical inorganic NPs with high atomic number apart from gold include lanthanides (e.g., Gd, Eu, and Yb) and heavy metal-based agents such as tantalum oxides and bismuth sulfides. Because of the long circulation time of NPs, delineation of soft tissues such as the vasculature has become a major application of the CT technique. Nevertheless, the critical issue in NP-based CT is its low sensitivity. The minimum detectable concentration difference between target and background is on the order of mM. Therefore, the main bottleneck of nanoparticulate CT is the total accumulation of NPs in the target sites, thus making the delivery of contrast agent the most important factor that limits the clinical application of nanoparticulate CT.

Photoacoustic imaging (PAI). PAI has emerged as a promising noninvasive imaging modality that harvests the advantages of both optical and acoustic imaging by directing (laser) light pulses into a sample and receiving acoustic information in the form of ultrasound to generate images. The key advantage of PAI is that the light in/sound out paradigm allows a detection depth into tissues of up to 5 cm at a relatively high spatial resolution. As the contrast mechanism in PAI is highly dependent on the optical absorption of the sample, NP-based contrast agents have great potential in PAI applications because they can be facilely engineered for optimum absorption in the visible or near-infrared (NIR) region with very high cross sections. Generally, NPs designed for PAI can be classified into two major types on the basis of the physical mechanism of light absorption, NPs based on surface plasmon resonance (SPR) and dye-containing NPs.

For SPR-based NPs, nanoscale metallic films, usually gold, are deposited onto the surface of NPs. The peak absorption can be facilely controlled, ranging from visible to NIR regions by simply tuning the physical dimensions of the metallic layer. For dye-encapsulated NPs, they are usually composed of NIR organic dyes (such as indocyanine green) embedded inside the NPs to enhance optical absorption. A recent advance in PAI material lies in the development of semiconducting polymer-based NPs, which offer a number of advantages (e.g., highly photostable, optically active, versatile in chemistry) over many traditional nondegradable inorganic contrast agents. The use of NP-based contrast agents greatly extends the applications of PAI. For example, it allows PAI to image deeper tissues with enhanced contrast, and targeting molecules can be conjugated onto the surface of NPs for cell-specific imaging. Moreover, PAI can be potentially integrated with photothermal therapy to achieve combined imaging and therapy because both techniques share similar mechanisms.

The past few years have witnessed enormous progress in in vivo imaging with NPs, which usually shows considerable advantages over small-molecule imaging agents. Novel NPs have displayed unprecedented properties that were seldom imagined over a decade ago, including imaging sensitivity, penetration depth, and multimodality capability. Because of this, they have also raised expectations from researchers and the public. A key to fulfilling these expectations is a sophisticated balance between safety concerns, synthetic simplicity or efficient scale-up production, and a suitable match to clinical needs. If these goals are realized satisfactorily, the above expectations of nanoparticulate imaging will be achieved.

Theranostics

A theranostic represents an agent that combines diagnostic capability (typically imaging) with a therapeutic property. Theranostics are being developed for both imaging and therapy using either a special probe or a drug that has diagnostic and therapeutic capabilities or linking therapeutic agents with imaging probes. The utilization of a theranostic approach can bring about the following benefits, such as providing simultaneous imaging and therapy, reducing the frequency of administration, enhancing patient compliance, decreasing the burden on patients and caregivers, and offering useful information on the biodistribution and clearance of drug. Accordingly, theranostics has recently become one of the core keywords in cancer research because of the assumption that if cancer growth can be hampered during the diagnostic stage, the subsequent cancer treatment would be much easier as cancer growth is retarded.

We have described above how multifunctional NPs realize imaging with many modalities or treatments with diverse therapeutic functionalities. NPs reflect the ideal design form for theranostics due to their highly modular characteristics. Advanced multifunctional NPs usually possess many of the properties that can meet the theranostics field requirements, such as targetable delivery, sustained and stimuli-responsive controlled release, enhanced delivery efficiency, synergistic therapeutics (e.g., multidrug combination therapy or drug plus heating/radiation/other therapeutic), as well as multimodality imaging capability. In general, theranostic NPs can be composed of at least three components including biomedical payload, carrier, and surface modifier. Biomedical payloads comprise imaging agents (e.g., organic dyes, quantum dots, MRI or CT contrast agents, etc.) and therapeutic agents (anticancer drugs, therapeutic DNA and small interfering RNA, proteins, ROS-generating agents, etc.). Carriers should provide sufficient physical protection for the payloads under physiological conditions during delivery to the desired target sites. Also, it is better to make the carriers become cancer-specifically disintegrated for better imaging or therapeutic efficacies. Finally, surface modifiers are often attached to the carriers to endow theranostic NPs with additional functions, such as long circulation time, barrier-crossing capability, as well as targeting ability. These three components have been extensively investigated for the

development of tailored multifunctional theranostics. While the clinical translation of nanoparticulate theranostics is virtually nonexistent at present and the future prospects seem challenging, it is undeniable that NPs have highly relevant properties and provide opportunities for exploitation of new diagnostic and therapeutic agents.

Imaging-Guided Surgery

As previously described, improvements in preoperative imaging tools have offered much help in the diagnosis of cancer by facilitating early detection, increasing diagnostic accuracy, and improving preoperative planning. Nevertheless, the eyes and hands of surgeons remain the dominant "imaging modalities" during surgery that are used to decide which tissues need to be removed or preserved. Palpation and visual inspection are not always accurate for discriminating between abnormal and normal tissues, which can lead to incomplete resections of malignant tissues or unnecessary removal of healthy tissue. For instance, many breast tumors are nonpalpable and hence the positive surgical margin rates are in the range of 5%–49%, which will inevitably increase patient pain. In order to successfully treat and cure patients with solid cancers, it is of great importance to precisely localize the tumor followed by complete removal of the tumor, while preserving healthy tissues as far as possible. To this end, molecular imaging techniques have tremendous potential in imaging-guided cancer surgery.

Ultrasonography and X-ray fluoroscopic imaging are sometimes utilized during cancer surgery to find occult tumors and define tumor vasculature. Furthermore, intraoperative MRI and CT have also been frequently used in preoperative staging and intraoperative planning of resection, especially in the field of neurosurgical image guidance. Nevertheless, these intraoperative techniques are expensive, require a complex infrastructure, and are mainly used for neurosurgery only at some specialized hospitals. In the past several years, intraoperative imaging using invisible NIR fluorescent light has entered the surgical consideration to fill the niche between preoperative imaging and intraoperative reality. In contrast to the case that visible light penetrates tissue on the micrometer scale, NIR light can travel millimeters—even up to centimeters—through blood and tissue. This greatly enhanced photon transport improves the recognition of targets below the background. Since the tissue shows almost no autofluorescence in the NIR spectrum range, the signal-to-background contrast can be maximized using fluorescent contrast agents responsive to NIR light. In addition, NIR light is invisible to the human eye and NIR imaging does not use ionizing radiation, making it an inherently safe technique. Therefore, to date, some specialized intraoperative imaging systems for open surgery, laparoscopy, and robot-assisted surgery have become available. Using these instruments, NIR fluorescent contrast agents can be visualized with acquisition time in the millisecond range, realizing real-time guidance during surgery.

In recent years, researchers have found that compared with NIR imaging at wavelengths in the 700–900 nm range (NIR-I region), increasingly more favorable optical properties of tissues can be exploited well when imaging at progressively longer wavelengths in the 1000–1700 nm range (NIR-II region). NIR-II fluorescence imaging can offer an even higher signal-to-noise ratio because of lower tissue autofluorescence and deeper tissue penetration because of lower signal attenuation. Although NIR-II imaging is a newly emerging field, numerous NIR-II fluorophores from small organic molecules to organic and inorganic NPs have been successfully developed, and their wide biomedical applications have been demonstrated. It is anticipated that the forthcoming crucial breakthrough in research into NIR-II fluorophores and imaging systems will make a substantial impact on precise imaging-guided cancer surgery.

Conclusion

NPs have gained tremendous popularity in the field of drug delivery, gene delivery, and diagnosis with great success. The major advantages of NPs lie in enhancing drug solubility, improving drug stability, facilitating biodistribution, controlling cargo release, realizing disease targeting, and interacting with biological barriers. Thus, nanoparticulate systems have demonstrated great promise for applications such as antitumor therapy, antiinflammation therapy, gene therapy, antiviral therapy, phototherapy, molecular imaging, and macromolecular delivery across multiple physiological barriers. Additionally, at the intersection between treatment and diagnosis, interest has grown in combining both paradigms into clinically effective formulations. With a proper combination thereof, precision nanomedicine that can simultaneously detect, image, and treat disease may one day become the norm rather than the exception. However, there is still major scope for improvement in the development of efficient NPs for biomedical utility. These improvements involve precise manipulation of NP properties (such as small size with low dispersity), controlled synthesis of materials with scale-up amenability, reduced material complexity with lower cost, synchronized nano-properties toward overcoming multiple biological barriers, long-term safety, and in vivo biodegradability. Various NPs are currently being developed for diagnosis and therapy, and with the elegant solution of the above-mentioned issues, it is envisioned that novel therapeutic/diagnostic NPs will realize ideal personalized medicines in the near future and contribute greatly to optimized therapy for individual patients in clinical fields.

Chapter Assessment Questions

1. Define NPs, and mention three major types of NPs.
2. Please list the major advantages and disadvantages of polymeric micelles, polymersomes, liposomes, and nanocapsules.
3. Define the term "critical micellar concentration." List three strategies to reduce the critical micellar concentration.
4. List at least five examples concerning the correlation between NP properties (size, surface charge, morphology, etc.) and functions.
5. Explain different mechanisms to noncovalently and covalently load drugs into NPs and compare their advantages/disadvantages.
6. Summarize the major systemic barriers to anticancer drug delivery and existing approaches to overcome these barriers.
7. List different endolysosomal escape mechanisms mediated by gene-delivery vectors.
8. List different intracellular gene release mechanisms mediated by polycationic vectors.
9. What are passive targeting and active targeting? List three approaches to realize passive targeting or active targeting, respectively.
10. List five different types of internal or external stimuli-responsive mechanisms in drug delivery.

1.4.1 Introduction to Materials Processing for Biomaterials

SHELLY E. SAKIYAMA-ELBERT

Department of Biomedical Engineering, The University of Texas at Austin, Austin, TX, United States

The processing of materials can be critical for altering their physical properties to modulate the biological response to the material. It can also greatly expand the number of applications that the material can be used for. In this section a number of different types of modifications will be covered, including surface modification to decrease fouling and increase specific interactions with cells, as well as fabrication of textiles and more three-dimensional structures through additive manufacturing.

The first chapter in this section focuses on physiochemical modifications of material surfaces to alter biological responses. Methods for the modification of surface chemistry through chemical reaction, grafting, and changing texture will all be discussed, as well as the characterization of modifications. The second chapter focuses specifically on nonfouling surfaces that have reduced protein adsorption and methods to generate such surfaces. In particular there is an emphasis on polymer grafting and thin films that can be applied to a broad variety of materials to lower protein adsorption.

For materials that come into contact with blood, and particularly for materials used in vascular applications, the risk of promoting undesired clot formation is one of the biggest challenges faced in medical device design, as the risk of myocardial infarctions or strokes can result. The third chapter focuses on key steps in thrombus formation and processing methods to reduce the thrombogenicity of materials either through preventing the activation of the coagulation cascade or preventing platelet activation. Specific surface modification strategies and polymer grafting are the primary methods, as well as use of antiplatelet agents and immobilization of fibrinolytic agents.

Beyond just pacifying materials surfaces or reducing protein adsorption, surface modification can also be used to promote specific interactions between biomaterials and biological systems. This can be accomplished through the grafting of peptides or proteins that can interact specifically with cell surface receptors or catalyze biological reactions (enzymes). The fourth chapter focuses on methods that can be used to functionalize surfaces, largely through covalent reactions and the use of "capture tags." Beyond uniform modification of surfaces, for some applications nonuniform surface modification can enhance the functionality of materials and further modulate the biological response. For example, cell migration to certain regions of the material or cell adhesion in specific shapes or patterns can improve tissue integration of materials. This chapter focuses on a variety of patterning techniques that can be used with different materials.

In addition to patterning, another key processing method for material is the texture and three-dimensional structure of the material. By processing biomaterials into fibers that can further be woven into textiles, the properties of the materials can be further altered. The fiber structure allows a much greater surface area-to-volume ratio and textiles can further increase the porosity and flexibility of materials. Woven biomaterials have been used for a variety of applications, which are highlighted in the fourth chapter along with methods for processing fiber and textile formation. More broadly textured surfaces can play a critical role in the enhancement of integration of materials with host tissue in both hard and soft tissues. This chapter specifically focuses on using texture materials to enhance cellular ingrowth and methods for fabricating texture materials on both the nano- and microscales. These approaches provide great versatility for materials processing.

The explosion of low-cost 3D printers has made additive manufacturing much more accessible for both researchers and the lay public. It has also led to the broad development of printers that can be used with biologics that cannot be processed under traditional printing conditions, and open source

hardware that can be adapted to specific user needs. The result is that complex three-dimensional materials can be printed to provide structures that are not accessible through other processing methods to provide porosity or complex architecture that better supports tissue integration or even recapitulates the structure of complex organs. The fifth chapter focuses on the different techniques that are currently available for additive manufacturing of materials with complex structures.

1.4.2

Physicochemical Surface Modification of Materials Used in Medicine

Introduction

Much effort goes into the design, synthesis, and fabrication of biomaterials and devices to ensure that they have the appropriate mechanical properties, durability, and functionality. To cite a few examples, a hip joint should withstand the high stresses associated with walking and running, a hemodialyzer should have the requisite permeability characteristics, and the pumping bladder in an artificial heart should flex for millions of cycles without failure. The bulk composition and organization of materials govern these properties.

The biological response to biomaterials and devices, on the other hand, is influenced by their surface chemistry and structure (see Chapters 1.2.4, 2.1.3 and 2.1.4). The rationale for the surface modification of biomaterials is therefore straightforward: to retain the key physical properties of a biomaterial while modifying only the outermost surface to influence the biointeraction. If such surface modification is properly effected, the mechanical properties and functionality of the device will be unaffected, but the bioresponse related to the tissue–device interface will be improved or modulated.

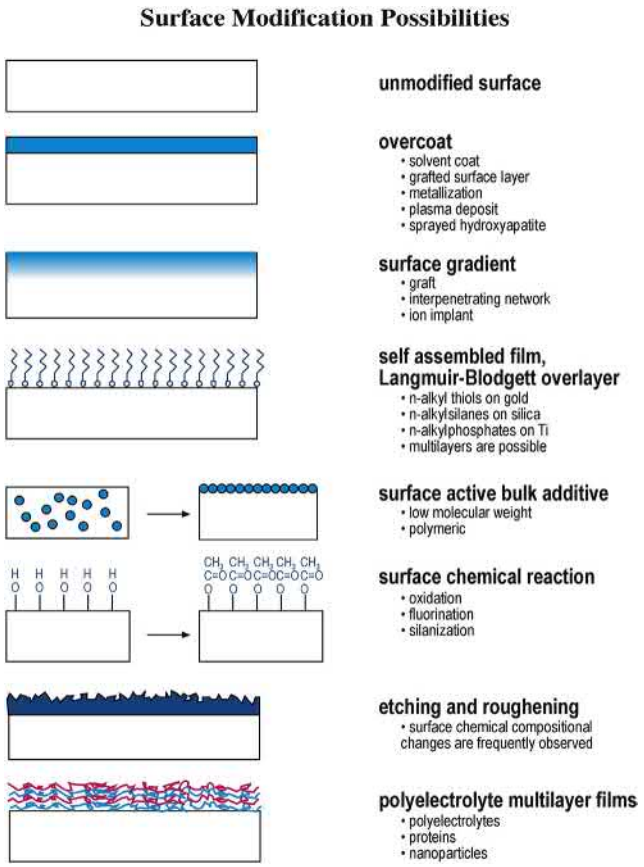
Materials can be surface modified by using biological, mechanical or physicochemical methods. Many biological surface modification schemes are covered in Chapter 1.4.4. Surface modification for creating nonfouling surfaces is reviewed in Chapter 1.4.2. Generalized examples of physicochemical surface modifications, the focus of this chapter, are illustrated schematically in Fig. 1.4.2.1. Surface modification with Langmuir–Blodgett (LB) films has elements of both biological modification and physicochemical modification. LB films will be discussed later in this chapter. Some applications for surface modified biomaterials are listed in Table 1.4.2.1. Physical and chemical surface modification methods, and the types of materials to which they can be applied, are listed in Table 1.4.2.2. Methods to modify or create surface texture or roughness will not be explicitly covered here (see Chapter 1.4.7).

General Principles

Surface modifications fall into three categories: (1) chemically or physically altering the atoms, compounds, or molecules in the existing surface (chemical modification, etching, mechanical roughening); (2) overcoating the existing surface with a material having a different composition (coating, grafting, thin film deposition); and (3) creating surface textures or patterns (Fig. 1.4.2.1). A few general principles provide guidance when undertaking surface modifications.

Thin Surface Modifications

Thin surface modifications are desirable. Modified surface layers that are too thick can change the mechanical and functional properties of the material. Thick coatings are also more subject to delamination and cracking. How thin should a surface modification be? Ideally, alteration of only the outermost few molecular layers (3–10 nm) should be sufficient. In practice, thicker films than this will be necessary, since it is difficult to ensure that the original surface is uniformly covered when coatings and treatments are molecularly thin. This is because of intrinsic nonuniformities in



• **Figure 1.4.2.1** Schematic representations of methods to modify surfaces.

many coating processes, and also because of surface roughness that exists on almost all surfaces at the nanometer scale. Also, extremely thin layers may be more subject to surface reversal (see below) and mechanical erosion. Some coatings intrinsically have a specific thickness. For example, the thickness of LB films is related to the length of the amphiphilic molecules that comprise them (2–5 nm). Other coatings, such as poly(ethylene glycol) (PEG) protein-resistant layers, may require a minimum thickness (a dimension related to the molecular weight of chains) to function (see Chapter 1.4.3A). In general, surface modifications should be the minimum thickness needed for uniformity, durability, and functionality, but no thicker. This is often experimentally defined for each system.

Delamination Resistance

The surface modified layer should be resistant to delamination and cracking. Resistance to delamination is achieved by covalently bonding the modified region to the substrate, intermixing the components of the substrate and the surface film at an interfacial zone (for example, an interpenetrating network or IPN), applying a compatibilizing ("primer") layer at the interface or incorporating appropriate functional groups for strong intermolecular adhesion between a substrate and an overlayer (Wu, 1982). Where the mechanical properties of the substrate and overlayer are significantly mismatched, delamination becomes increasingly of concern.

TABLE 1.4.2.1 Examples of Surface-Modified Biomaterials by Physicochemical Methods

To Modify Blood Compatibility
Octadecyl group attachment to surfaces (albumin affinity)
Silicone-containing block copolymer additive
Plasma fluoropolymer deposition
Plasma siloxane polymer deposition
Grafted poly(ethylene glycol) (PEG) or PEG-containing polymers
Chemically modified polystyrene for heparin-like activity
To Modulate Cell Adhesion and Growth
Oxidized polystyrene surface
Ammonia plasma-treated surface
Plasma-deposited acetone or methanol film
Plasma fluoropolymer deposition (reduce corneal endothelial adhesion and modify blood interactions)
Varying surface modulus
Antibacterial treatments?
To Control Protein Adsorption
Surface with immobilized poly(ethylene glycol) (reduce adsorption)
Treated ELISA dish surface (increase adsorption)
Affinity chromatography column
Surface cross-linked contact lens (reduce adsorption)
To Improve Lubricity
Plasma treatment?
Radiation grafting (hydrogels)
Interpenetrating polymeric networks
To Improve Wear Resistance and Corrosion Resistance
Ion implantation
Diamond deposition
Anodization
To Alter Transport Properties
Polyelectrolyte grafting
Surface self-assembled film barrier
Plasma-deposited barrier layer
To Modify Electrical Characteristics
Polyelectrolyte grafting
Magnetron sputtering of titanium
Surface fluoropolymer insulation

Surface Rearrangement

Surface rearrangement can readily occur. It is driven by a thermodynamic minimization of interfacial energy and enhanced by molecular mobility. Surface chemistries and structures can

[b]For polymers with ionic groups.

"switch" due to diffusion or translation of surface atoms or molecules in response to the external environment (see Chapter 1.2.4 and Fig. 1.2.4.2 in that chapter). A newly formed surface chemistry can migrate from the surface into the bulk or molecules from the bulk can diffuse to cover the surface. Such reversals occur in metallic and other inorganic systems, as well as in polymeric systems. Terms such as "reconstruction," "relaxation," and "surface segregation" are often used to describe mobility-related alterations in surface structure and chemistry (Ratner and Yoon, 1988; Garbassi et al., 1989; Somorjai, 1990, 1991; Cometa et al., 2010). The driving force for these surface changes is a minimization of the interfacial energy. However, sufficient atomic or molecular mobility must exist for the surface changes to occur in reasonable periods of time. For a modified surface to remain as intended, surface reversal must be prevented or inhibited. This can be done by cross-linking, by sterically blocking the ability of surface structures to move, by incorporating a rigid, impermeable layer between the substrate material and the surface modification, or by reducing the hydrophilic character of the modified surface, which will reduce water uptake and the mobility of surface atoms.

Surface Analysis

Surface modification and surface analysis are complementary and sequential technologies. The surface-modified region is usually thin, and consists of only minute amounts of material. Undesirable contamination can readily be introduced during modification reactions. The potential for surface reversal to occur during surface modification is also high. The surface reaction should be monitored to ensure that the intended surface is indeed being formed. Since conventional analytical methods are often insufficiently sensitive to detect surface modifications, special surface analytical tools are called for to probe the physical, chemical, and biological behaviors of the coating (Chapter 1.2.4).

Manufacturability and Commercializability

The end products of biomaterials research are devices and materials that are manufactured to exacting specifications for use in humans. A surface modification that is too complex will be challenging and expensive to reproducibly manufacture and commercialize. In many instances, surface modification will require significant investment in infrastructure, may change the regulatory approach to the product (i.e., introducing nanoparticles), or simply add too much cost to the final product. It is also best to minimize the number of steps in a surface modification process, and to design each step to be relatively insensitive to small changes in the preparation processes.

Methods for Modifying the Surfaces of Materials

General methods to modify the surfaces of materials are illustrated in Fig. 1.4.2.1, with many examples listed in Table 1.4.2.2. A few of the more widely used of these methods will be briefly described. Some of the conceptually simpler methods, such as solution coating of a polymer onto a substrate or metallization by sputtering or thermal evaporation, will not be elaborated upon here.

Chemical Reaction

There are hundreds of chemical reactions that can be used to modify the chemistry of a surface. Chemical reactions, in the context of this chapter, are those performed with reagents that react with atoms or molecules at the surface, but do not overcoat those atoms or molecules with a new layer. Chemical reactions can be classified as nonspecific and specific.

Nonspecific reactions leave a distribution of different functional groups at the surface. An example of a nonspecific surface chemical modification is the chromic acid oxidation of polyethylene surfaces leading to numerous surface oxygen species including carboxylic acid, carbonyl, hydroxyl, etc. Other examples include the corona discharge modification of materials in air; radio frequency glow discharge (RFGD) (plasma) treatment of materials in oxygen, argon, nitrogen, carbon dioxide, fluorinated gases, or water vapor; and the oxidation of metal surfaces to a mixture of metallic suboxides.

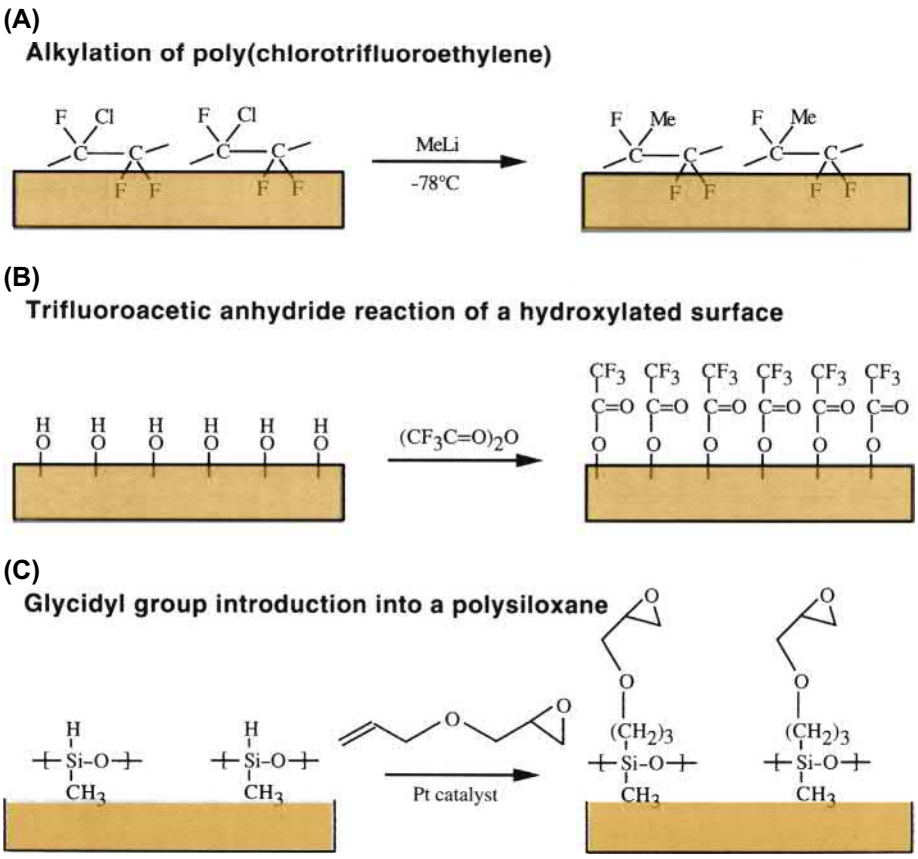
Specific chemical surface reactions change only one functional group into another with a high yield and few side reactions. A few examples of specific chemical surface modifications for polymers are presented in Fig. 1.4.2.2. Certain specific reactions can be used for inorganic (silicon) surfaces as well as polymeric surfaces (Filler and Bent, 2003). Still another example (expanded upon in the section, below, titled "Specific Chemical Reactions for Forming Surface Grafts") uses atomic transfer radical polymerization (ATRP) chain growth on surfaces (Hucknall et al., 2009). Others have also used radical addition chain transfer polymerization (RAFT) to graft polymer chains to a surface with high precision. This may be done by conjugating the chain transfer agent (CTA) to the surface and then initiating graft polymerization of a monomer to the CTA using a typical free radical initiator (Boyer et al., 2009; Golden et al., 2010).

Protein immobilization is typically (although not always) a surface modification reaction performed with high chemical specificity. Detailed chemistries for biomolecule immobilization are described in Chapter 1.4.4.

Surface Grafting: Radiation Grafting, Photografting, and Newer Methods

Surface grafting methods have been widely applied for the surface modification of biomaterials since the early days of the field (Hoffman et al., 1972). Comprehensive review articles are available (Ratner, 1980; Hoffman, 1981; Hoffman et al., 1983; Stannett, 1990; Safrany, 1997; Ma et al., 2007). Surface grafting methods can be divided into two general categories: (1) using energetic or highly reactive species to activate a chemically inert surface, permitting the attachment of desired surface species; and (2) taking advantage of well-defined, reactive surface chemical groups to covalently attach the surface-modifying species (a polymer, a low-molecular-weight compound, a drug, a protein, etc.). These category (2)-specific reactions for forming surface grafts will be addressed in a separate section below.

The earliest biomedical surface modification studies focused on attaching chemically reactable groups (–OH, –COOH, $–NH_2$, etc.) to the surfaces of relatively inert hydrophobic polymers using methods from category (1), above. Four types of reactions can be distinguished in category (1): grafting using ionizing radiation sources (most commonly, a cobalt 60 or cesium 137 gamma radiation source) (Dargaville et al., 2003; Luk et al., 2017); grafting using UV radiation (photografting) (Matsuda and Inoue, 1990; Dunkirk et al., 1991; Swanson, 1996; Sebra et al., 2007); grafting using high-energy electron beams (Singh and Silverman, 1992); and grafting using a reactive, surface-activating species such as ozone (Chiang et al., 2009). In all cases, similar processes occur. The radiation or reactive chemical breaks chemical bonds in the material to be grafted, forming free radicals, peroxides, or



• **Figure 1.4.2.2** Some specific chemical reactions to modify surfaces.

other reactive species. These reactive surface groups are then exposed to a monomer. The monomer reacts with the free radicals at the surface and propagates as a free radical chain reaction incorporating other monomers into a surface-grafted polymer. Electron beams and gamma radiation sources are also used for biomedical device sterilization (see Chapter 3.1.2 Total Product Lifecycle for Biomaterial-based Medical Devices). Note that glow discharge plasma reactions to surfaces also have similarities to these nonspecific surface modification approaches. Plasma reaction will be discussed in its own section, below.

High-energy surface modification technologies are strongly dependent on the source energy, the radiation dose rate, and the amount of the dose absorbed. The energy of the radiation produced by gamma sources is roughly 1 MeV (1 eV = 23.06 kcal/mol; for comparison, a carbon–carbon bond has a strength of approximately 85 kcal/mol). Typical energies for electron beam processing are in the range 5–10 MeV. UV radiation sources are of much lower energy (<6 eV). Radiation dose rates are low for UV and gamma, and very high for electron beams. The amount of energy absorbed is measured in units of Grays (Gy), where 1 kGy (Kgy) = 1000 J/kg. Units of megarads (MR) are often used for gamma sources, 1 MR = 1×10^6 erg/g.

Three distinct reaction modes can be described: (1) in the mutual irradiation method, the substrate material is immersed in an oxygen-free solution (monomer ± solvent) that is then exposed to the radiation source; (2) the substrate materials can also be exposed to the radiation under an inert atmosphere or at low temperatures (to stabilize free radicals) (in this case, the materials are later contacted with a monomer solution to initiate the graft process); (3) finally, the exposure to the radiation can take place in air or oxygen, leading to the formation of peroxide groups on the surface. Heating the material to be grafted in the presence of monomer or addition of a redox reactant (e.g., Fe^{2+}) which will decompose the peroxide groups to form free radicals can initiate the graft polymerization (in O_2-free conditions).

Graft layers formed by energetic irradiation of the substrate are often relatively thick (>1 μm) and are comprised of high-molecular-weight polymer chains. However, they are typically well-bonded to the substrate material, and thus resist delamination. Since many polymerizable monomers are available, a wide range of surface chemistries can be created. Mixtures of monomers can form unique graft copolymers (Ratner and Hoffman, 1980). For example, the hydrophilic/hydrophobic ratio of surfaces can be controlled by varying the ratio of a hydrophilic and a hydrophobic monomer in the grafting mixture (Ratner et al., 1979; Ratner and Hoffman, 1980).

Photoinitiated grafting (usually with visible or UV light) represents a unique subcategory of surface modifications for which there is growing interest (Deng et al., 2009; Park et al., 2009). There are many approaches to effect this photoinitiated covalent coupling. For example, a phenyl azide group can be converted to a highly reactive nitrene upon UV exposure. This nitrene will quickly react with many organic groups. If a synthetic polymer is prepared with phenyl azide side groups,

and this polymer is exposed simultaneously to UV light and a substrate polymer or polymeric medical device, the polymer containing the phenyl azide side groups will be immobilized to the substrate (Matsuda and Inoue, 1990). Another method involves the coupling of a benzophenone molecule to a hydrophilic polymer (Dunkirk et al., 1991). In the presence of UV irradiation, the benzophenone is excited to a reactive triplet state that can covalently couple with many polymers. As still another example, a dithiocarbamate-functionalized polyurethane was used to photo-pattern an extracellular-matrix-like coating (Sebra et al., 2007).

Radiation, electron beam, and photografting have frequently been used to bond hydrogels to the surfaces of hydrophobic polymers (Matsuda and Inoue, 1990; Dunkirk et al., 1991; Sebra et al., 2007; Luk et al., 2015). Electron beam grafting of N-isopropyl acrylamide to polystyrene has been used to create a new class of temperature-dependent surfaces for cell growth (Kwon et al., 2000) (also see Chapter 1.4.4). The protein interactions (Horbett and Hoffman, 1975), cell interactions (Ratner et al., 1975; Matsuda and Inoue, 1990), blood compatibility (Chapiro, 1983; Hoffman et al., 1983), and tissue reactions (Greer et al., 1979) of hydrogel graft surfaces have been investigated.

RFGD Plasma Deposition and Other Plasma Gas Processes

RFGD plasmas, as used for surface modification, are low-pressure ionized gas environments typically at ambient (or slightly above ambient) temperature. They are also referred to as glow discharge or gas discharge depositions or treatments. Plasmas can be used to modify existing surfaces by ablation or etching reactions or, in a deposition mode, to overcoat surfaces (Fig. 1.4.2.1). Good review articles on plasma deposition and its application to biomaterials are available (Yasuda and Gazicki, 1982; Hoffman, 1988; Ratner et al., 1990; Chu et al., 2002; Kitching et al., 2003; Desmet et al., 2009). Some biomedical applications of plasma-modified biomaterials are listed in Table 1.4.2.3.

RFGD plasma surface modifications are widely used in biomaterials research and development. Because such coatings and treatments are now used in commercialized biomaterials products and have special promise for improved biomaterials, they will be emphasized in this chapter. The specific advantages of plasma-deposited films (and to some extent, plasma-treated surfaces) for biomedical applications are:

1. They are conformal. Because of the penetrating nature of a low-pressure gaseous environment in which mass transport is governed by both molecular (line-of-sight) diffusion and convective diffusion, complex geometric shapes can be treated.
2. They are generally free of voids and pinholes. This continuous barrier structure is suggested by transport studies and electrical property studies (Charlson et al., 1984). However, at short deposition times (very thin films), substrate-dependence and less than uniform coatings may be noted (Vasilev et al., 2010).
3. Plasma-deposited films can coat almost any clean solid, including polymers, metals, ceramics, and semiconductors. Other surface grafting or surface modification technologies are highly dependent upon the chemical nature of the substrate.
4. They can be tuned to give good adhesion to the substrate. The energetic nature of the gas phase species in the plasma reaction environment can induce mixing, implantation, penetration, and reaction between the overlayer film and the substrate.
5. Unique film chemistries can be produced. The chemical structure of the polymeric overlayer films generated from the plasma environment usually cannot be synthesized by conventional chemical methods.
6. They can serve as excellent aqueous barrier films, or can be tuned to be hydrogel-like and permeable to water (Förch et al., 2005; Lopez et al., 1993).
7. Plasma-deposited layers generally show low levels of leachables. Due to their highly cross-linked nature, plasma-deposited films contain negligible amounts of low-molecular-weight components that might lead to an adverse biological reaction. They can also inhibit leaching of low-molecular-weight material from the substrate and, in the case of drug-delivery implants or inserts, they can reduce the rate of drug diffusion out of the device (Hendricks et al., 2000).
8. These films are easily prepared. Once the apparatus is set up and optimized for a specific deposition, treatment of additional substrates is rapid and simple.

TABLE 1.4.2.3 Biomedical Applications of Glow Discharge Plasma-Induced Surface Modification Processes

A. Plasma treatment (etching)
   1. Clean
   2. Sterilize
   3. Cross-link surface molecules

      e. Control drug delivery rate
   2. Modify cell and protein reactions
      a. Modulate biointeractions
      b. Promote selective protein adsorption
      c. Enhance cell adhesion
      d. Improve cell growth
      e. Form nonfouling surfaces
      f. Increase lubricity

Antibacterial Properties?

   3. Provide reactive sites
      a. For grafting or polymerizing polymers
      b. For immobilizing biomolecules

9. Plasma deposition is a mature technology. The microelectronics industry has made extensive use of inorganic plasma-deposited films for many years (Sawin and Reif, 1983; Nguyen, 1986).
10. Plasma surface modifications, although chemically complex, can be characterized by:
    (a) infrared (IR) spectroscopy (Inagaki et al., 1983; Haque and Ratner, 1988; Krishnamurthy et al., 1989)
    (b) nuclear magnetic resonance (NMR) (Kaplan and Dilks, 1981),
    (c) electron spectroscopy for chemical analysis (ESCA) (Chilkoti et al., 1991a; Nisol and Reniers, 2015; McArthur, 2006)
    (d) chemical derivatization methods (Everhart and Reilley, 1981; Gombotz and Hoffman, 1988; Griesser and Chatelier, 1990; Chilkoti et al., 1991a; Pippig et al., 2009)
    (e) static secondary ion mass spectrometry (SIMS) (Chilkoti et al., 1991b, 1992; Johnston and Ratner, 1996; Delcorte et al., 2015; Bernard et al., 2018; Mishra et al., 2010).

    Also, their behaviors and structure in aqueous environments can be characterized using:
    (a) quartz crystal microbalance (QCM) (Askew, 2018)
    (b) surface plasmon resonance (SPR) (Förch et al., 2005)

11. Plasma-treated surfaces are sterile when removed from the reactor, offering an additional advantage for cost-efficient production of medical devices.
12. New developments in the generation of atmospheric pressure plasmas may permit plasma processing without the need for a vacuum environment (Pappas, 2011).

Although plasma treatments have many advantages, there are concerns with plasma surface modification that should be discussed. First, the chemistry produced on a surface is often ill-defined. For example, if tetrafluoroethylene gas is introduced into the reactor, polytetrafluoroethylene (PTFE) will not be deposited on the surface. Rather, a complex, branched fluorocarbon polymer will be produced with a stoichiometry different from PTFE. This scrambling of monomer structure has been addressed in studies dealing with retention of monomer structure in the final film (Lopez and Ratner, 1991; Lopez et al., 1993; Panchalingam et al., 1993; Shard et al., 2004; Mishra and McArthur, 2010). Second, the apparatus used to produce plasma depositions can be expensive. A good laboratory-scale reactor will cost $10,000–$30,000, and a production reactor can cost $100,000 or more. Third, uniform reaction within tubes and narrow pores can be difficult to achieve. Finally, contamination can be a problem, and care must be exercised to prevent extraneous gases and pump oils from entering the reaction zone. However, the advantages of plasma reactions outweigh these potential disadvantages for many types of modifications that cannot be accomplished by other methods.

The Nature of the Plasma Environment

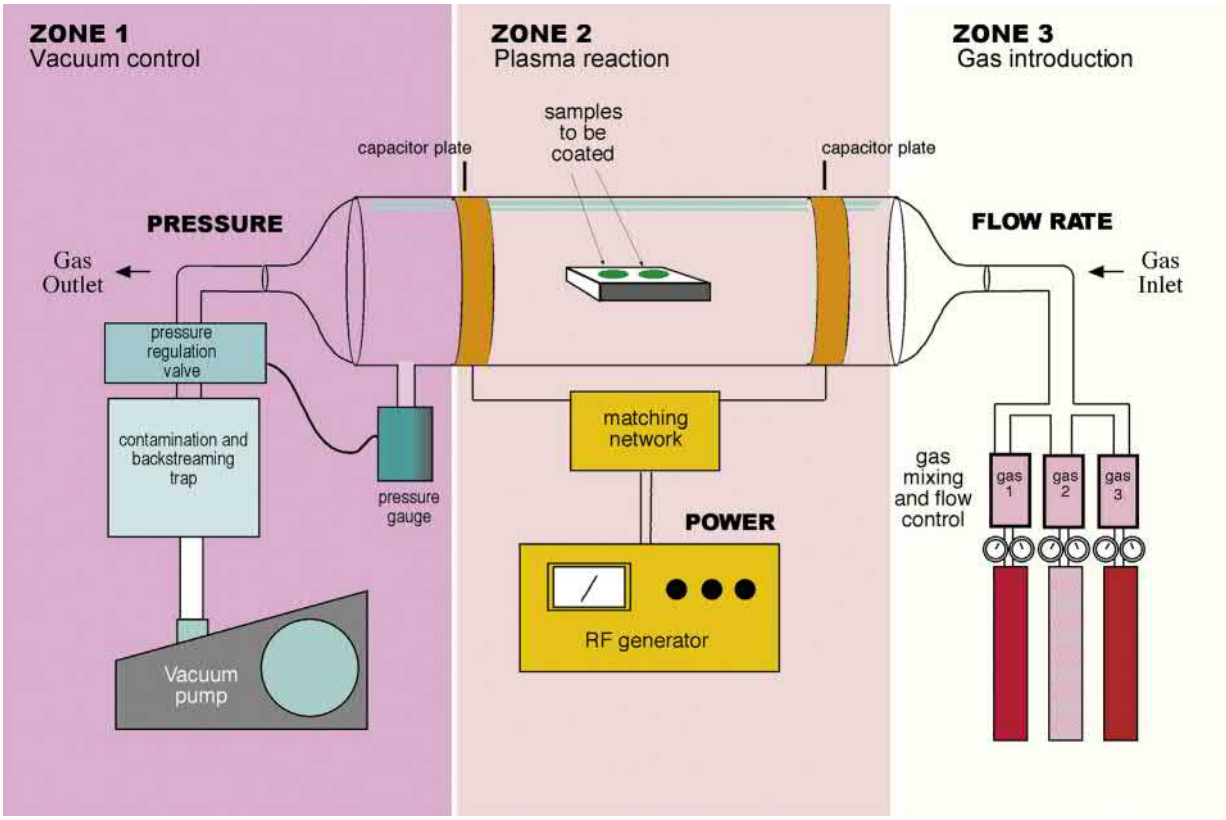
Plasmas are atomically and molecularly dissociated gaseous environments. A plasma environment contains positive ions, negative ions, free radicals, electrons, atoms, molecules, and photons (visible and near UV). Typical conditions within the plasma include an electron energy of 1–10 eV, a gas temperature of 25–60°C, an electron density of 10^{-9} to 10^{-12}/cm^2, and an operating pressure of 0.025–1.0 torr.

Many processes can occur on the substrate surface that lead to the observed surface modification or deposition. First, a competition takes place between deposition and etching by the high-energy gaseous species (ablation) (Yasuda, 1979). When ablation is more rapid than deposition, no deposition will be observed. Because of its energetic nature, the ablation or etching process can result in substantial chemical and morphological changes to the substrate.

A number of mechanisms have been postulated for the deposition process. The reactive gaseous environment may create free radical and other reactive species on the substrate surface that react with and polymerize molecules from the gas phase. Alternatively, reactive small molecules in the gas phase could combine to form higher molecular weight units or particulates that may settle or precipitate onto the surface. Most likely, the depositions observed are formed by some combination of these two processes.

The Apparatus to Generate Plasmas for Surface Modification

Many experimental variables relating both to reaction conditions and to the substrate onto which the deposition is placed affect the final outcome of the plasma deposition process. A diagram of a typical capacitively coupled radio frequency plasma reactor is presented in Fig. 1.4.2.3. The major subsystems that comprise this apparatus are a gas introduction system (control of gas mixing, flow rate, and mass of gas entering the reactor), a vacuum system (measurement and control of reactor pressure and inhibition of backstreaming of molecules from the pumps), an energizing system to efficiently couple energy into the gas phase within the reactor, and a reactor zone in which the samples are treated. Radio frequency, acoustic, or microwave energy can be coupled to the gas phase. Devices for monitoring the molecular weight of the gas phase species (mass spectrometers), the optical emission from the glowing plasma (spectrophotometers), and the deposited film thickness (ellipsometers, vibrating quartz crystal microbalances) are also commonly found on plasma reactors. Technology has been developed permitting atmospheric pressure plasma deposition (Klages et al., 2000; Massines et al., 2000; Pappas, 2011). Another important development is "reel-to-reel" (continuous) plasma processing opening the way to low-cost, high-throughput treatment of films, fibers, and tubes. Finally, methods have been developed to assist in the retention of polymer chemical structure during plasma deposition. These methods include using pulsed plasmas



• **Figure 1.4.2.3** A capacitively coupled RF plasma reactor. Reddish colors indicate gas storage and mixing. Yellow colors are components that power the reactor. Zone 1: vacuum system (pressure measurement and control); zone 2: plasma generation and sample placement; zone 3: gas introduction and flow control.

(Panchalingam et al., 1993; Mishra and McArthur, 2010), condensing vapors on a cold stage during the plasma process (Lopez and Ratner, 1991), and using very low plasma powers (Pan et al., 2001; Förch et al., 2005). Such controlled chemistry plasma deposition might be thought of as at some intermediate location on a continuum between the scrambled surface chemistries achieved with conventional plasma deposition of polymers, and the precise graft structures described in the section below titled "Specific Chemical Reactions for Forming Surface Grafts."

RFGD Plasmas for the Immobilization of Molecules

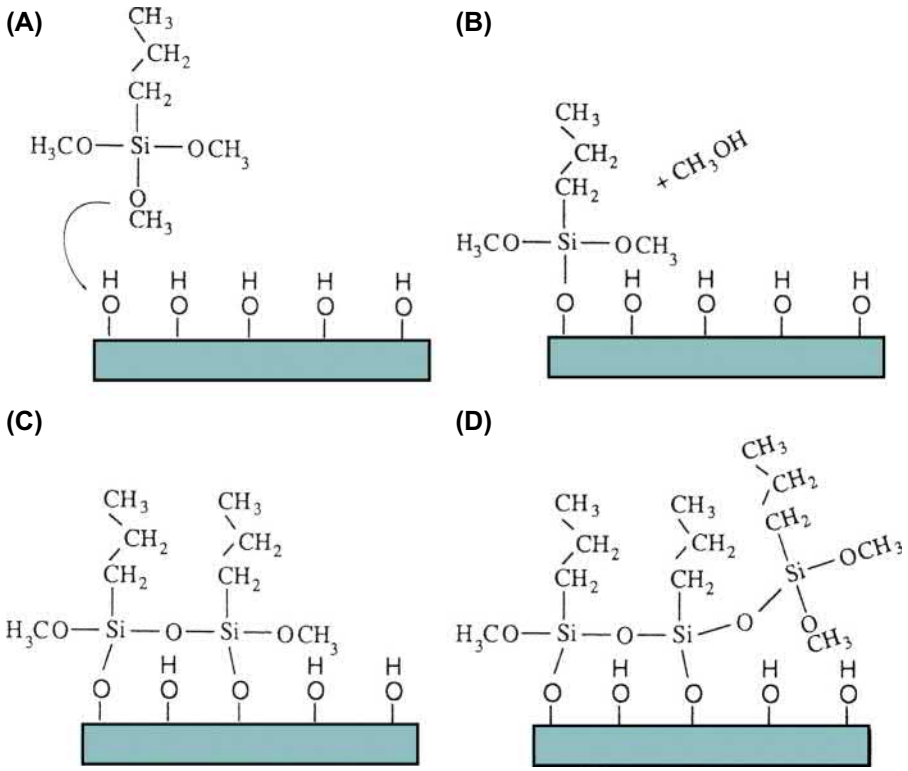
Plasmas have often been used to introduce reactive organic functional groups (e.g., amine, hydroxyl) on a surface that can be activated to attach biomolecules (see Chapter 1.4.4). Certain reactive gas environments can also be used for directly immobilizing organic molecules such as surfactants. For example, a poly(ethylene glycol)-n-alkyl surfactant will adsorb to polyethylene (PE) via the hydrophobic alkyl block. If the polyethylene surface with the adsorbed surfactant is briefly exposed to an argon plasma, the n-alkyl chains will cross-link to surface atoms of PE, thereby leading to the covalent attachment of pendant poly(ethylene glycol) chains (Sheu et al., 1992).

High-Temperature and High-Energy Plasma Treatments

The plasma environments described above are of relatively low energy and low temperature. Consequently, they can be used to deposit organic layers on polymeric or inorganic substrates. Under higher energy conditions, plasmas can effect unique and important inorganic surface modifications on inorganic substrates. For example, flame-spray deposition involves injecting a high-purity, relatively finely divided (~100 mesh) metal powder into a high-velocity plasma or flame. The melted or partially melted particles impact the surface and rapidly solidify (see Chapter 1.3.3). Examples of plasma thermal spray coating on titanium are seen in Gruner (2001), and Vidigal et al. (2009).

Specific Chemical Reactions for Forming Surface Grafts

Techniques such as radiation grafting and plasma deposition create polymer surface grafts, although the polymeric species are generally highly cross-linked, chemically rearranged, and difficult to characterize. A new generation of polymer reactions permits surface grafts with precision in chain length, control of chain architectures (for example, diblock and triblock units), and minimization of unwanted branching and other side reactions (Zhou et al., 2016; Matyjaszewski et al., 2007; Lego et al., 2009). These polymer reactions applied



• **Figure 1.4.2.4** The chemistry of a typical silane surface modification reaction: (A) a hydroxylated surface is immersed in a solution containing n-propyl trimethoxysilane (nPTMS); (B) one of the methoxy groups of the nPTMS couples with a hydroxyl group releasing methanol; (C) two of the methoxy groups on another molecule of the nPTMS have reacted, one with a hydroxyl group and the other with a methoxy group from the first nPTMS molecule; (D) a third nPTMS molecule has reacted only with a methoxy group. This molecule is tied into the silane film network, but is not directly bound to the surface.

to surface grafting include ATRP (Hucknall et al., 2009; Siegwart et al., 2012), reversible addition-fragmentation chain transfer (RAFT) polymerization (Boyer et al., 2009; Golden et al., 2010), and CLICK chemistry (Fleischmann et al., 2008; Arslan and Tasdelen, 2018; Escorihuela et al., 2015).

Silanization

Silane treatments of surfaces involve a liquid phase or vapor phase chemical reaction, and are straightforward to perform and of low cost. A typical silane surface modification reaction is illustrated in Fig. 1.4.2.4 (although some details of this reaction have been questioned, see Schlecht and Maurer, 2011). Silane reactions are most often used to modify hydroxylated surfaces. Since glass, silicon, alumina, titania, and quartz surfaces, as well as other metal oxide surfaces, are rich in hydroxyl groups, silanes are particularly useful for modifying these materials. Numerous silane compounds are commercially available, permitting a broad range of chemical functionalities to be incorporated on surfaces (Table 1.4.2.4). The advantages of silane reactions are their simplicity and stability, attributed to their covalent, cross-linked structure. However, the linkage between a silane and a hydroxyl group is also subject to hydrolysis, and film breakdown under some conditions must be considered (Wasserman et al., 1989).

TABLE 1.4.2.4 Silanes for Surface Modification of Biomaterials

X = Leaving Group		R = Functional Group

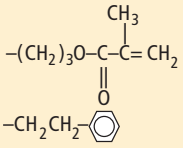
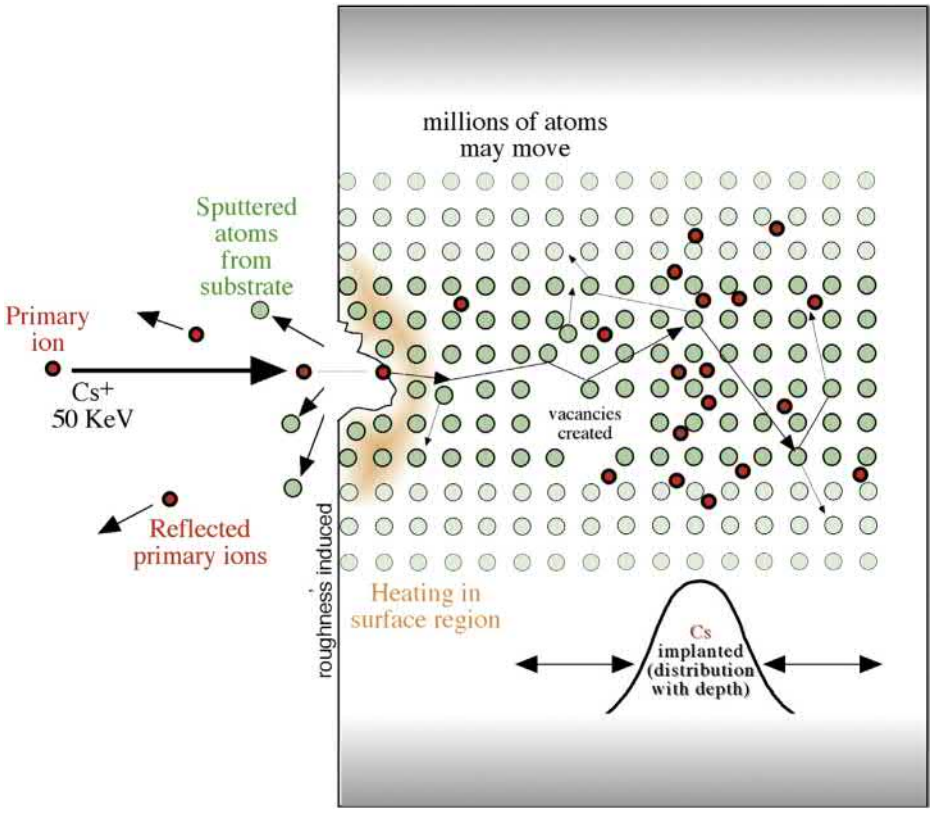
$-OCH_2CH_3$		$-(CH_2)_2(CF_2)_5CF_3$
		


Silanes can form two types of surface film structures. If only surface reaction occurs (perhaps catalyzed by traces of adsorbed surface water), a structure similar to that shown in Fig. 1.4.2.4 can be formed. However, if more water is present, a thicker silane layer can be formed consisting of both Si–O groups bonded to the surface, and silane units participating in a "bulk," three-dimensional, polymerized



• **Figure 1.4.2.5** Ion impact and implantation considerations with a 50 KeV cesium ion accelerated into a surface.

network. The initial stages in the formation of a thicker silane film are suggested by the further reaction of the group at the right side of Fig. 1.4.2.4D with solution phase silane molecules. Without careful control of silane liquid purity, water, and reaction conditions, thicker silane films can form and be rough and inhomogeneous.

A new class of silane-modified surfaces based upon monolayer silane films and yielding self-assembled, highly ordered structures is of particular interest in the precision engineering of surfaces (Pomerantz et al., 1985; Maoz et al., 1988; Heid et al., 1996; Haensch et al., 2010). These self-assembled monolayers are described in more detail later in this chapter.

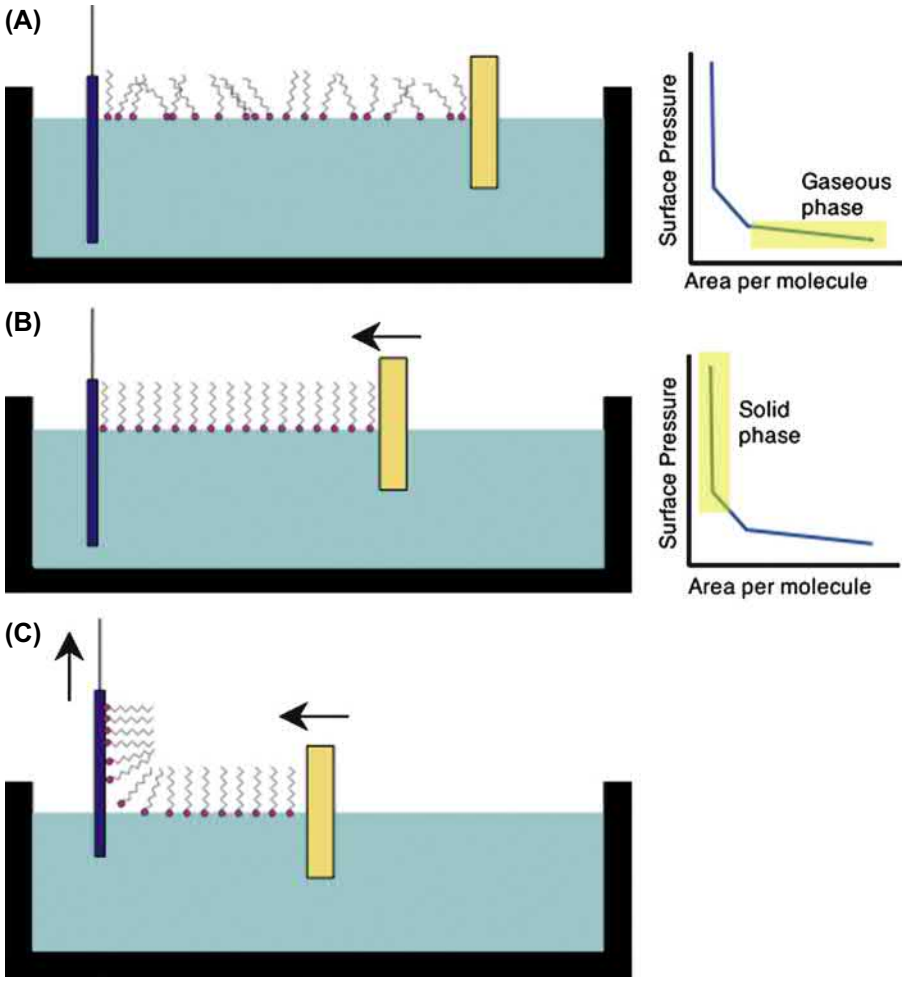
Many general reviews and basic science studies on surface silanization are available (Arkles, 1977; Plueddemann, 1980; Rye et al., 1997). Applications for silanized surface-modified biomaterials are on the increase, and include cell attachment (Hickman and Stenger, 1994; Matsuzawa et al., 1997), biomolecule and polymer immobilization (Mao et al., 1997; Xiao et al., 1997), nonfouling surfaces (Lee and Laibinis, 1998), surfaces for DNA studies (Hu et al., 1996), biomineralization (Archibald et al., 1996), and model surfaces for biointeraction studies (Jenney and Anderson, 1999).

Ion Beam Implantation

The ion beam method injects accelerated ions with energies ranging from 10^1 to 10^6 eV (1 eV = 1.6 × 10^{-19} J) into the surface zone of a material to alter its properties. It is largely, but not exclusively, used with metals and other inorganics such as ceramics, glasses, and semiconductors. Ions formed from most of the atoms in the periodic table can be implanted, but not all provide useful modifications to the surface properties. Important potential applications for biomaterial surfaces include modification of hardness (wear), lubricity, toughness, corrosion, conductivity, and bioreactivity.

If an ion with kinetic energy greater than a few electron volts impacts a surface, the probability that it will enter the surface is high. The impact transfers much energy to a localized surface zone in a very short time interval. Some considerations for the ion implantation process are illustrated in Fig. 1.4.2.5. These surface changes must be understood quantitatively for engineering of modified surface characteristics. Many review articles and books are available on ion implantation processes and their application for tailoring surface properties (Picraux and Pope, 1984; Colligon, 1986; Sioshansi, 1987; Nastasi et al., 1996; Rautray et al., 2010).

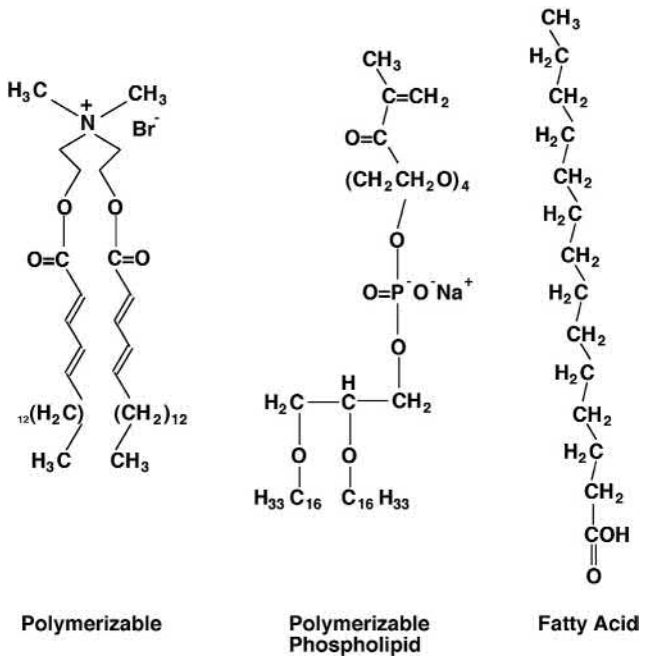
Specific examples of biomaterials that have been surface altered by ion implantation processes are plentiful. Iridium was ion implanted in a Ti-6Al-4V alloy to improve corrosion resistance (Buchanan et al., 1990). Nitrogen implanted into titanium greatly reduces wear (Sioshansi, 1987). The ion implantation of boron and carbon into type 316L stainless steel improves the high cycle fatigue life of these alloys (Sioshansi, 1987). Silver ions implanted into polystyrene permit cell attachment (Tsuji et al., 1998).



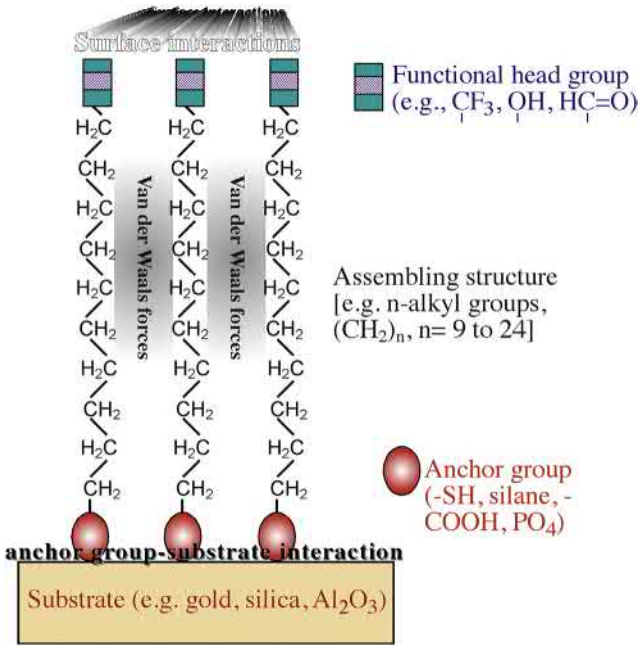
• **Figure 1.4.2.6** Deposition of a lipid film onto a glass slide by the Langmuir–Blodgett method: (A) the lipid film is floated on the aqueous layer; (B) the lipid film is compressed by a moveable barrier; (C) the vertical glass slide is withdrawn while pressure is maintained on the floating lipid film with the moveable barrier.

Langmuir–Blodgett Deposition

The Langmuir–Blodgett (LB) deposition method overcoats a surface with one or more highly ordered layers of surfactant molecules. Each of the molecules that assemble into this layer contains a polar "head" group and a nonpolar "tail" group. The deposition of an LB film using an LB trough is illustrated schematically in Fig. 1.4.2.6. By withdrawing the vertical plate out of the aqueous phase and through the air–water interface (keeping the surface film at the air–water interface compressed at all times, as illustrated in Fig. 1.4.2.6), an assembled structure coats the glass with the hydrophilic tail group contacting the hydrophilic glass surface. By next pushing the plate back down through the air–water interface, another layer can be deposited, this time with the hydrophobic tails of the two layers in contact; dipping in and out with the film at the water surface always compressed permits multilayer structures to be created. Some compounds that form organized LB layers are shown in Fig. 1.4.2.7. Other techniques to create such ordered lipid structures at surfaces include Langmuir–Schaefer transfer and vesicle fusion (Li et al., 2008). The advantages of films deposited on surfaces by this method are their high degree of order and uniformity, and also their resemblance to the lipid



• **Figure 1.4.2.7** Three examples of molecules that form organized Langmuir–Blodgett Films.



• **Figure 1.4.2.8** General characteristics of molecules that form self-assembled monolayers.

bilayer membranes surrounding living cells. Also, since a wide range of chemical structures can form LB films, there are many options for incorporating new chemistries at surfaces. The stability of LB films can be improved by cross-linking or internally polymerizing the molecules after film formation, often through double bonds in the alkyl portion of the chains (Meller et al., 1989). A number of research groups have investigated LB films for biomedical applications (Hayward and Chapman, 1984; Bird et al., 1989; Cho et al., 1990; Heens et al., 1991; Knoll et al., 2008). A cross between silane thin films and LB layers has been developed for biomedical surface modification (Takahara et al., 2000). Many general reviews on these surface structures are available (Knobler, 1990; Ulman, 1991; Park and Advincula, 2011).

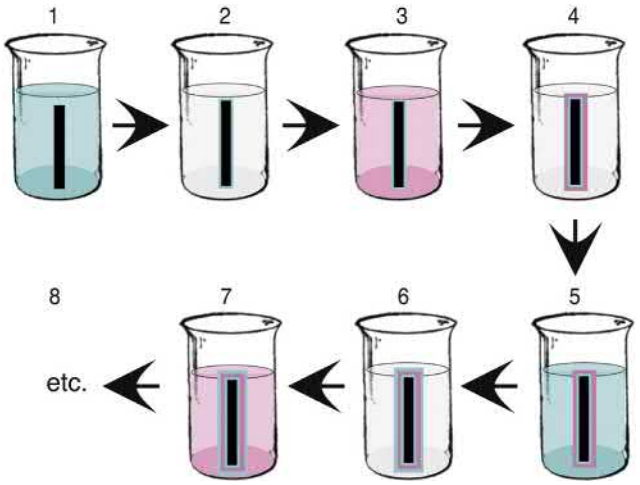
Self-Assembled Monolayers

Self-assembled monolayers (SAMs) are surface films that spontaneously form as highly ordered structures (two-dimensional crystals) on specific substrates (Maoz et al., 1988; Ulman, 1990, 1991; Whitesides et al., 1991; Knoll, 1996; Raynor et al., 2009). In some ways SAMs resemble LB films, but there are important differences, in particular their ease of formation. Examples of SAM films include n-alkyl silanes on hydroxylated surfaces (silica, glass, alumina), alkane thiols [e.g., $CH_3(CH_2)_nSH$] and disulfides on coinage metals (gold, silver, copper), amines and alcohols on platinum, carboxylic acids on aluminum oxide, and silver and phosphates (phosphoric acid or phosphonate groups) on titanium or tantalum surfaces. Silane SAMs and thiols on gold are the most commonly used types. Most molecules that form SAMs have the general characteristics illustrated in Fig. 1.4.2.8. Two processes are particularly important for the formation of SAMs (Ulman, 1991): a moderate-to-strong adsorption of an anchoring chemical group to the surface (typically 30–100 kcal/mol), and van der Waals interaction of the alkyl chains. The bonding to the substrate (chemisorption) provides a driving force to fill every site on the surface, and to displace contaminants from the surface. This process is analogous to the compression to the LB film by the movable barrier in the trough. Once adsorption sites are filled on the surface, the chains will be in sufficiently close proximity so that the weaker van der Waals interactive forces between chains can exert their influence and lead to a crystallization of the alkyl groups. Too few CH_2 groups do not provide sufficient interactive force to stabilize the two-dimensional quasi-crystal and are difficult to assemble. More than 24 CH_2 groups have too many options for defects in the crystal, and are also difficult to assemble. Molecules with lengths between 9 and 24 methylene groups will assemble well. Molecular mobility is an important consideration in this surface crystal formation process, so that: (1) the molecules have sufficient time to maneuver into position for tight packing of the binding end groups at the surface; and (2) the chains can enter the quasi-crystal.

The advantages of SAMs are their ease of formation, their chemical stability (often considerably higher than chemically related LB films), and the many options for changing the outermost group that interfaces with the external environment. Many biomaterials applications have already been suggested for SAMs (Lewandowska et al., 1989; Mrksich and Whitesides, 1996; Ferretti et al., 2000; Raynor et al., 2009). Useful SAMs for creating molecularly engineered functional surfaces include headgroups of ethylene glycol oligomers, biotin, free-radical initiators, N-hydroxysuccinimide esters, ATRP or RAFT chain transfer agents, anhydrides, perfluoro groups, and amines, to list only a small sample of the many possibilities. Although most SAMs are based on n-alkyl chain assembly, SAMs can form from other classes of molecules including peptides, proteins (Sara and Sleytr, 1996), porphyrins, nucleotide bases, and aromatic ring hydrocarbons.

Layer-By-Layer Deposition and Multilayer Polyelectrolyte Deposition

Layer-by-layer (L-b-L) deposition of thin films, and the most common variant of this method, multilayer polyelectrolyte adsorption, has become an important strategy for the surface modification of biomaterials (Decher, 1996; Ariga et al., 2007). For L-b-L surface treatment, a molecule (or polymer or protein) is chosen that adsorbs strong to the substrate (adsorbate 1). Then the substrate is rinsed (retaining adsorbate 1), and dipped in a solution of a molecule that interacts strongly with adsorbate 1 (adsorbate 2). After rinsing, the surface layer is again dipped in a solution of adsorbate 1. Absorbate 1, adsorbate 2, and the rinsing step are alternated until the coating has the desired multilayer thickness (Fig. 1.4.2.9). Commonly, the substrate has a fixed positive or negative charge, permitting multilayers of polyanions and polycations. The rinse step is important for the removal of any unadsorbed polyions, as well as for removal of

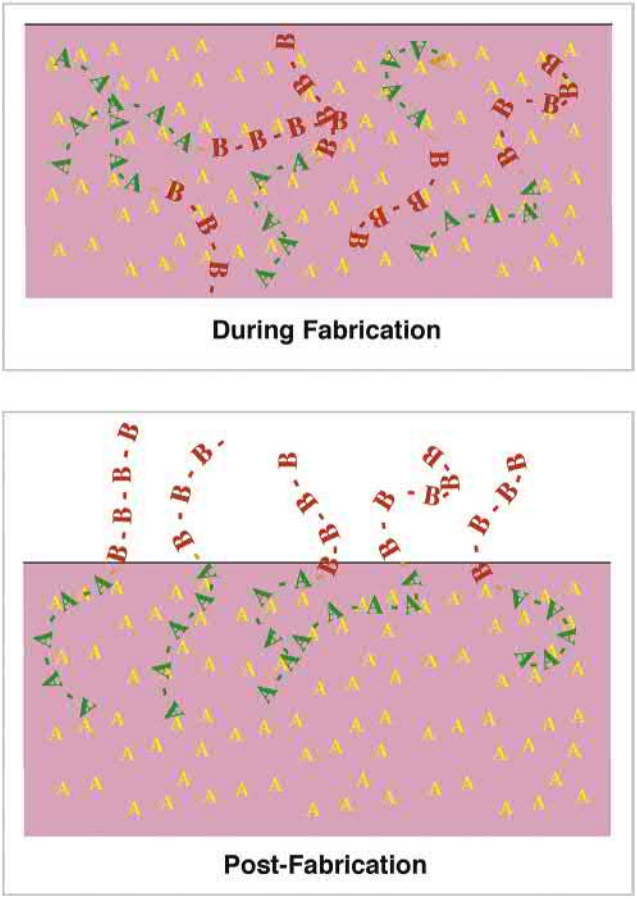


• **Figure 1.4.2.9** Layer-by-layer deposition of a multilayer surface coating. A series of adsorption-rinse steps lead to a multilayer surface deposition: (1) the "blue" compound is adsorbed to the substrate; (2) the adsorbed layer is rinsed in solvent (frequently water) to remove weakly adherent material; (3) the "pink" compound is adsorbed to the blue layer on the substrate; (4) the adsorbed layer is rinsed in solvent to remove weakly adherent material; (5) the "blue" compound is adsorbed to the "pink" adsorbed layer; (6) the adsorbed layer is rinsed in solvent to remove weakly adherent material; (7) the "pink" compound is adsorbed to the blue layer; (8) this process continues to build as many layers as desired.

the counter-ions released upon formation of each layer of the polyion complex. Some surfaces are intrinsically charged (for example, mica), others can be modified with methods already described in this chapter. Once a thin layer of a charged component absorbs, it will repel additional adsorption of the component of the same charge, thus tightly controlling the layer thickness and uniformity. The outermost layer can be the positively or negatively charged component. This strategy works well with charged biomolecules, for example hyaluronic acid (–) and chitosan (+). Layers formed are durable, and assembly of these multilayer structures is simple. The pH and ionic strength of polyelectrolyte solutions are important process variables. The L-b-L process has been used with interacting layers of proteins, nucleotides, saccharides, nanoparticles, acid–base pairs, and H-bonding pairs. L-b-L has been used to coat surfaces (Hsu et al., 2016), microspheres, nanoparticles (Correa et al., 2016), electrospun scaffolds (Easton et al., 2014) and even living cells (Fukuda et al., 2018; Zeng and Matsusaki, 2019). L-b-L layers can be used as reservoirs to contain drug for release or as rate-limiting diffusion barriers. L-b-L films have been used to treat contact lenses, to improve comfort and retard biofilm build-up.

Surface-Modifying Additives

Specifically designed and synthesized surface-active compositions can be added in low concentrations to a material during fabrication, and will spontaneously rise to and dominate the surface (Ward, 1989; Wen et al., 1997). These surface-modifying additives (SMAs) are well-known for both organic and inorganic systems. A driving force to minimize the interfacial energy leads to the concentration of the SMA at the surface after blending homogeneously with a material. For efficient



• **Figure 1.4.2.10** A block copolymer surface-modifying additive comprised of an "A" block and a "B" block is blended into a support polymer (the bulk) with a composition similar to "A" block. During fabrication, the block copolymer is randomly distributed throughout the support polymer. After curing or annealing, the "A" block anchors the surface-modifying additive into the support, while the low-energy "B" block migrates to the air–polymer interface.

surface concentration, two factors must be considered. First, the magnitude of interfacial energy difference between the system without the additive and the same system with the SMA at the surface will determine the driving force leading to an SMA-dominated surface. Second, the molecular mobility of the bulk material and the SMA additive molecules within the bulk will determine the rate at which the SMA reaches the surface or if it will get there at all. An additional concern is the durability and stability of the SMA at the surface.

A typical SMA designed to alter the surface properties of a polymeric material will be a relatively low-molecular-weight diblock or triblock copolymer (see Chapter 1.3.2). The "A" block will be soluble in, or compatible with, the bulk material into which the SMA is being added. The "B" block will be incompatible with the bulk material and will have lower surface energy. Thus, the A block will anchor the B block into the material to be modified at the interface. This is suggested schematically in Fig. 1.4.2.10. During initial fabrication, the SMA might be distributed uniformly throughout the bulk. After a period for curing or an annealing step, the SMA will migrate to the surface. Low-molecular-weight

endgroups on polymer chains can also provide the driving force to bring the endgroup to the surface.

As an example, an SMA for a polyurethane might have a low-molecular-weight polyurethane "A" block and a poly(dimethyl siloxane) (PDMS) "B" block. The PDMS component on the surface may confer improved blood compatibility to the polyurethane. The "A" block will anchor the SMA in the polyurethane bulk (the polyurethane "A" block should be reasonably compatible with the bulk polyurethane), while the low surface energy, highly flexible, silicone "B" block will be exposed at the air surface to lower the interfacial energy (note that air is "hydrophobic"). The "A" block anchor should confer stability to this system. However, consider that if the system is placed in an aqueous environment, a low surface energy polymer (the "B" block) is now in contact with water—a high interfacial energy situation. If the system, after fabrication, still exhibits sufficient chain mobility, it might phase-invert to bring the bulk polyurethane or the "A" block to the surface. Unless the system is specifically engineered to do such a surface phase reversal, this inversion is undesirable. Proper choice of the bulk polymer and the "A" block can impede surface phase inversion.

An example of a polymer additive that was developed by 3M specifically to take advantage of this surface chemical inversion phenomenon is a stain inhibitor for fabric. Although not intended as a biomaterial, it illustrates design principles for this type of system. The compound has three "arms." A fluoropolymer arm, the lowest energy component, resides at the fabric surface in air. Fluoropolymers and hydrocarbons (typical stains) do not mix, so hydrocarbons are repelled. A second arm of hydrophilic poly(ethylene oxide) will come to the surface in water, and assist with the washing out of any material on the surface. Finally, a third arm of hydrocarbon anchors this additive into the fabric.

Many SMAs for inorganic systems are known. For example, very small quantities of nickel will completely alter the structure of a silicon (111) surface (Wilson and Chiang, 1987). Copper or silver will accumulate at the surface of gold alloys (Tanaka et al., 1988). Also, in stainless steels, chromium will concentrate (as the oxide) at the surface, imparting corrosion resistance.

There are a number of additives that spontaneously surface-concentrate, but are not necessarily designed as SMAs. A few examples for polymers include PDMS, some extrusion lubricants (Ratner, 1983), and some UV stabilizers (Tyler et al., 1992). The presence of such additives at the surface of a polymer may be unplanned, and they will not necessarily form stable, durable surface layers. However, they can significantly contribute (either positively or negatively) to the bioresponse to the surface.

Conversion Coatings

Conversion coatings modify the surface of a metal into a dense oxide-rich layer that imparts corrosion protection (Sørensen et al., 2009), enhanced adhesivity, altered appearance (e.g., color), and sometimes lubricity to the metal. For example, steel is frequently phosphated (treated with phosphoric acid) or chromated (treated with chromic acid). Aluminum is electrochemically anodized in chromic, oxalic, or sulfuric acid electrolytes. Electrochemical anodization may also be useful for surface modifying titanium and Ti–Al alloys (Kasemo and Lausmaa, 1985; Bardos, 1990).

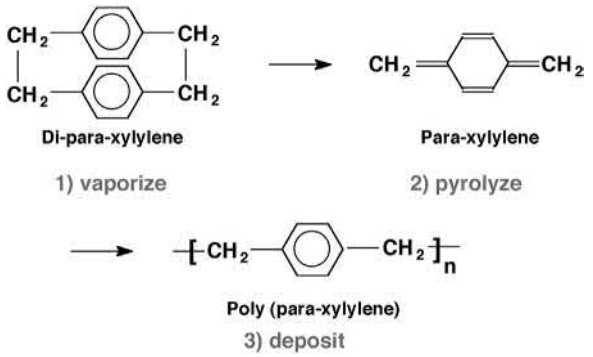
The conversion of metallic surfaces to "oxide-like," electrochemically passive states is a common practice for base metal alloy systems used as biomaterials. Standard and recommended techniques have been published (e.g., ASTM F4-86), and are relevant for most musculoskeletal load-bearing surgical implant devices. The background literature supporting these surface passivation technologies has been summarized (von Recum, 1986).

Base metal alloy systems, in general, are subject to electrochemical corrosion ($M * M^{+} + e^{-}$) within saline environments. The rate of this corrosion process is reduced 10^3–10^6 times by the presence of a dense, uniform, minimally conductive, relatively inert oxide surface. For many metallic devices, exposure to a mineral acid (e.g., nitric acid in water) for times up to 30 min will provide a passivated surface. Plasma-enhanced surface passivation of metals, laser surface treatments, and mechanical treatments (e.g., "shot peening") can also impart many of these characteristics to metallic systems.

The reason that many of these surface modifications are called "oxide-like" is that the structure is complex, including OH, H, and subgroups that may or may not be crystalline. Since most passive surfaces are thin films (5–500 nm), and are transparent or metallic in color, the surface appears similar before and after passivation. Further details on surfaces of this type can be found in Chapters 1.2.4, 1.3.2E and 2.4.4.

Parylene Coating

Parylene (para-xylylene) coatings occupy a unique niche in the surface modification literature, because of their wide application to biomedical devices and the good quality of the thin-film coatings formed (Loeb et al., 1977a; Nichols et al., 1984; Kim and Meng, 2016). The deposition method is also unique and involves the simultaneous evaporation, pyrolysis, deposition, and polymerization of the monomer, di-para-xylylene (DPX), according to the following reaction:



The DPX monomer is vaporized at 175°C and 1 torr, pyrolyzed at 700°C and 0.5 torr, and finally deposited on a substrate at 25°C and 0.1 torr. The coating has excellent

electrical insulation and moisture barrier properties, and has been used for protection of implant electrodes (Loeb et al., 1977b; Nichols et al., 1984) and implanted electronic circuitry (Spivack and Ferrante, 1969). A parylene coating has been used on stainless steel cardiovascular stents between the metal and a drug-eluting polymer layer (see Chapter 2.5.2B).

Laser Methods

Lasers can rapidly and specifically induce surface changes (roughness, crystallinity, chemistry) in organic and inorganic materials (Picraux and Pope, 1984; Dekumbis, 1987; Chrisey et al., 2003). The advantages of using lasers for such modifications are precise control of the frequency of the light, the wide range of frequencies available, the high energy density, the ability to focus and raster the light, the possibilities for using both heat and specific excitation to effect change, and the ability to pulse the source and control reaction time. Lasers commonly used for surface modification include ruby, neodymium:yttrium aluminum garnet (Nd:YAG), argon, argon-fluoride eximer, and CO_2. Treatments are pulsed (nanosecond to picoseconds pulse times) and continuous wave (CW), with interaction times often less than 1 ms. Laser-induced surface alterations include annealing, etching, deposition, and polymerization. Polymers, metals, ceramics, and even tooth dentin have been effectively surface modified using laser energy. The major considerations in designing a laser surface treatment include the absorption (coupling) between the laser energy and the material, the penetration depth of the laser energy into the material, the interfacial reflection and scattering, and heating induced by the laser.

Hundreds of papers have been published on laser surface modification. Examples include: (1) an Nd:YAG laser was used to treat titanium implants permitting improved hydroxyapatite nucleation and more rapid integration into bone (Faeda et al., 2009); (2) laser irradiation at 810 nm of silicone rubber induced a "lotus leaf-like" texture that imparted superhydrophobic properties to the silicone polymer (Yoon et al., 2008); (3) eximer laser irradiation at 193 nm permitted fine spatial patterning of polystyrene for improved protein adsorption and cell interactions (Pfleging et al., 2009).

Patterning

Essentially all of the surface modification methods described in this chapter can be applied to biomaterial surfaces, either as a uniform surface treatment or as patterns on the surface with length scales of millimeters, microns, or even nanometers. There are many options to pattern biomaterial surfaces. These include ion beam etching, electron beam lithography, laser methods, inkjet printers, and stochastic patterns made by phase separation of two components (Takahara et al., 2000). Chapter 1.4.5 elaborates on methods to pattern biomaterials.

Conclusions

Surface modifications are widely applied to modulate or enhance the biointeractions of biomedical devices and improve other aspects of performance. Surface modification is used in the laboratory setting, and also for the treatment of medical devices used in the clinic. Since a medical device may already have appropriate physical properties and be well-understood in the clinic, surface modification provides a means to alter only the biointeractions of the device without the need for redesign, retooling for manufacture, and retraining of medical personnel.

Introduction

"Nonfouling" surfaces (NFSs) refer to surfaces that resist the adsorption of proteins and/or adhesion of cells. They are also loosely referred to as protein-resistant surfaces and "stealth" surfaces. It is generally acknowledged that surfaces that strongly adsorb proteins will generally bind cells, and that surfaces that resist protein adsorption will also resist cell adhesion. It is also generally recognized that hydrophilic surfaces are more likely to resist protein adsorption, and that hydrophobic surfaces will usually adsorb a monolayer of tightly adsorbed protein. Exceptions to these generalizations exist but, overall, they are accurate statements. Further details on protein adsorption can be found in Chapter 2.1.2.

Given that proteins have a strong tendency to adsorb to almost all surfaces, how might NFSs work to inhibit such adsorption? Although there are many potential mechanisms for action, most NFSs seem to have strong interactions with water. This water–polymer interaction highly hydrates and expands surface hydrophilic polymer chains. Also, the NFSs bind water tightly, and this water shield separates the proteins from the material of the surface. These mechanisms will be elaborated on later.

An important area for NFSs focuses on bacterial biofilms (see Chapter 2.2.8). Bacteria are believed to adhere to surfaces via a "conditioning film" of organic molecules that adsorbs first to the surface. The bacteria stick to this conditioning film and begin to exude a gelatinous slime layer (the biofilm) that aids in their protection from external agents (for example, antibiotics) (Fig. 1.4.3A.1). Such layers are particularly troublesome in devices such as urinary catheters and endotracheal tubes. However, they also form on vascular grafts, hip joint prostheses, heart valves, and other long-term implants, where they can stimulate significant inflammatory reaction to the infected device. If the conditioning film can be inhibited, bacterial adhesion and biofilm formation can also be reduced. NFSs offer this possibility.

NFSs have medical and biotechnology uses as blood-compatible materials (where they may resist fibrinogen adsorption and platelet attachment), implanted devices (where they may reduce the foreign-body reaction and simplify device removal), biosensors (where they may minimize nonspecific protein adsorption and maximize specific binding), urinary catheters, affinity separation processes, microchannel flow devices, intravenous syringes and tubing, and nonmedical uses such as biofouling-resistant heat exchangers and ship hulls. It is important to note that many of these applications involve in vivo implants or extracorporeal devices, while others involve in vitro diagnostic assays, sensors, and affinity separation processes. As well as having considerable medical and economic importance, all these applications are closely related to an important phenomenon in biomaterials science: protein adsorption. Hence NFSs have been the subject of many investigations. Aspects of NFSs are addressed in many other chapters of this textbook, including the chapters on water at interfaces (Chapter 1.2.5), surface modification (Chapter 1.4.2), and protein adsorption (Chapter 2.1.2).

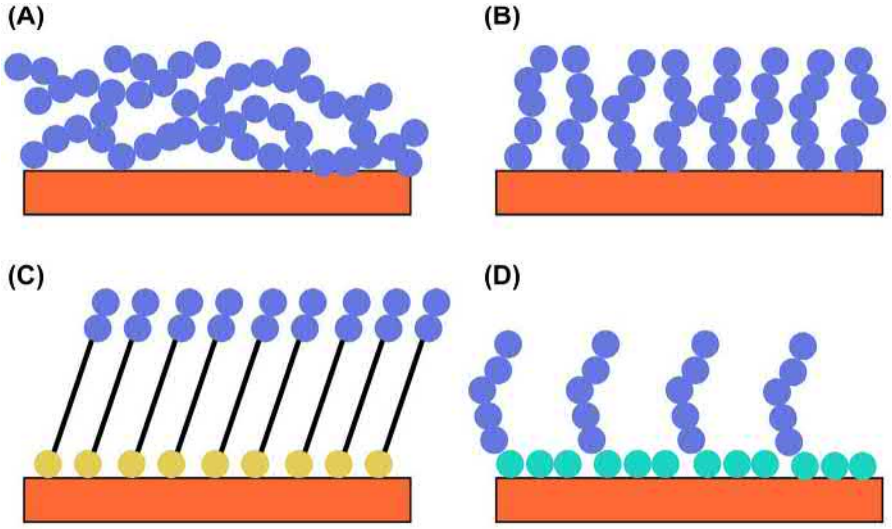
• **Figure 1.4.3A.1** Several distinct processes govern biofilm formation (Bryers and Ratner, 2004).



• **Figure 1.4.3A.2** Four surfaces that can show nonfouling behavior. The *blue dot* represents a nonfouling chemical moiety such as $(CH_2CH_2O)_n$. (A) Cross-linked network of long, polymeric chains; (B) polymer brushes grown from the surface; (C) oligo-nonfouling headgroups on a self-assembled monolayer (the *yellow dot* is the anchor group such as a thiol); (D) surfactant or copolymer adsorbed to the surface. The hydrophobic tails are represented by *turquoise dots*.

The significant portion of the literature on NFSs focuses on surfaces containing the relatively simple polymer poly(ethylene glycol) (PEG):

$$-(CH_2CH_2O)_n-$$

When n is in the range 15–3500 (molecular weights of approximately 400–100,000), the PEG designation is used. When molecular weights are greater than 100,000, the molecule is commonly referred to as poly(ethylene oxide). When n is in the range 2–15, the term oligo(ethylene glycol) (OEG) is often used. Other natural and synthetic polymers besides PEG show nonfouling behavior, and they will also be discussed in this chapter. Fig. 1.4.3A.2 schematically illustrates types of surfaces that show nonfouling properties.

NFSs are important in medical devices where they may inhibit bacterial colonization and blood cell adhesion. They are also valuable for ship hulls where they prevent marine organism build-up, and heat exchangers where they reduce biofilm formation. For further reading, see Jiang and Cao (2010).

Background and Mechanism

The published literature on protein and cell interactions with biomaterial surfaces has grown significantly in the past 40 years, and the following concepts have emerged:

- It is well established that hydrophobic surfaces have a strong tendency to adsorb proteins, often irreversibly (Hoffman, 1986; Horbett and Brash, 1987, 1995). The driving force for this action is most likely the unfolding of the protein on the surface, accompanied by release of many bound water molecules from the solid surface at the interface (see Chapter 1.2.5), leading to a large entropy gain for the system (Hoffman, 1999). Note that adsorbed proteins can be displaced (or "exchanged") from the surface by solution-phase proteins (Brash et al., 1974).
- It is also well known that, at low ionic strengths, cationic proteins bind to anionic surfaces and anionic proteins bind to cationic surfaces (Horbett and Hoffman, 1975; Bohnert et al., 1988; Hoffman, 1999). The major

thermodynamic driving force for these actions is a combination of ion–ion coulombic interactions, accompanied by an entropy gain due to the release of counter-ions along with their bound water molecules. However, these interactions are diminished under physiologic conditions by shielding of the protein ionic groups at an ionic strength of 0.15 N (Horbett and Hoffman, 1975). Still, lysozyme, a highly charged cationic protein at physiologic pH, strongly binds to hydrogel contact lenses containing anionic monomers (see Bohnert et al., 1988, and Chapter 2.5.6).

- It has been a common observation that proteins tend to adsorb in monolayers, i.e., proteins do not adsorb nonspecifically onto their own monolayers (Horbett, 1993). This is probably due to retention of hydration water by the adsorbed protein molecules, preventing close interactions of the protein molecules in solution with the adsorbed protein molecules. In fact, adsorbed protein films are, in themselves, reasonable NFSs with regard to other proteins (but not necessarily to cells). For example, albumin or casein is often used as a blocking agent to reduce nonspecific protein adsorption.
- The mechanism of protein resistance by the polymeric PEG surfaces may be due to a combination of factors, including the resistance of the PEG molecule to release both bound and free water from within the hydrated coil (called "osmotic repulsion") (Gombotz et al., 1991; Antonsen and Hoffman, 1992; Heuberger et al., 2005) plus the resistance of the polymer coil to compression due to its desire to retain the more expanded volume of a random coil (called "entropic repulsion" or "elastic network" resistance) (Jeon et al., 1991). Surface hydration often plays a key role, as conformational flexibility will strengthen, but is not required to achieve NFSs (Chen et al., 2006).
- The surface-packing density of the nonfouling groups/polymers on a surface is recognized as another crucial factor that affects protein adsorption. Both molecular simulation (Zheng et al., 2004) and experimental (Li et al., 2007) studies of OEG self-assembled monolayers (SAMs) showed that there is a correlation between OEG surface density and its resistance to protein adsorption.
- It has been realized that protein solution concentration and complexity also determine protein adsorption on NFSs. Although some NFSs (e.g., OEG SAMs) resist nonspecific protein adsorption in a single protein solution or 10% blood serum, these surfaces may fail when contacting biologically complex media (e.g., whole blood or undiluted blood plasma or serum). Surfaces consisting of long nonfouling polymers improve nonfouling behavior due to the high surface-packing density of nonfouling groups (Ladd et al., 2008).

The thermodynamic principles governing the adsorption of proteins onto surfaces involve a number of enthalpic and entropic terms favoring or resisting adsorption. These terms are summarized in Table 1.4.3A.1. The major factors favoring adsorption will be the entropic gain of released water and the enthalpy loss due to cation–anion attractive interactions between ionic protein groups and surface groups. The major factors favoring resistance to protein adsorption will be the retention of bound water in the case of an immobilized hydrophilic polymer along with the entropic and osmotic repulsion of the polymer coils.

TABLE 1.4.3A.1 Thermodynamics of Protein Adsorption

Favoring Adsorption	
ΔH_{ads}	– Van der Waals interactions (short range)
	– Ion–ion interactions (long range)
ΔS_{ads}	+ Desorption of many H_2O's
	+ Unfolding of protein
Opposing Adsorption	
ΔH_{ads}	+ Dehydration (interface between surface and protein)
	+ Unfolding of protein
	+ Chain compression (PEG)
ΔS_{ads}	– Adsorption of protein
	– Protein hydrophobic exposure
	– Chain compression (PEG)
	– Osmotic repulsion (PEG)

PEG, Poly(ethylene glycol).

Observations on SAMs (described in Chapter 1.4.2) with different head groups have been particularly important in the understanding of NFSs. OEG SAMs prepared to explore NFSs were formed on gold surfaces with a set of molecules based on this alkyl thiol structure: $HS(CH_2)_{11}(OCH_2CH_2)_nOH$. The OEG chain length, n, was 0, 1, 2, 4, 6, or 17. OEGs with larger n (more ethylene glycol units) were more protein resistant, but the minimum of $n = 3$ is needed. The surface packing density of these OEG-thiol units needed to achieve nonfouling behavior decreased with increasing n (Prime and Whitesides, 1993). Thus the improved nonfouling behavior of this surface can be attributed to both chain flexibility and the ability of ethylene glycol units to interact with water. Thus protein resistance by OEG-coated surfaces may be related to a "cooperativity" between the hydrated, short OEG chains in the "plane of the surface," wherein the OEG chains interact together to bind water to the surface in a manner analogous to the hydrated coil and its osmotic repulsion, as previously described. While hydration is the primary factor to achieve NFSs, chain flexibility, although helpful, is not necessary when hydration is strong enough. The excellent nonfouling ability of mixed SAMs containing charged pairs was achieved due to their strong electrostatically induced hydration (Chen et al., 2006) although the lattice structure of the mixed SAMs (or the absence of chain flexibility) was observed from atomic force microscopy experiments.

Four common properties shared by many nonfouling groups were summarized after a survey of structure–property

relationships of surfaces that resist protein adsorption (Ostuni et al., 2001): hydrophilic, electrically neutral, and containing groups that are hydrogen-bond acceptors, but not hydrogen-bond donors. While the first three factors are well recognized, hydrogen-bond donors are more complicated. Hydroxyl-terminated PEG surfaces (Li et al., 2007) and mannitol (Luk et al., 2000) with abundant hydrogen-bond donors or hydroxyl groups exhibit excellent nonfouling behavior. However, cellulose surfaces with abundant hydroxyl groups generated high complement activation (Poppelaars et al., 2018).

The packing density of nonfouling groups on surfaces is clearly an important factor in preparing NFSs. Nevertheless, one may conclude that the one common factor connecting all NFSs is their resistance to the release of bound water molecules from the surface. This argument is supported by neutron reflectivity measurements by Skoda et al. (2009), where they found a depletion of protein concentration around 4–5 nm above an OEG surface that might be attributable to a tightly bound water layer interfering with the protein approach to the actual surface. Also, direct measurements by D_2O exchange and sum frequency generation (see Chapter 1.2.4) of water organization at the interface of nonfouling and fouling SAMs demonstrate that NFSs lead to a more bound, organized water (Stein et al., 2009). Interfacial water may be reorganized both by hydrophobic groups and by hydrophilic interactions. In the latter case, the water may be H-bonded to neutral polar groups, such as hydroxyl (–OH) or ether (–C–O–C–) groups, or it may be polarized by ionic groups, such as COO– or $–NH_3^+$. The more profound molecular reorganizations of water seen in NFSs are associated with certain hydrophilic surfaces. The overall conclusion from all of these observations is that resistance to protein adsorption at biomaterial interfaces is directly related to retention by interfacial groups of their bound water molecules of hydration.

The significance of protein solution concentration for surface protein resistance requires further discussion. In relatively dilute protein solutions, such as are used in diagnostic assays and sometimes in cell culture, all of the surfaces described so far will demonstrate nonfouling behavior. However, at protein concentrations similar to that in the bloodstream or in body fluids, many of these surfaces no longer appear nonfouling. The surfaces that exhibit nonfouling behavior at higher protein concentrations are comprised of longer hydrophilic chains with high conformational freedom (Zhang et al., 2008; Ma et al., 2004). Surfaces comprised of short oligo units of nonfouling chemistries probably function by tightly binding water. It may be that at high solution protein content, the protein molecules compete for the bound surface water, and the nonfouling effect vanishes. On the other hand, when longer, flexible chains are present, more bound water molecules along with the entropic repulsion effect described earlier permit these surfaces to remain free of adsorbed protein, as long as the hydrophilic polymer surface density is high enough.

TABLE 1.4.3A.2 "Nonfouling" Materials

Nonionic Synthetic Materials

- PEG polymers and surfactants
- Poly[poly(ethylene glycol) methyl ether methacrylate]
- Poly(2-methoxyethyl acrylate)
- Poly(2-hydroxyethyl methacrylate)
- Poly[*N*-(2-hydroxypropyl) methacrylamide]
- Polyacrylamide and poly(*N*-methyl acrylamide)
- Poly(*N*-vinyl 2-pyrrolidone)
- Poly(2-methyl-2-oxazoline)
- Gas discharge-deposited coatings (especially from PEG-like monomers)

Zwitterionic Synthetic Materials

- Poly(2-methacryloyloxyethyl phosphorylcholine)
- Poly(sulfobetaine)
- Poly(carboxybetaine)
- Mixed-charge synthetic polymers or polyampholytes
- Amino acid-derived zwitterionic polymers

Natural Hydrophilic Materials

- Passivating proteins (e.g., albumin and casein)
- Polysaccharides (e.g., hyaluronic acid)
- Liposaccharides
- Phospholipid bilayers
- Glycoproteins (e.g., mucin)

PEG, Poly(ethylene glycol).

Resistance to protein adsorption at biomaterial interfaces is directly related to resistance of interfacial groups to the release of their bound waters of hydration. For further reading, see Antonsen and Hoffman (1992), Heuberger et al. (2005), and Shao and Jiang (2015).

Nonfouling Materials and Methods

Based on these conclusions, it is obvious why the most common materials used to reduce protein adsorption and cell adhesion on surfaces have been those that strongly interact with water. Some commonly used nonfouling materials are listed in Table 1.4.3A.2.

As discussed earlier, the nonfouling property of the materials is tightly correlated with a hydration layer near the surface, which forms a physical and energetic barrier to prevent protein adsorption onto the surface. Water molecules residing on and/or penetrating into nonfouling materials can be classified into two types of "surface-bound" waters: formed by hydrogen bonding or ionic solvation. Thus nonfouling materials may also be classified into two types correspondingly. The first type of material is neutral and hydrophilic, interacting with water via hydrogen bonding. These materials consist of hydroxyl (–OH), ether (–C–O–C–), or amide (–CONH–) groups. Nonionic synthetic materials listed in Table 1.4.3A.2 belong to this type. Some natural hydrophilic materials, such as polysaccharides and liposaccharides, also belong to this type. Another class of nonfouling materials is characterized by their ionic nature, interacting with water via electrostatically induced hydration. Materials with ionic solvation can

hold water even stronger than those with hydrogen bonding. However, since negatively charged materials adsorb positively charged proteins and vice versa via electrostatic interactions, only those zwitterionic materials with overall neutral charge demonstrate strong resistance to nonspecific protein adsorption (Chen et al., 2005; Kane et al., 2003; Chen et al., 2009; Shao et al., 2015). While zwitterionic materials containing both positively and negatively charged groups in the same unit exhibit excellent nonfouling properties, these oppositely charged groups do not need to be in the same molecule. Surfaces prepared with mixed-charge SAMs or copolymers demonstrate strong resistance to nonspecific protein adsorption when positively and negatively charged components are uniformly mixed with a ratio of 1:1 (Kane et al., 2003; Chen et al., 2009). Interestingly, abundant glutamic acid (E) and lysine (K) residues were found to be randomly distributed on the surfaces of proteins and molecular chaperones, which form mixed-charge surfaces and contribute to the reduction of nonspecific interactions (White et al., 2012).

To achieve NFSs of biomaterials or medical devices, one can coat nonfouling materials discussed previously via various chemical or physical approaches. These approaches can be generally classified into two categories as "graft-to-surface" and "graft-from-surface." In the so-called "graft-to-surface" approach, nonfouling materials adsorb or bind onto a surface out of a solution. In the "graft-from-surface" approach, nonfouling polymer brushes are initiated and propagated from a surface. The "graft-to-surface" approach is easier to perform, but requires extensive optimization to achieve high surface-packing densities. On the other hand, the "graft-from-surface" approach is easier to achieve high surface-packing densities, but they often require specific surface pretreatments and sophisticated chemistries in controlled environments. Examples of some of these strategies are:

- Physical adsorption of surfactants or other surface-active molecules that are coupled to nonfouling moieties. Examples include: adsorption of poly(ethylene glycol-propylene glycol) block copolymers (Lee et al., 1989); surface attachment of biomimetic analogs of muscle adhesive peptides coupled to PEG chains (Dalsin et al., 2003); and surface coating by zwitterionic block copolymers consisting of poly(propylene oxide) and poly(sulfobetaine methacrylate) (Chang et al., 2006).
- Immobilization of nonfouling polymers onto surfaces via covalent bonds. Examples include: nonfouling surfactants such as Pluronic polyols used to covalently bind polymer surfaces in gas discharge (Sheu et al., 1993); photoreactive polymers bearing zwitterionic phosphorylcholine and benzophenone groups on the side chain immobilized on polyolefin surfaces via ultraviolet irradiation to form antifouling coatings (Lin et al., 2015); and poly(carboxybetaine) hydrogel coated onto multiple surfaces via superglue to fabricate durable NFSs (Wang et al., 2017).
- Grafting nonfouling polymers from surfaces via different chemistries. Examples include: fouling resistant brushes of poly[poly(ethylene glycol) methyl ether methacrylate] or poly(carboxybetaine) chains grown from surfaces via atom transfer radical polymerization (Ma et al., 2004; Ladd et al., 2008); NFSs prepared on polydimethylsiloxane with poly(2-methacryloyloxyethyl phosphorylcholine) grafted via surface-initiated photoinduced radical polymerization (Goda et al., 2006); and substrate-independent surface modification for controlled protein adsorption achieved by chemical vapor deposition (Rong Yang et al., 2012).

A variety of methods have been reported to fabricate NFSs on biomaterial surfaces. However, it is hard to coat all surfaces via one universal approach due to huge differences among material surfaces in terms of physical and chemical properties. The coating approach critically affects the grafting density, defects, and durability of the resulting NFSs. An appropriate approach needs to be chosen for a specific material surface to achieve the optimum antiprotein adsorption performance.

While PEG and other hydrophilic materials achieve hydration via hydrogen bonding, zwitterionic materials, such as poly(2-methacryloyloxyethyl phosphorylcholine), poly(sulfobetaine), and poly(carboxybetaine), can bind water molecules even more strongly via electrostatically induced hydration. As a result of strong hydration, polyzwitterions demonstrate superhydrophilicity and strong repulsion to nonspecific protein adsorption. Some examples of the applications of polyzwitterions include: poly(2-methacryloyloxyethyl phosphorylcholine) used for medical devices, such as contact lenses and artificial hip joint implants (Lewis, 2000; Ishihara, 2015); poly(sulfobetaine) applied to coat membranes to improve blood compatibility (Chang et al., 2011); and poly(carboxybetaine) used as an implant material to prevent foreign body reaction (Zhang et al., 2013).

Conclusions and Perspectives

It is remarkable how many different surface compositions appear to be nonfouling although the majority of surfaces used in medicine and biology adsorb protein. Although the unifying mechanisms require further studies, it appears that the major factor favoring resistance to protein adsorption is the retention of bound water by the surface molecules. Entropic and osmotic repulsion of the polymer coils also play an important role. In addition to the nonfouling material itself, surface coating density also plays a key role when the nonfouling material is attached to a surface.

Here are a few considerations for future perspectives. First, little is known about how long an NFS will remain nonfouling in vivo. Longevity and stability for nonfouling biomaterials remain an uncharted frontier. Also, it has been pointed out that susceptibility of PEGs to oxidative damage may reduce their utility and longevity as nonfouling surfaces in real-world situations (Kane et al., 2003; Li et al., 2007). Second, resistance to bacterial adhesion and biofilm formation remains an unsolved problem. It should be noted that bacteria tend to adhere to and colonize almost any surface, including many protein-resistant NFSs. The best NFSs can often provide acute resistance to or delay biofilm build-up better than others (Johnston et al., 1997). Defects (e.g., pits and uncoated areas) in NFSs may provide "footholds" for bacteria and cells to begin colonization. A deeper understanding of how to

optimize the surface density and composition of NFSs will lead to improvements in coating quality with fewer microdefects. Strategies that incorporate antimicrobial activities into NFSs may potentially help solve these problems (Cheng et al., 2008; Mi et al., 2014). Third, in addition to bulk materials and surfaces, NFSs are also very important in nanotechnology for nanoparticles (NPs) used in drug delivery and diagnostics. Similar to many bulk surfaces, proteins tend to adsorb on the surfaces of NPs and form protein corona. The protein corona may destabilize NPs, affect surface ligands, increase cellular uptake and trigger immune responses in vivo. Protecting NPs with NFSs could efficiently prolong their blood circulation half-life and increase delivery efficiency. Exploration of NFSs for drug delivery NPs remains an active research topic. Selection of NFSs for drug delivery NPs is challenging due to the complexity of in vivo environments and the immune systems. Although PEG has been the most widely used NFSs for NPs, the development of anti-PEG immunity has brought complications in these applications (Zhang et al., 2016). Alternative nonfouling materials are needed to overcome these challenges.

1.4.3B

Nonthrombogenic Treatments and Strategies

MICHAEL V. SEFTON[1], MAUD B. GORBET[2]

[1]Department of Chemical Engineering and Applied Chemistry, Institute of Biomaterials and Biomedical Engineering, University of Toronto, ON, Canada

[2]Department of Systems Design Engineering, University of Waterloo, ON, Canada

Introduction

This chapter addresses the methods to improve the blood compatibility of biomaterials, the subject of a large body of literature in the biomaterials field and a topic of great importance clinically. To appreciate the contents of this chapter, a familiarity with materials in Chapters 1.4.2, 1.4.4, 2.2.6 and 2.3.5 is expected. A recent set of reviews "The Blood Compatibility Challenge," emphasizes the features of broad agreement and provides commentary on those aspects of the problem that remain in dispute (Sefton et al., 2019; Jaffer and Weitz, 2019; Brash et al., 2019; Gorbet et al., 2019; Maitz et al., 2019). The intent of that set of reviews was to encourage fresh approaches to address this long-standing but as yet unsolved challenge.

Historical

In 1963, Dr. Vincent Gott at the Johns Hopkins University changed the field of biomaterials by failing to reproduce an earlier experiment. He was trying to show that an applied electric field could minimize thrombus formation on a metal surface. He obtained this result, but was somewhat mystified when he discovered that the wire leading to his negative graphite electrode was broken. He soon realized the importance of rinsing his electrode with a common disinfectant (benzalkonium chloride) and heparin prior to implantation. Thus, the first heparinized material was born. Lehninger et al. (1966) at Battelle Memorial Institute in Columbus, Ohio, followed up with better quaternary ammonium compounds, and soon afterward a host of chemical derivatization methods were devised to adapt the original GBH (graphite benzalkonium heparin) method to plastics and other materials. The principles underlying these strategies and others for lowering the thrombogenicity of materials are detailed here with examples.

Criteria for Nonthrombogenicity

Thrombogenicity is defined (Williams, 1987) as the ability of a material to induce or promote the formation of thromboemboli (Box 1.4.3.B.1). Here we are concerned with strategies to lower thrombogenicity, if not actually reduce it to zero, "nonthrombogenicity." Thrombogenicity should be thought of as a rate parameter, since low rates of thrombus or emboli formation are probably tolerable because the fibrinolytic or other clearance systems exist to remove "background" levels of thromboemboli. We are principally concerned with rates of thrombi formation that are sufficient to occlude flowpaths in medical devices (e.g., block the lumen of catheters) or rates of emboli formation that cause downstream problems such as myocardial infarction or transient ischemic attacks. The mechanisms of thrombogenicity are described in Chapter 2.2.6, the methods to measure thrombogenicity are described in Chapter 2.3.5, while the effects of fluid flow on thrombus development and embolization are described in Chapters 2.3.5 and 2.1.6.

Thrombi are produced through aggregation of activated platelets and/or the thrombin-dependent polymerization of fibrinogen into fibrin. Thrombin is directly responsible for fibrin formation but it is also an important agonist of platelet activation. Computational models have been developed to provide a better understanding of the interactions between surface thrombogenicity, variation in flow, and platelet activation (Wu et al., 2017; Tomaiuolo et al., 2014). These novel simulation tools may help in the design of low thrombogenic surfaces as recently highlighted by Wu et al. (2016).

• BOX 1.4.3B.1 Associated Facts: Characterizing Thrombogenicity

Many investigators exploring methods of improving thrombogenicity rely on protein adsorption (especially fibrinogen) and platelet adhesion as surrogate markers of thrombogenicity to demonstrate the success of their modification. Surrogate markers are typically easier, indirect measurements of the potential for thrombus formation. However, these represent a limited assessment of the thrombogenicity of a surface, and imply a causative mechanism of action that is often not warranted. For example, the lack of platelet adhesion does not always correlate with the absence of platelet activation. In vitro and in vivo studies by Hanson et al. (1980), as well as Gemmell et al. (1995, 1997), have demonstrated significant platelet activation in the fluid phase in the absence of platelet adhesion. Many factors contribute to material-induced thrombogenicity (Gorbet and Sefton, 2004), and a limited understanding of the mechanism means that assessing thrombogenicity requires more than looking at surface adsorption and adhesion.

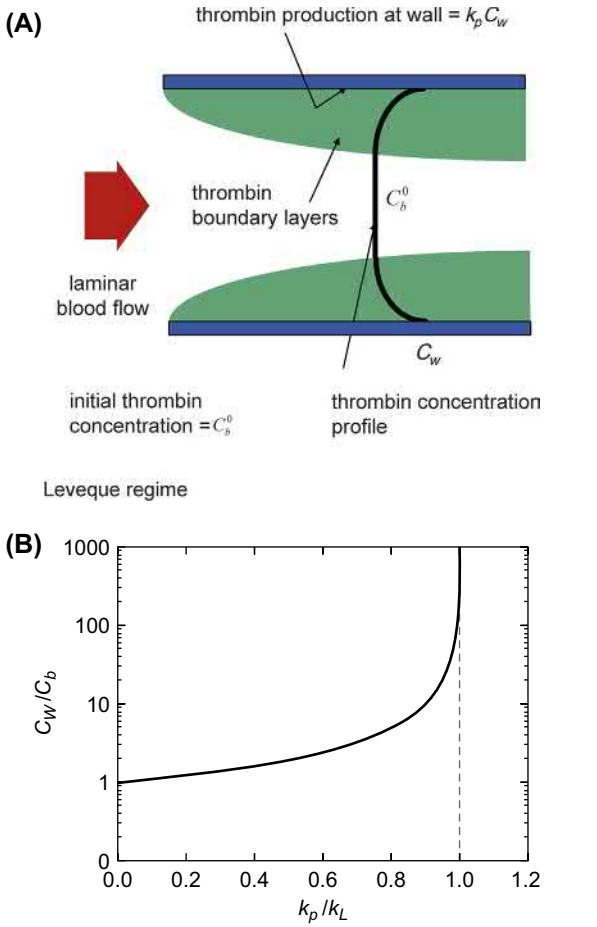
A simple, analytical, model of thrombin generation is illustrated in Fig. 1.4.3B.1A. The variety of mechanisms that lead to thrombin generation are lumped into a single parameter, k_p (cm/s), a rate constant that relates the rate of production of thrombin (per unit area), R_p (g/cm^{2}s), to the thrombin concentration at the surface of a material C_w (g/mL):

$$R_p = k_p C_w \qquad \textbf{(1.4.3B.1)}$$

k_p includes both the procoagulant effect of the material (via clotting factors and platelets) less any coagulation inhibition processes. A material balance (Basmadjian, 1990; Rollason and Sefton, 1992) equating the rate of production at the surface to the rate of transport away from the surface $k_L\,(C_w - C_b)$ for tubes greater than about 0.1 mm in diameter (Leveque region) gives:

$$\frac{C_w}{C_b^0} = \frac{1}{1 - k_p / k_L\,(x)} \qquad \textbf{(1.4.3B.2)}$$

where C_b^0 is the concentration of thrombin at the inlet to a tube. $k_L(x)$ is the local mass transfer coefficient which is infinite at the tube inlet and decreases as one proceeds down the tube. Hence, C_w/C_b^0 increases progressively down the tube (Fig. 1.4.3B.1B). When $k_L = k_p$, C_w becomes infinite and a thrombus is expected. For a simple tube in laminar flow, k_L is in the order of 10^{-3} cm/s, and so k_p must be less than this to avoid a thrombus. Experimental results suggest that k_p is in the order of 10^{-3} for simple materials like polyethylene, but $<10^{-4}$ for heparinized materials (Rollason and Sefton, 1992). According to this model, only such low k_p materials can be expected to minimize thrombin production. This is one of the reasons heparinization and other active methods of inhibiting thrombin formation are so popular as strategies for imparting low thrombogenicity. There are, however, other criteria that must also be met.



• **Figure 1.4.3B.1** (A) Model illustrating thrombin production at the surface of a tube as a balance between auto-accelerative production at the surface and mass transfer away from the wall. (B) Schematic illustration of Eq. (1.4.3B.2) showing the dramatic increase in wall to bulk concentration ratio as the mass transfer coefficient k_L becomes equal to the first-order autocatalytic production constant (k_p). Since k_L decreases with increasing axial position down a tube, increasing k_p/k_L corresponds to increasing x. (Adapted from Rollason, G., Sefton, M.V., 1992. Measurement of the rate of thrombin production in human plasma in contact with different materials. J. Biomed. Mat. Res. 26, 675–693.)

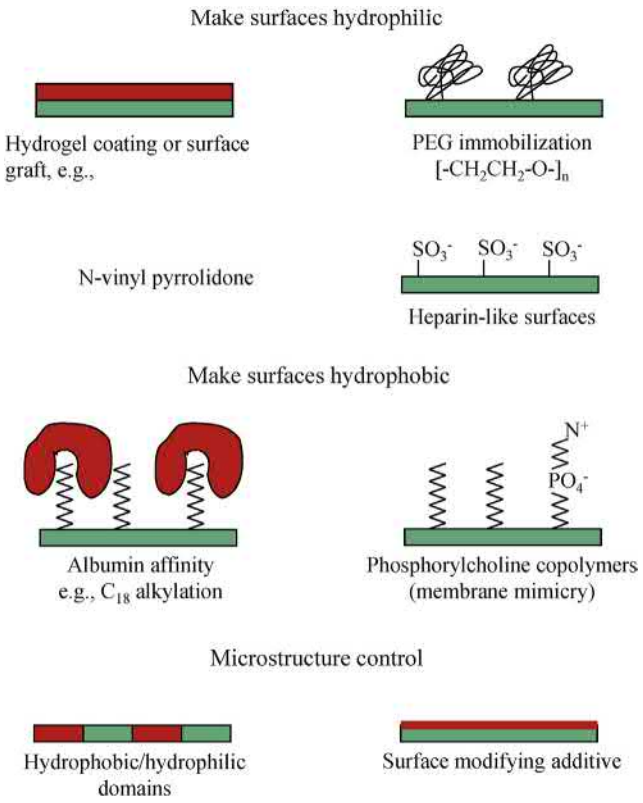
It is also a requirement that platelet interactions with the surface do not lead to thrombosis. To some extent, platelet adhesion is inevitable. Once adherent, platelets change shape and release their granule contents which can activate bulk platelets. While it is intuitive to suggest that a nonthrombogenic surface should not support platelet adhesion it has not, unfortunately, been that simple. While most studies focus on evaluating the platelet compatibility of surfaces by measuring in vitro platelet adhesion, some ex vivo studies (Hanson et al., 1980; Cholakis et al., 1989) have demonstrated that even in the absence of adhesion, platelets can be "consumed." That is, the platelets are activated by the material leading to their premature removal from the circulation (Chapter 2.3.5). This becomes apparent as a significant shortening of platelet lifespan, if not also a decrease in systemic platelet count. Whether this process is initiated by nonadhesive direct contact with the

material or is the result of adherent platelet release, or even the effect of complement activation is currently unknown. Nevertheless, such an observation suggests that low platelet adhesion is not a sufficient criterion of in vivo platelet compatibility. Rather, low thrombogenicity is characterized by both low platelet adhesion and low platelet activation (see Chapter 2.2.6 for a definition of activation); the latter may even be more important than the former. Leukocyte activation (expression of procoagulant activities such as tissue factor or CD11b upregulation; Gorbet and Sefton, 2004) and complement activation may also be key components in thrombogenicity (see Chapters 2.2.4 and 2.2.6), and in the future these too may become critical parameters defining the thrombogenicity of the surface (Gorbet et al., 2019). In an attempt to evaluate more than just platelet adhesion on biomaterials, flow cytometric techniques have been developed to measure bulk (or circulating) activated platelets, platelet microparticles, platelet–leukocyte aggregates, and activated leukocytes (such as C11b upregulation) (Gemmell et al., 1995; Baker et al., 1998; Snyder et al., 2007). It is expected that such assays will result in better correlation between in vitro and ex vivo/in vivo performances.

While blood cells play an important role in material-induced thrombosis, concerns over in-stent thrombosis have renewed the interest in developing biomaterials to support and promote endothelialization. The potential thrombogenicity of these cells on a biomaterial adds another dimension to this topic (McGuigan and Sefton, 2007).

Inert Materials

Much of the effort in biomaterials research over the past 35 years has been directed toward the development of inert materials that do not react with platelets and coagulation factors. As outlined in Fig. 1.4.3B.2, a number of approaches, often conflicting, have been developed. For example, there is still no consensus as to whether a surface should be hydrophilic or hydrophobic. The lack of agreement is largely due to our incomplete understanding of the biological pathways to materials failure and our inability to fully evaluate blood–material responses. In developing materials with lower thrombogenicity, researchers have primarily focused their efforts on modifying the surfaces of existing polymeric materials, like polyurethanes, silicone rubber, and polyethylene. This approach is reasonable, since it is only the surface chemistry of a material that should dictate its biological responses. As illustrated by the following discussion, the full range of surface modification strategies outlined in Chapter 1.4.2 has been used, albeit with limited success. On the other hand, in comparing many plasma-modified surfaces, Sefton et al. (2001) did not identify a modification chemistry that was superior to the base material in terms of platelet or leukocyte activation. Despite the successes in reducing protein and cellular deposits on some materials, a truly nonthrombogenic surface does not yet exist.

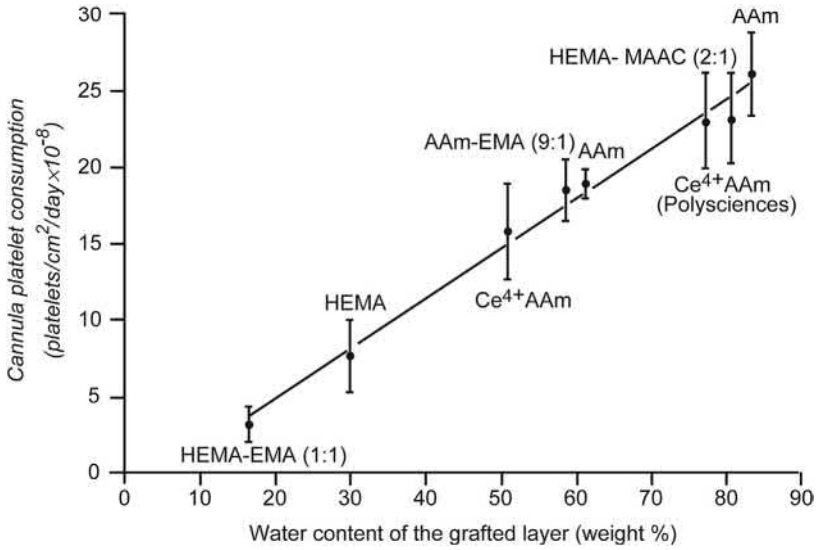


• **Figure 1.4.3B.2** Potential strategies for preparing inert surfaces with low thrombogenicity.

Hydrogels

A popular method to improve the blood compatibility of biomaterials is to increase surface hydrophilicity by incorporating a hydrogel at the surface. All commonly used hydrogels (see Chapter 1.3.2E) that can be cast, chemically cross-linked, or surface-grafted have been used. By definition, hydrogels permit the retention of large amounts of water without dissolution of the polymer itself. This makes them similar to biological tissues, in that they are permeable to small molecules and possess low interfacial tension. It was Andrade who first postulated that since the interfacial free energy between blood and vascular endothelium was near zero, material surfaces which tend to have an interfacial energy of zero should have minimal thrombogenicity (Andrade et al., 1973). Today, considerable experimental evidence supports the claim that materials with minimal interfacial energy, like hydrogels, do not strongly support cell and/or thrombus adhesion. Unfortunately, such generalizations are always flawed by exceptions. A hydrogel (cellulose) used as a dialysis membrane material (Cellophane) is well recognized as being thrombogenic, possibly because it is also a strong activator of the complement system (Chapter 2.2.4). Furthermore, low adhesion (or low protein adsorption) is not the same as low thrombogenicity.

In the early 1980s, a number of polymers were grafted with hydrogel surfaces in an effort to decrease their thrombogenicity. For example, in a large ex vivo study (Hanson et al., 1980), a variety of surface-grafted copolymers were



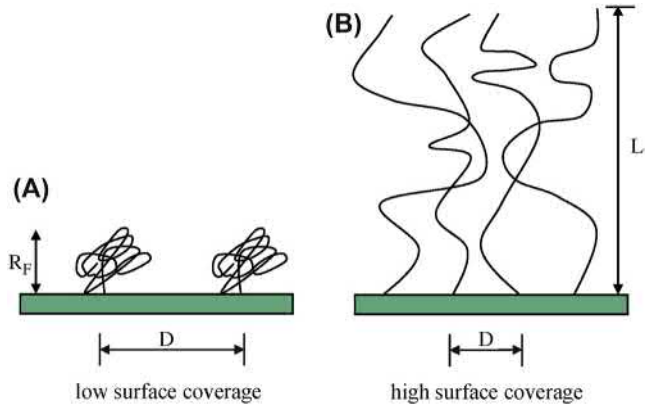
• **Figure 1.4.3B.3** Rate of cannula platelet consumption per unit area (in baboons) is directly related to the graft water content of shunts grafted with eight acrylic and methacrylic polymers and copolymers. *AAm*, acrylamide; *EMA*, ethyl methacrylate; *HEMA*, hydroxyethyl methacrylate; *MAAC*, methacrylic acid. Mean values ± 1 S.E. (From Hanson, S.R., Harker, L.A., Ratner, B.D., Hoffman, A.S., 1980. In vivo evaluation of artificial surfaces with a nonhuman primate model of arterial thrombosis. J. Lab. Clin. Med. 95, 289–304, with permission.)

prepared and evaluated for platelet consumption in a baboon shunt model of arterial thrombogenesis. Although few platelets were found adherent to the graft surface, the higher the water content, the greater the rate at which the graft tubing caused the destruction of the circulating platelets (Fig. 1.4.3B.3). Even though this study concluded that hydrogels did not possess low thrombogenicity, utilization of hydrogels remains a popular approach to lower thrombogenicity. It is likely that platelet consumption will be of concern only in applications with large surface areas. On the other hand, platelet consumption is evidence of platelet activation, and the local (as opposed to systemic) consequences of such activation have yet to be defined.

Rather than radiation grafting of hydrogels onto materials, surfaces can also be simply coated with hydrophilic polymers, such as poly(vinyl pyrrolidone) (PVP). While coating with PVP is intended to increase lubricity and ease catheter insertion, benefits on thrombogenicity (and bacterial adhesion) have also been noted (Francois et al., 1996).

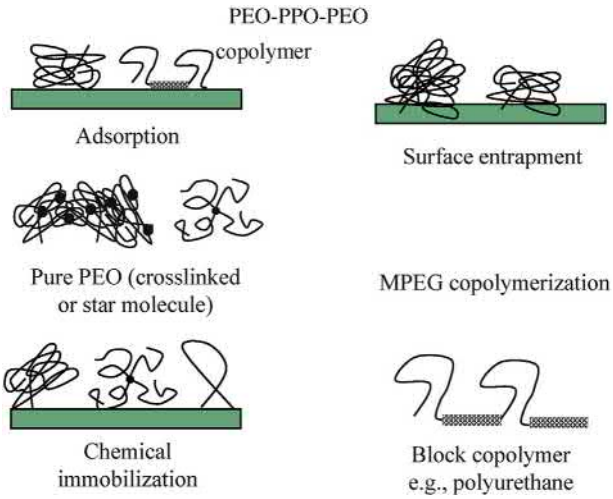
Polyethylene Glycol (PEG) Immobilization

Immobilization of the water-soluble synthetic polymer, polyethylene glycol (PEG, $-CH_2CH_2O-$), is a widely used approach to making a biomaterial surface more protein and cell resistant. It also makes the surface hydrogel-like. This approach was promoted by Edward Merrill, who recognized the lack of hydrogen bond donor sites on the PEG molecule and postulated that such sites might be involved with protein binding (Merrill and Salzman, 1983). A widely recognized theory that helps to explain the nonthrombogenicity of PEG-containing surfaces was presented by Nagaoka et al. (1984). They reasoned that the presence of diffuse

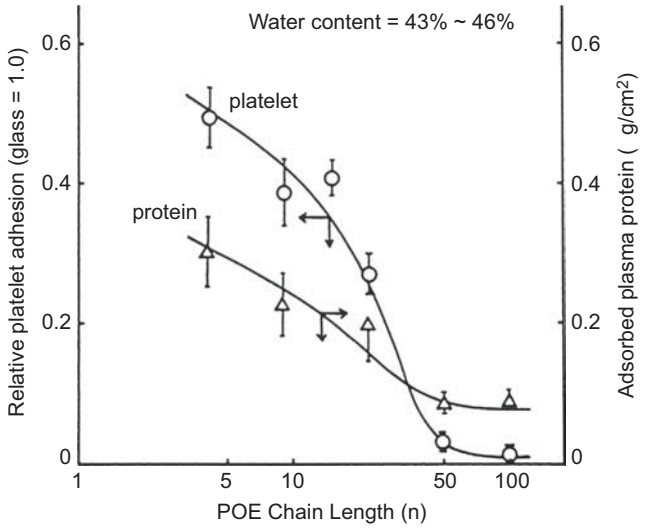


• **Figure 1.4.3B.4** Structure of polyethylene glycol (PEG)-modified surfaces. (A) At low surface coverage (D>>RF), molecules assume conformation and size similar to random coil. (B) At high surface coverage (D<<RF), molecules are more extended, chain-like, and form a dense brush. (Adapted from de Gennes, P.G., 1980. Conformation of polymers attached to an interface. Macromolecules 13, 1069–1075.)

hydrophilic polymers, covering a significant portion of a biomaterial surface, would exert a steric repulsion effect toward blood proteins and cells (Fig. 1.4.3B.4). The dominance of steric repulsion over the van der Waals attractive forces was hypothesized to be dependent on the extension and flexibility of the polymer chain in the bulk solution. The resulting excluded volume effect results from a loss in configurational entropy of the PEG that in turn results from the rise in the local osmotic pressure occurring when PEG chains are compressed when blood elements approach the surface. This effect is dependent on both the chain length (N, monomers/chain), and the surface density of chains (σ, number of chains per unit area). A simple scaling relationship relates these parameters (and a, the monomer size) to



• **Figure 1.4.3B.5** Methods for incorporating polyethylene glycol (PEG) onto the surfaces of materials. *MPEG*, methoxypolyethylene glycol methacrylate; *PEO*, poly(ethylene oxide); *PPO*, poly(propylene oxide).



• **Figure 1.4.3B.6** Effect of PEG (or "POE") chain length (*n*) on the adhesion of platelets (from activated platelet-rich plasma) and adsorption of plasma proteins (from plasma) onto poly(methyl methacrylate co-methoxypolyethylene glycol methacrylate) gels. Mean values and standard deviation are shown. Both protein adsorption and platelet adhesion were measured by total protein analysis. A relative platelet adhesion value of 0.3 corresponded to a scanning electron microscopy (SEM) platelet adhesion density of ~80 platelets/1000 μm^2. (From Nagaoka, S., Mori, Y., Takiuchi, H., Yokota, K., Tanzawa, H., Nishiumi, S., 1984. Interaction between blood components and hydrogels with poly(oxyethylene) chains. In: Shalaby S., Hoffman A.S., Ratner, B.D., Horbett, T.A. (Eds.), Polymers as Biomaterials, Plenum Press, pp. 361–371, with permission.)

the thickness, L, of the polymer layer at the surface, for the case of a good solvent (specifically an athermal solvent), and when the chain density is high (the distance between chains (D) is less than the Flory radius (RF)) (de Gennes, 1980):

$$L \simeq N a \sigma^{1/3} \qquad \textbf{(1.4.3B.3)}$$

Jeon et al. (1991) and Jeon and Andrade (1991), among others, have theoretically modeled protein–surface interactions in the presence of PEG and concluded that steric repulsion by surface-bound PEG chains was largely responsible for the prevention of protein adsorption on PEG-rich surfaces.

As shown in Fig. 1.4.3B.5, a number of approaches have been used to enrich surfaces with PEG. For example, it has been grafted to surfaces via a backbone hydrogel polymer, such as in the preparation of methoxypolyethylene glycol monomethacrylate copolymers (Nagaoka et al., 1984). It has also been covalently bonded directly to substrates via derivatization of its hydroxyl end groups with an active coupling agent or, alternatively, the hydroxyl end groups have been reacted with active coupling agents introduced onto the surface (Desai and Hubbell, 1991a; Chaikof et al., 1992; Tseng and Park, 1992). The commercial availability of a large number of reactive PEG molecules (e.g., amino-PEG, tresyl-PEG, N-hydroxysuccinimidyl-PEG) has greatly facilitated the use of covalent immobilization strategies. Unfortunately, it is difficult to achieve the required high surface coverages by immobilization, since the first molecules immobilized sterically repel later molecules that are attached, unless thermodynamically poor solvents are used. The surface fraction may then be too low to completely "mask" the other functional groups that may be present. Pure monolayers of star PEG have been grafted to surfaces in an attempt to increase surface coverage (Sofia and Merrill, 1998), and radio frequency plasma polymerization of tetraglyme has been used to the same end (Shen et al., 2001). Other investigators have used block copolymers (e.g., Pluronic) of PEG and PPO [poly(propylene oxide)] by adsorption, gamma irradiation, or as an additive (McPherson et al., 1997); some have combined PEG with other strategies such as phosphorylcholine (Kim et al., 2000), cyclodextrin (Zhao and Courtney, 2007), and negatively charged side groups (from vinyl sulfonic acid sodium salt) (Lee et al., 2004).

PEG has also been incorporated, by both ends, into polyetherpolyurethanes (Merrill et al., 1982; Okkema et al., 1989). Unfortunately, the results in this case depend on a combined effect of surface microphase separation and the hydrogel (hydrated chain steric exclusion) effect of the PEG side chains. While some have noted lower thrombogenicity, others have not. For example, Okkema et al. (1989) synthesized a series of poly(ether-urethanes) based on PEG and poly(tetramethylene oxide) (PTMO) soft segments, and noted that the higher PEG-containing polymers were more thrombogenic in a canine ex vivo shunt model. Since PEG-containing polyurethanes have a considerable non-PEG phase, Chaikof et al. (1989) prepared a cross-linked network of PEG chains using only small polysiloxane units.

A number of investigators have noted that the beneficial effect of PEG is molecular weight dependent. Nagaoka et al. (1984) were among the first to demonstrate that increasing the PEG chain length of hydrogels containing methoxy poly(ethylene glycol) monomethacrylates led to reductions in protein and platelet adhesion (Fig. 1.4.3B.6). To some extent, however, the benefit of high-molecular-weight

PEO[1] is compromised by the crystallizability of long-chain PEO. In some cases, the benefit of longer chains may reflect particular process advantages (such as surface entrapment). Chaikof et al. (1992), with end-linked PEO, and Desai and Hubbell (1991b), with physically entrapped PEO, found lowest protein and platelet or cell deposition with high-molecular-weight PEO (>18,000 Da). However, when studying PEG-modified polyurethanes, Tan and Brash (2008) noted the importance of PEG surface density over length: the shortest PEG chain (MW: 550) allowed for a higher surface density and provided the greatest reduction in protein reduction compared to modification with longer chains of PEG (MW 2000 and 5000).

It is clear that incorporation of PEG results in reduced levels of cell (including platelet) adhesion and protein adsorption when compared to unmodified and typically hydrophobic substrates. It is far less clear whether the reduced adhesion or adsorption translates to lower material thrombogenicity (Llanos and Sefton, 1993a,b). Further, it is not clear whether reduced adhesion/adsorption is due specifically to the thermodynamic effects of PEG or PEO, or to the increase in surface hydrophilicity after its immobilization [refer to Brash et al., 2019, for a critical discussion on how protein adsorption is thought to govern (or not) blood reactivity]. While the in vitro results have looked promising, the lack of correlation between the few in vitro and ex vivo studies is of concern. Efforts with plasma deposited tetraglyme (Shen et al., 2001) have led to surfaces with ultra-low adsorbed fibrinogen, suggesting that previous attempts at using PEG modification have not been successful because of the inability to achieve the desired ultra-low (<5 ng/cm^2) levels of adsorbed protein. On the other hand, other studies from the same group (Zhang et al., 2008; Zhang and Horbett, 2009) show that such surfaces are not as resistant to protein adsorption as expected when exposed to physiological conditions (undiluted plasma). Low amounts of adsorbed von Willebrand factor (vWF) (and not fibrinogen only) also played a significant role in platelet adhesion under high shear rates. There is also evidence that properties of PEO and PEG surfaces may also be affected by the sterilization process (see Box 1.4.3B.2). This highlights the importance of testing modified surfaces under physiological conditions before drawing conclusions from in vitro studies using (surrogate) markers such as platelet adhesion or fibrinogen adsorption.

Albumin Coating and Alkylation

The early observation that surfaces coated with albumin did not support protein adsorption and platelet adhesion (reviewed by Andrade and Hlady, 1986) led many investigators to lower material thrombogenicity by either albumin coating or enhancing the affinity of albumin for surfaces via alkylation. Albumin adsorbs relatively tightly onto hydrophobic surfaces, while having a poor affinity for hydrophilic surfaces. Consequently, utilization of this strategy entails increasing the hydrophobicity of the surface, which is the opposite of the above-discussed strategies whereby the hydrophilicity of the surface was increased. Albumin coating is consistent with another hypothesis, developed early in the 1970s, which suggested that hydrophobic surfaces with critical surface tensions (conceptually related to surface free energy) around 20–30 dyn/cm would have a lower thrombogenicity (Baier et al., 1970).

A limitation of relying on albumin coating is that other proteins will adsorb to the surface displacing the albumin, limiting the long-term effectiveness of this strategy (see Chapter 2.1.2). To prevent displacement, glutaraldehyde cross-linking (Kottke-Marchant et al., 1989) or covalent immobilization has been used (Hoffman et al., 1972; Matsuda and Inoue, 1990). Reduced platelet adhesion was observed in vitro with a multilayer of albumin on polyethersulfone deposited using a layer-by-layer technique (Sperling et al., 2006). Since albumin has binding pockets for long alkyl chains, Munro et al. (1981) demonstrated that surfaces with long carbon chains (C-16 or C-18) have a high affinity for albumin, and provided for a dynamically renewable natural albumin layer. Albumin adsorption (from diluted plasma) was enhanced on alkylated cellulose membranes (Frautschi et al., 1995). Butylation (but not longer alkyl chains) of polyvinyl alcohol hydrogel also dramatically reduced platelet reactivity in a dog shunt (Strzinar and Sefton, 1992), suggesting that some of the observed benefit was due to the creation of a hydrophobic surface (Duncan et al., 1997).

• BOX 1.4.3B.2 Associated Facts: Effect of Sterilization Procedure on Hydrogel Properties

Most in vitro blood experiments are completed in 2 hours or less and little consideration is given to sterilization. However, sterilization may affect the materials' surface properties and thrombogenicity. For example, sterilizing PEG hydrogels using current methods (ethylene oxide, gamma, or plasma) may result in changes in surface roughness, protein adsorption, or the presence of radical species (Lleixa et al., 2008; Kanjickal et al., 2008). These changes lead to significant differences in the biocompatibility response between unsterilized and sterilized samples. Thus, it is important to test a surface-modified material in a "final product state," since processing may significantly alter its ability to reduce thrombogenicity in vivo. Removing endotoxin is another important consideration, at least in understanding the role of leukocytes and endothelial cells (Gorbet and Sefton, 2005a).

Zwitterionic Group/Phospholipid-Mimicking Surfaces

A number of investigators have hypothesized that a surface similar to the external zwitterionic outer phospholipid membrane of cells should be nonthrombogenic.[2] Since

[1] PEG >10 kD is called PEO [poly(ethylene oxide)], reflecting the different monomer and polymerization process used.

[2] Upon cell activation, the negatively-charged phospholipids that are preferentially located on the cytoplasmic face of the cell membrane flip to the outer membrane, which accelerates blood clotting by enabling assembly of the prothrombinase and tenase complexes.

phosphorylcholine (PC) is the major lipid head group on the external surface of blood cells and red blood cells are inert in coagulation assays, PC has been the choice of many investigators for incorporation into surfaces.

Durrani et al. (1986) prepared a series of reactive derivatives of phosphorylcholine that were designed to react with surface hydroxyl groups and surface acid chlorides on various materials. Another approach involved coating materials (Campbell et al., 1994; Lewis et al., 2000; Iwasaki et al., 2002), or blending a polyurethane (Ishihara et al., 1995, 1999) with a methacryloylphosphorylcholine (MPC; Fig. 1.4.3B.7)/polyacrylate copolymer. Platelet adhesion was significantly reduced on phosphorylcholine-coated expanded polytetrafluoroethylene (ePTFE) grafts at 90 min in dogs, and anastomotic neointimal hyperplasia and neointimal cell proliferation were also reduced (Chen et al., 1998). Ishihara et al. (1998) have attributed the low protein adsorption of their phospholipid polymers to the high free water fraction, a mechanism that has been confirmed by other investigations (Chen et al., 2005). A further modification has involved grafting only the polar part of phosphorylcholine onto ammonia plasma-treated ePTFE to promote more of the red blood cell-like properties while preventing lipid uptake (Chevallier et al., 2005). This led to a significant reduction in both platelet and leukocyte adhesion.

A recent approach has also been to modify materials (for example polyurethane) using zwitterionic polymers/monomers such as carboxybetaine or sulfobetaine (Fig. 1.4.3B.8A,B) to mimic the cell membrane (Yuan et al., 2003; Jiang et al., 2004; Kitano et al., 2005). Zhang et al. (2008) prepared polymeric brushes containing zwitterionic groups by surface-initiated atom transfer radical polymerization using sulfobetaine methacrylate (polySBMA) and carboxybetaine methacrylate (polyCBMA) on gold surfaces. Not only did such zwitterionic polymeric brushes exhibit super-low protein adsorption, with the polyCBMA brushes adsorbing less than 0.4 ng total protein/cm^2 (experiments performed in 100% plasma), but significantly reduced platelet adhesion was also observed. The polyCBMA also demonstrated unique anticoagulant properties, suggesting that such a material may offer excellent blood compatibility, although the mechanism by which polyCBMA is superior to polySBMA is currently unclear. Most recent studies have however focused on surface coating with polySBMA; some promising results were obtained in a porcine model with minimal platelet activation and adhesion after a 26-day implantation period (Iqbal et al., 2019).

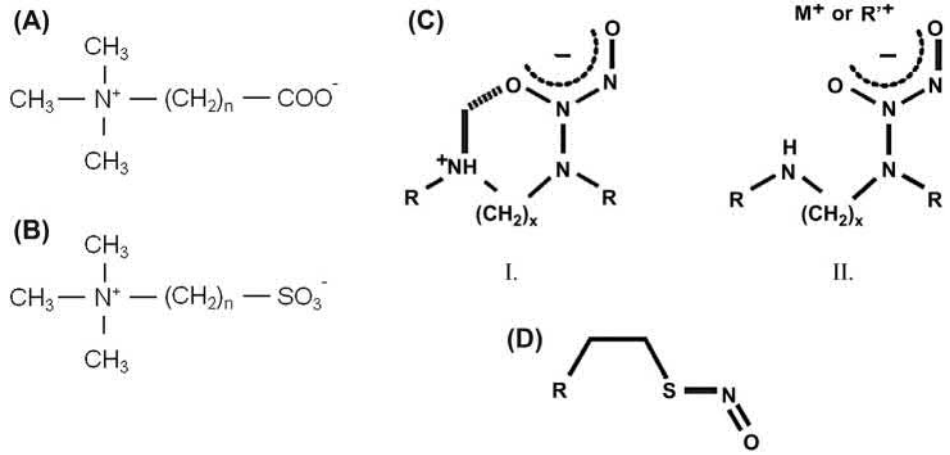
Surface-Modifying Additives (SMAs)

The blending of a copolymer, composed of polar and nonpolar blocks, to a base polymer appears to be a successful means to lower material thrombogenicity. The strategy, originally developed by Thoratec Laboratories Inc., is a means to alter the surface properties of materials without affecting bulk properties (Ward et al., 1984). The copolymers, added in low concentration, migrate to the base polymer surface during and after fabrication, and dramatically change the outermost surface molecular layers that comprise the region that determines biocompatibility (Tsai et al., 1994). The copolymers have a structure which is amphipathic, that is, certain groups or segments will have an attraction for the continuous phase (major polymer component of the blend), while other portions of the molecule will have little attraction for the base polymer and will be of lower polarity (Ward et al., 1984) (see Chapter 1.4.2). They have been used to lower the thrombogenicity of cardiopulmonary bypass and hemodialysis components by using SMA-blended polymers or SMA-coated surfaces. A clinical evaluation of the effects



• **Figure 1.4.3B.8** Generic structures of zwitterionic molecules ((A) carboxybetaine and (B) sulfobetaine) and two common NO donors: (C) zwitterionic (I) and cation-stabilized (II) diazeniumdiolates, and (D) an S-nitrosothiol. (From Frost, M.C., Reynolds, M.M., Meyerhoff, M.E., 2005. Polymers incorporating nitric oxide releasing/generating substances for improved biocompatibility of blood-contacting medical devices. Biomaterials 26, 1685–1693.)

of SMA on cardiopulmonary bypass circuits demonstrated a reduction in platelet interactions with no effect on complement activation (Gu et al., 1998).

Fluorination

The incorporation of fluorine into materials is also a strategy to lower thrombogenicity. Polymers with fluorinated chains are highly hydrophobic, and it is believed that the fluorine group's low surface energy modulates protein adsorption and platelet adhesion/activation. Preparing fluorine-rich surfaces is often facilitated by the tendency of fluorine-containing functional groups to concentrate on the surface of the polymer during preparation. Kiaei et al. (1988) found a strong effect of a fluoropolymer plasma on thrombus formation and plasma-induced graft polymerization of a fluorocarbon on polyethylene also reduced platelet adhesion (Lin et al., 2000). Fluoroalkyl groups as chain extenders have also been used to prepare nonthrombogenic polyurethanes (Kashiwagi et al., 1993). Using a similar approach, Wang and Wei (2005) showed that increasing fluorine content in polyurethanes by decreasing soft segment length resulted in a decrease in platelet adhesion and activation (of adherent platelets). Fluorinated surface-modifying macromolecules (SMMs) used to increase polyetherurethane biostability also improved blood compatibility (Jahangir et al., 2002), although the effect does not appear to be directly correlated with a decrease in fibrinogen adsorption (Massa et al., 2005).

Heparin-Like Materials

A number of polymers have been synthesized or modified in order to prepare polymers with chemical similarity to heparin, and thus possess heparin-like activities. For example, Fougnot et al. (1983) synthesized sulfonate/amino acid sulfamide polystyrene derivatives in order to create insoluble heparin-like materials. Some investigators (e.g., Grasel and Cooper, 1989) only incorporated sulfonate groups in an effort to lower thrombogenicity by surface thrombin inhibition. Enhanced binding and inactivation of thrombin was found, suggesting that these weak heparin-like molecules are sufficiently dense to lower thrombogenicity. A later approach combined sulfonation and PEG-like materials in the use of sulfonated cyclodextrin polymers (Park et al., 2002); and improved blood compatibility was seen in a canine shunt model (Han et al., 2006).

Self-Assembled Surface Layers

Self-assembled surface layers (Whitesides et al., 1991) have been envisioned as useful templates to nucleate or organize ordered, designed biomaterials (Ratner, 1995; see Chapter 1.4.2). Self-assembled monolayers (SAMs) of alkylsilanes supported on oxidized polydimethyl siloxane (PDMS) rubber have been used as a model system (Silver et al., 1999). The authors reported that surfaces grafted with hydrophobic head groups (CH_3 and CF_3) had significantly lower platelet and fibrinogen deposition than the surfaces composed of hydrophilic head groups in a canine ex vivo arteriovenous series shunt model. In a later in vitro study (Sperling et al., 2005), contradictory results were obtained whereby SAMs with $–CH_3$ exhibited the most platelet adhesion compared to –COOH and –OH. Reduced thrombin formation was observed for $–CH_3$ and –COOH. These studies highlight the difficulty of generalizing the effect of surface modification on blood compatibility. In addition to producing zwitterionic polymeric brushes (see the section "Zwitterionic Group/Phospholipid Mimicking Surfaces"), Zhang et al. (2008) produced a series of SAM surfaces using oligoethyleneglycol, phosphorylcholine, oligophosphorylcholine, mixed $SO_3^-/N^+(CH_3)_3$, and mixed $COO^-/N^+(CH_3)_3$; there was no significant difference in platelet adhesion or fibrinogen adsorption among these SAMs.

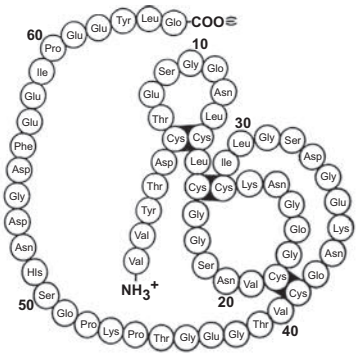
Active Materials

The limited success of the various surface treatments for lowering thrombogenicity has encouraged researchers to pursue other strategies. The most popular strategy, and the one that started the field, is the heparinization of surfaces, although the incorporation of other antithrombotic and antiplatelet agents into materials also gained popularity (Fig. 1.4.3B.9). Currently, the antithrombotic agents utilized have mainly been against thrombin (hirudin, curcumin, thrombomodulin).

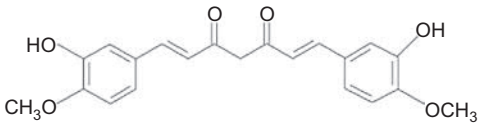
The incorporation of antiplatelet agents into materials has been limited by the instability and complex mechanism of action of these agents. Platelet GPIIb/IIIa antagonists (e.g., ReoPro, Centocor) and agents against factor Xa (low-molecular-weight heparins, LMWH) or inhibitors of tissue factor expression (extrinsic pathway) are currently being used systemically during cardiovascular surgery. There is potential for such drugs to be included in novel strategies to modify materials.

Heparinization

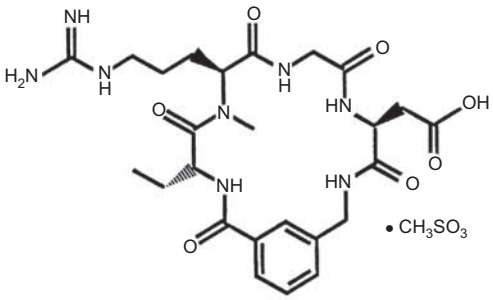
Heparinization of surfaces continues to be the most popular technique for lowering the thrombogenicity of materials. As illustrated in Fig. 1.4.3B.10, heparin is a linear, acidic carbohydrate composed of repeating disaccharide units that are O- and N-sulfated. The molecular weights of heparin chains range from 1200 to 40,000 Da, with a mean molecular weight of approximately 10,000. Depending on its molecular weight and structure, it can inhibit, in association with its cofactor (antithrombin III), the serine proteases: thrombin and factor X. Since thrombin is also a potent platelet activator, binding it into an inactive complex should help minimize platelet activation. Investigators have been able to covalently, ionically, and physically attach heparin to various substrates utilizing a number of chemistries. The main concern has been that once immobilized, the heparin should be able to assume its native conformation, and be able to interact with antithrombin III.



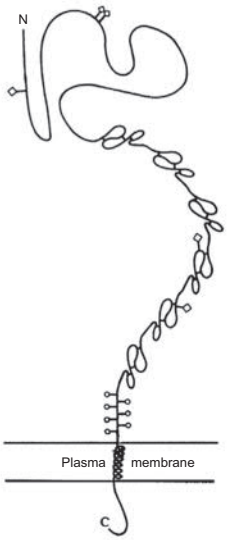
Hirudin



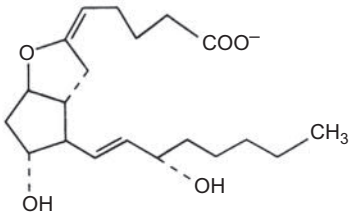
Curcumin



DMP 728



Thrombomodulin



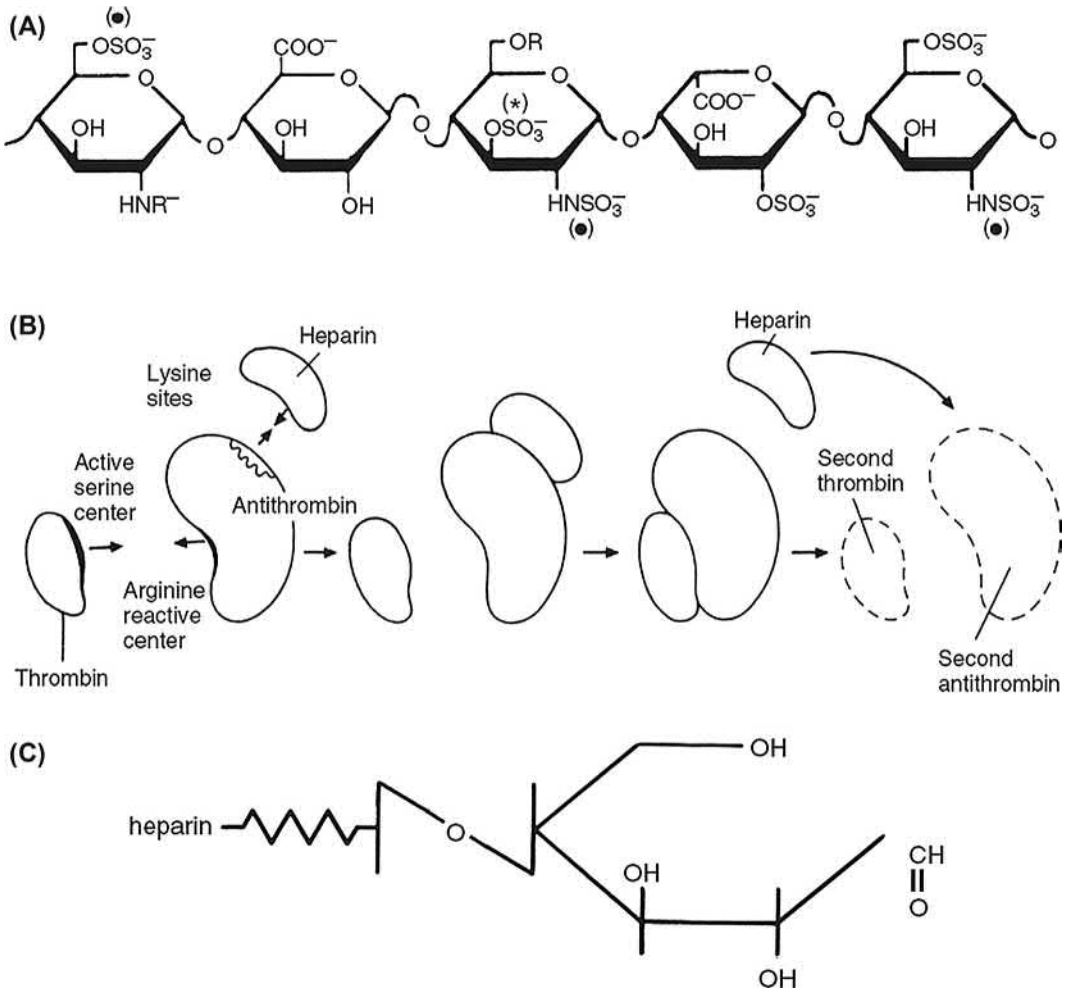
Prostacyclin

• **Figure 1.4.3B.9** Agents, other than heparin that have been incorporated into biomaterials to actively control thrombogenicity. Hirudin and curcumin are thrombin inhibitors. Prostacyclin (PGI2) is a natural inhibitor of platelet function, while DMP728 is a small-molecule GPIIb/IIIa antagonist. Thrombomodulin inhibits thrombin by activating protein C.

The effectiveness of heparin as an agent capable of increasing synthetic venous graft patency and reducing downstream anastomotic neointimal hyperplasia and cell proliferation was demonstrated using a novel polytetrafluoroethylene-based local drug-delivery device. Heparin was infused adjacent to the graft wall and at downstream anastomotic sites for 14 days and demonstrated effectiveness (Chen et al., 1995).

Ionically Bound Heparin and Controlled-Release Systems

If negatively charged heparin is bound ionically to the surface, then heparin will be slowly released over time due to exchange with the blood. A similar effect is obtained if heparin is dispersed within a hydrophobic polymer. Selected techniques to produce materials which release heparin at biologically significant rates have been discussed in depth by a number of investigators (Sefton et al., 1987; Amiji and Park, 1993). Ionic approaches involve binding the highly negatively charged heparin onto a cationic surface through ionic binding. The limitation is that the leaching of heparin will eventually leave the surface unprotected. Certain nonionic approaches are also characterized by high release rates (due to relatively unstable bonds), so that determining the heparin release rate (in addition to amount bound) is a primary means of characterizing these surfaces. Limitations to the use of dispersed systems include the loading capacity of heparin, which prevents long-term usage and the heterogeneity of heparin, leading to the early release of lower molecular weight chains.



• **Figure 1.4.3B.10** (A) Antithrombin III-binding pentasaccharide of heparin. The pentasaccharide sequence is composed of three glucosamine (units 1, 3, and 5), one glucuronic acid (unit 2), and one iduronic acid (unit 4) units. Structural variants are indicated by –R′ (–H or $–SO_3–$) or –R″ ($–COCH_3$ or $–SO_3–$). The 2-O-sulfate groups (asterisk), a marker component for the antithrombin-binding region, and sulfate groups indicated by (•) are essential for high-affinity binding to antithrombin. (B) The mechanism of action of heparin and antithrombin III. (C) The reducing end of heparin formed by treatment with nitrous acid. ((A) From Fiore, L., Deykin, D., 1995. Anticoagulant therapy. In: Beutler E., Lichtman M.A., Collen B.S., Kipps, T.J. (Eds.), Williams Hematology, fifth ed. McGraw-Hill, pp. 1563; and (B) From Bauer, K.A., Rosenberg, R.D., 1995. Control of coagulation reactions. In: Beutler E., Lichtman M.A., Collen B.S., Kipps, T.J. (Eds.), Williams Hematology, fifth ed. McGraw-Hill, pp. 1241, with permission.)

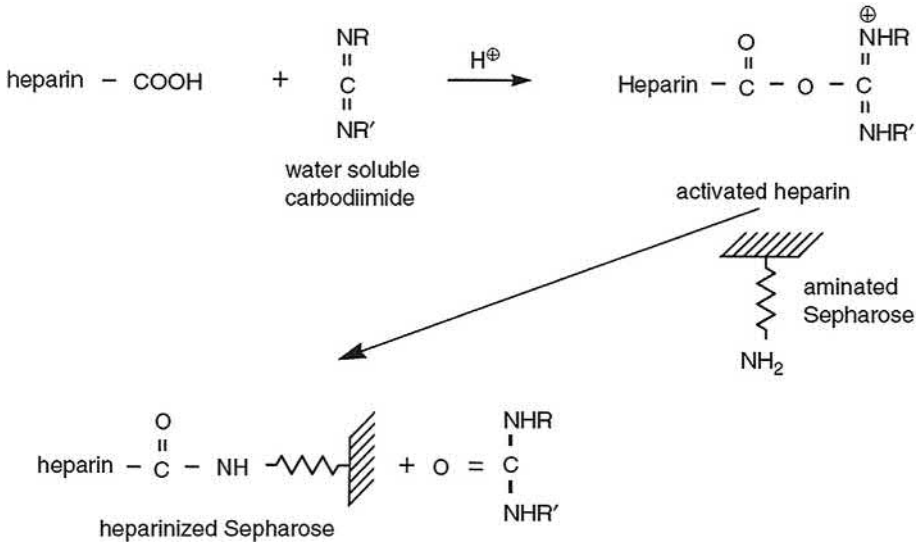
The thromboresistance of heparinized materials based on controlled release appears to be due to a microenvironment of heparin in solution at the blood–material interface. The relationship between release rate (N, g/cm^{2}s) and surface concentration (C_s, g/cm^3) for heparin or any other agent released from the inside wall of a tube of radius r_0 is given by (Basmadjian and Sefton, 1983):

$$\frac{C_s}{Nr_0/D} = 1.22\left[\frac{x/r_0}{\mathrm{Re}Sc}\right]^{1/3} \qquad \textbf{(1.4.3B.4)}$$

where D = diffusivity (cm^2/s); r_0 = tube radius; x = axial position; Re = Reynold's number = $2r_0v\varrho/\mu$; Sc = Schmidt number = $\mu/\varrho D$; v = average velocity; ϱ = density; μ = viscosity. The diffusivity of heparin is ~7.5×10^{-7} cm^2/s and the critical C_s (minimum therapeutic level) for heparin is ~0.5 μg/mL.

Use of tridodecyl methylammonium chloride (TDMAC; Lehninger, 1966), a lipophilic, cationic surfactant, eliminated the need for the graphite coating that was part of the original graphite–benzalkonium–heparin (GBH) method (Gott et al., 1963). TDMAC and the many other quaternary ammonium compounds enabled heparin to be ionically bound to a wide range of biomaterials. Unfortunately, such compounds are surfactants with potentially toxic consequences, and are known to be eluted from the surfaces within a week.

Quaternizable amino groups have also been incorporated directly into polymers to improve the stability of the ionically bound heparin. Tanzawa et al. (1973) synthesized a graft copolymer with a dimethylaminoethyl group by UV-initiated copolymerization of N,N-dimethylaminoethyl methacrylate (DMAEM) and methoxypolyethylene glycol



• **Figure 1.4.3B.11** One-step carbodiimide activation of carboxyl groups of heparin for binding to aminated Sepharose. For EDC, R = $(CH_2)3N(CH_3)_2$. For a carboxylated substrate (e.g., hydrolyzed polymethyl acrylate) its carboxyl groups may be activated by carbodiimide in a separate step for subsequent reaction with the free amine groups of heparin.

methacrylate (MPEG). Use of this technique (Angiocath, Toray Industries) to coat poly(urethane) catheters indicated that a minimal heparin elution rate of 0.04 μg/cm^2/min was needed to render the catheter thrombus free in vivo (Idezuki et al., 1975). This value is consistent with Eq. (1.4.3B.4).

A commercial procedure (Baxter Bentley Healthcare Systems, Irvine, CA) to ionically bind heparin (Duraflo II) has been used to coat cardiopulmonary bypass circuits and other devices. While heparin coating of extracorporeal circuits is designed to reduce surface thrombus formation, its effect on complement, contact activation, and inflammation is unclear and often contradictory (see below).

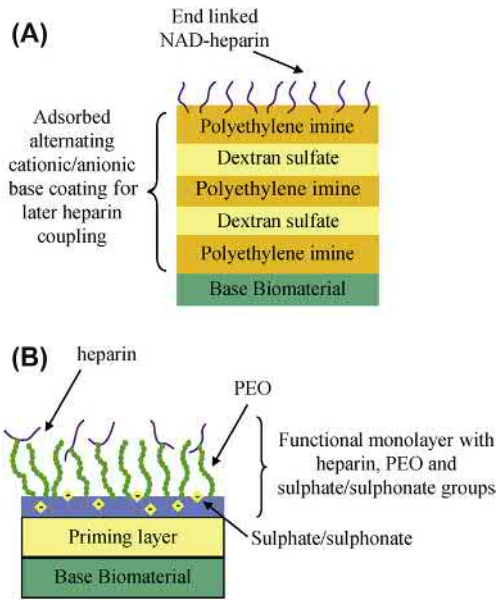
Covalently Bound Heparin

To impart a degree of activity longer than that possible with ionic linkages, heparin has been covalently immobilized to material surfaces. It is now recognized that the conformation of the attached heparin and the point of attachment (end point vs. multipoint) are critical factors determining the catalytic efficiency of the immobilized heparin. Lindhout et al. (1995) studied the antithrombin activity of surface-bound heparin under flow conditions. They demonstrated that the rate of thrombin inactivation of the antithrombin–heparin surface equals the maximal rate of transport of thrombin toward the surface when the surface coverage of antithrombin exceeds 10 pmol/cm^2; thus indicating that a higher intrinsic catalytic efficiency of a surface does not necessarily result in a higher antithrombin activity.

Many of the coupling methods listed in Chapter 1.4.4 have been used for heparin. For example, Heyman et al. (1985) attached 1-ethyl-3-(3-dimethylaminopropyl) carbodimide (EDC)-activated heparin covalently onto chemically modified polyetherurethane catheters through a diamino alkane spacer. The immobilized heparin retained its ability to bind and inactivate thrombin and factor Xa. Unfortunately, carbodiimides (Fig. 1.4.3B.11) are recognized as less than ideal activating agents for immobilizing heparin, since the acidic conditions used can result in a loss of anticoagulant activity.

Larm et al. (1983) developed a technique by which heparin can be covalently end point-attached (commercialized as the Carmeda BioActive Surface, CBAS and marketed, for example, as Cortiva BioActive Surface by Medtronic for extracorporeal circulation devices) to the surface of plastics, as well as glass and steel. Heparin is first partially depolymerized by deaminative cleavage using nitrous acid to produce heparin fragments terminating in an aldehyde group (Fig. 1.4.3B.10C). The heparin is then covalently linked to the primary amino groups of polyethylene imine (PEI) (Fig. 1.4.3B.12A). This technique results in a highly stable, low-thrombogenicity coating that retained its efficacy in vivo for 4 months in dogs (Arnander et al., 1987), and during patient treatment with an artificial lung (Bindslev et al., 1987). There was also a beneficial effect on *in vivo* bacterial colonization of treated polyurethane central venous catheters (Appelgren et al., 1996).

The commercial Trillium coating (developed by Bio-Interactions Ltd. and marketed by Medtronic) combines covalently binding heparin with polyethelene oxide and sulfonate groups (Fig. 1.4.3B.12B). Clinical studies with Duraflo, Carmeda, and Trillium have shown that while they enable the use of reduced systemic anticoagulation (Ovrum et al., 2001), they do not reduce the postoperative acute phase response (van den Goor et al., 2004; Hoel et al., 2004). Complement and leukocyte activation play an important role in the biocompatibility of extracorporeal circulation devices, and while several in vitro studies suggest that heparin coating may have other effects (see review of Biron and Pond, 2017), it appears that the in vivo benefit of heparin coatings is limited to anticoagulation.



• **Figure 1.4.3B.12** Commercial surface treatments used for cardiopulmonary bypass (CPB) and potentially also for vascular grafts. (A) Carmeda method for immobilizing nitrous acid-treated heparin (end-linked heparin) to dextran sulfate and polyethylene imine-treated surface. (B) Trillium coating: The priming layer is hydrophilic and strongly binds to the base material, PEO chains and sulfate and sulfonate groups are covalently attached to the priming layer, while heparin is covalently bound to PEO. (Adapted from Shivpal, S., Luthra, A., 2002. New biointeracting materials. Med. Dev. Technol. 10, 26.)

Heparin has also been covalently immobilized via its terminal serine at the end of the protein–carbohydrate linkage region to polyvinyl alcohol hydrogel. The heparin is bound during the Lewis acid-catalyzed cross-linking of polyvinyl alcohol chains with glutaraldehyde. The heparinized polyvinyl alcohol hydrogel possessed significant anticoagulant activity, although the platelet incompatibility of the hydrogel substrate led to significant platelet consumption in an ex vivo canine shunt model (Cholakis et al., 1989).

Park et al. (1988) covalently bound heparin to a polyurethane using PEG spacer groups. The increasingly mobile nature of the longer hydrophilic spacer chains was considered to have increased the observed bioactivity of immobilized heparin by providing a more bulk-like environment for the heparin. An intravascular oxygenator and carbon dioxide removal device (IVOX; CardioPulmonics, Salt Lake City, UT) also uses covalent heparin bound to a PEG spacer. The PEG is grafted onto a plasma-polymerized polysiloxane on a base material after plasma amination of the surface. Heparin has also been immobilized on silicone via an N-succinimidyl carbonate PEG and the grafted heterobifunctional PEG allowed for high heparin density resulting in both low fibrinogen adsorption and high specificity for ATIII (Chen et al., 2005).

Du et al. (2007) covalently grafted an antithrombin/heparin complex onto a PEO-modified polyurethane in the presence of a free radical initiator. This increased anti-FXa activity compared to grafted heparin alone, and was shown to significantly reduce material thrombogenicity in a chronic rabbit model (Klement et al., 2006).

There are now several commercially available heparin-coated cardiovascular devices on the market both for short-term (e.g., shunts, arteriovenous access, and extracorporeal circuits) and long-term (e.g., below-the-knee vascular grafts) use. While these coated devices cost significantly more than their uncoated counterparts, there is evidence that, in some applications, patency is significantly higher with heparin coating and thus there is a cost benefit associated with their use (Vergnaud et al., 2018; Villemoes et al., 2018). With the increased use of heparin-coated cardiovascular devices in the past 10 years, the value of heparin coating is currently an area of great debate in the cardiovascular community (Lazarides et al., 2016; Zea et al., 2016; Ashfaq et al., 2018; Samson et al., 2016). Most conclusions are based on retrospective studies and prospective studies will be needed to better assess the overall benefits of heparin coating, especially since other surface modifications to reduce thrombogenicity may be as effective at a lower cost (Giorni et al., 2019).

Thrombin Inhibition Without Heparin

Recognizing the importance of inhibiting material-induced thrombin generation, agents other than heparin have been used to inhibit thrombin and thereby lower the thrombogenicity of the material. For example, hirudin, a potent thrombin inhibitor, has been covalently bound to biomaterials. Compared with heparin, hirudin is advantageous because it has no influence on platelet function, no immune-mediated platelet-activating activity and, most importantly, it does not require the presence of endogenous cofactors like antithrombin III. Thus, the polypeptide hirudin is thought to be able to block clot-bound thrombin that is inaccessible to inhibition by a heparin/antithrombin III complex. On the other hand, heparin functions as a catalyst. That is immobilized heparin, if not blocked by adsorbed protein, can continually accelerate the inactivation of thrombin by antithrombin III. It is unclear how long a covalently immobilized hirudin surface would remain effective, and even whether an immobilized hirudin could gain access to the clot-bound thrombin. Nevertheless, Ito et al. (1991) used heterobifunctional cross-linking reagents to derivatize hirudin to form covalent cross-links between hirudin and albumin, producing active conjugates for immobilization to surfaces. Others have immobilized hirudin to a polylactide–glycolide copolymer (Seifert et al., 1997). Another group has exploited controlled release of hirudin for this purpose (Kim et al., 1998). Small-molecule thrombin inhibitors, like D-Phe-Pro-Arg chloromethyl ketone (PPACK) and others may prove useful as alternatives.

Because of the affinity of benzamidine toward thrombin and its potential to reduce complement activation (which may participate in platelet activation), amidine derivatives were considered to enhance blood compatibility. Gouzy et al. (2004) immobilized a benzamidine derivative (with a hydrocarbon side chain) onto a maleic anhydride copolymer

via a PEG spacer; platelet adhesion and activation was reduced on the modified surface, as well as thrombin–antithrombin complex formation. They subsequently correlated thrombin binding to the amount of immobilized benzamidine derivative, with the amount immobilized being dependent on spacer length and immobilization chemistry (Salchert et al., 2005). Yim and Sefton (2008) converted the surface nitrile groups of polyacrylonitrile-co-vinyl chloride films into amidine groups by first reacting nitrile with diethyl ether and hydrogen chloride followed by reaction with ammonia in ethanol. While the amidine surface modification was limited, reduced platelet adhesion and activation was observed.

Another approach involves immobilizing thrombomodulin, an endothelial cell-associated protein that inhibits thrombin by activating protein C. Using a small-scale dialyzer it was demonstrated that immobilized human thrombomodulin (on cellulose) still had co-enzyme activity for activation of protein C and anticoagulant activity (Kishida et al., 1995). An amino-terminated silane was used to couple thrombomodulin to glass, and the authors reported both anticoagulant activity and reduced platelet adhesion (Han et al., 2001). Thrombomodulin has also been immobilized (using an azido group via PEG) onto pancreatic islets, with a view to minimizing the thrombogenicity of the islet and enhancing islet engraftment after portal vein infusion (Stabler et al., 2007). Further work is needed to appreciate the potential of such surfaces.

Immobilization of Antiplatelet Agents

There has been considerable interest in incorporating antiplatelet agents into materials to lower material thrombogenicity. Endothelial cells lining the natural vessel wall help prevent thrombus formation by secreting antiplatelet agents such as nitric oxide (NO) and prostacyclin (PGI2). Thus, a biomaterial containing antiplatelet agents is consistent with our understanding of endothelial cell function. Prostacyclin is potent yet unstable, and efforts to maintain its biological activity during immobilization, coupled with concern for the ability of platelets in the bloodstream to be affected by the immobilized prostacyclin, have limited the enthusiasm for such a strategy. On the other hand, a simpler approach, which also more closely mimics the biological environment, is to incorporate PGI_2 or NO into materials for release. Unfortunately, the inability to load sufficient drug into materials for release limits the materials' lifespan, and this approach may be limited to use in short-term cardiovascular devices such as oxygenators, sensors, and catheters. A novel approach to overcome such limitations is to use endogenous NO donors to generate NO at the blood–material interface. NO is an antiplatelet agent and a potent inhibitor of smooth muscle proliferation. This approach is described in more detail below.

Despite these challenges, many investigators have incorporated antiplatelet agents into surfaces. For example, Ebert et al. (1982) immobilized prostaglandin F2α using a diaminododecane spacer arm. The F2α was subsequently converted to the unstable prostacyclin. The benefits of spacer arms are described elsewhere (Chapter 1.4.4). A related approach is to add an antiplatelet agent, such as prostaglandin E1 (PGE1), in addition to heparin into a polymer. A PGE1-heparin compound was synthesized and incorporated into a polyurethane (Jacobs et al., 1985). Also, prostacyclin has been incorporated into polymer matrices for controlled release (McRea and Kim, 1978). Aspirin, capable of inhibiting the generation of the platelet activator thromboxane A2, has also been incorporated into polyvinyl alcohol membranes used in hemodialysis (Paul and Sharma, 1997), while a dipyrimadole derivative was photo-immobilized on a polyurethane (Aldenhoff et al., 1997).

Two basic approaches exist to create NO-releasing polymers: N-diazeniumdiolates or S-nitrosothiols (Fig. 1.4.3B.8C,D). These can either be blended into polymers or covalently bonded to a side chain or to the polymer backbone (Frost et al., 2005). While S-nitrosothiol-based NO-releasing materials have been synthesized [e.g., with polyvinyl alcohol (PVA) and PVP (Seabra and de Oliveira, 2004)], there is currently only limited biocompatibility data on such an approach (Bohl and West, 2000). On the other hand, NO-releasing materials using diazeniumiolates have demonstrated great efficiency in reducing thrombus formation in various animal models (Frost et al., 2005; Skrzypchak et al., 2007). Another approach is to use endogenous NO donors to produce NO locally. Duan and Lewis (2002) used endogenous S-nitrosoproteins in plasma to produce NO from immobilized cysteine to minimize platelet adhesion on a polyurethane and a poly(ethylene terephthalate). A lipophilic copper complex has also been incorporated into polyvinyl chloride (PVC) and polyurethane (PU) films that was able to generate NO from nitrite under physiological conditions (Oh and Meyerhoff, 2004) as well as in vivo in a rabbit model of extracorporeal circulation (Major et al., 2011). Significantly reduced thrombus formation as well as decreased monocyte activation were also observed in vivo with the NO-generating biomaterial (Major et al., 2011).

A new generation of antiplatelet agents based on inhibiting fibrinogen binding to activated platelet GPIIb/IIIa receptors offers a fresh approach to lowering the thrombogenicity of surfaces via drug release. These agents, from blocking monoclonal antibodies to small peptides and compounds (e.g., DMP728, Fig. 1.4.3B.9), not only block platelet aggregation, but will also likely block platelet adhesion to artificial surfaces. Some have already been incorporated into stents for release (see the section "Strategies to Lower the Thrombogenicity of Metals," below, and Chapter 2.5.2B).

Immobilization of Fibrinolytic Agents

Some investigators have sought to promote fibrinolysis on artificial surfaces by the surface generation of plasmin. Clot lysis is achieved by the action of plasmin (formed from plasminogen) on fibrin. However, the action of such surfaces may be "too little too late." Sugitachi and Takagi (1978) immobilized urokinase, a fibrinolytic enzyme that

acts on plasminogen, on various materials. A slightly different approach is to immobilize plasminogen and then convert it to plasmin, so as to impart fibrinolytic activity to a surface (Marconi et al., 1996). A disadvantage of utilizing streptokinase and urokinase to cleave plasminogen to plasmin is that these agents activate both circulating and fibrin-bound plasminogen. This contrasts with the action of tissue plasminogen activator (tPA), an endogenous serine protease that converts only fibrin-bound plasminogen to plasmin. A nonpharmacological approach to developing fibrinolytic surfaces for blood-contacting applications was the preparation of lysine-derivatized polyurethane surfaces (Woodhouse and Brash, 1992). The expectation was that these surfaces exhibit fibrinolytic activity because the lysine residues promote the selective adsorption of plasminogen from plasma through the lysine-binding sites in the plasminogen molecule.

Use of Endothelial Cells and RGD Peptides

It is intuitive to believe that the ideal nonthrombogenic surface for vascular grafts and other devices will consist of an intact luminal endothelial cell layer. Herring et al. (1984) seeded Dacron and ePTFE grafts with endothelial cells in a preliminary clotting step with blood and endothelial cells. Autologous endothelial cells were seeded onto ePTFE grafts (6–7 mm inner diameter) for 153 patients, and a significant improvement in the patency rate in the infrainguinal position at 7 years was reported (Meinhart et al., 2001).

To promote endothelialization of vascular grafts either in situ or in vitro, the roles of surface chemistry, pore size, and protein coatings have been investigated (McGuigan and Sefton, 2007). Using a rat model, Wang et al. (2004) found increased endothelialization in porous polyurethane grafts. To increase endothelial cell attachment and proliferation, surface modification using an anhydrous ammonia gaseous plasma technique (Sipehia, 1990; Pu et al., 2002) or UV irradiation (Olbrich et al., 2007) has proven successful in vitro. Some approaches are focused on modifying the surface with proteins or peptides that will promote adhesion and proliferation of endothelial cells. Coating or covalent binding of materials with extracellular matrix (ECM) proteins such as fibronectin (Van Wachem and Hubbell, 1987), collagen, laminin, and elastin or glycosaminoglycans such as chondroitin sulfate (Thalla et al., 2014) have shown some success in vitro. A more elegant approach (Massia and Hubbell, 1990) has been to immobilize RGD ECM peptide sequences (see Chapter 1.4.4) to encourage endothelial cell attachment. This approach has been adopted by many others, but most results remained at the proof-of-concept stage with in vitro studies (for a thorough review of the potential use of peptides to enhance vascular graft endothelialization, refer to de Mel et al., 2008).

Immobilizing growth factors, such as VEGF, or a metalloproteinase inhibitor have also been shown to promote endothelial cell proliferation on graft materials in vitro. It is important to note that while graft endothelialization might occur from cell migration from the anastomosis or from infiltration, it is thought that endothelial progenitor cells (EPC)[3] may also play a role in graft endothelialization, and thus increasing the capture of EPC through surface modification (e.g., anti-CD34 antibody immobilization; Aoki et al., 2005) is another approach.

Several coating strategies for endothelialization are also now being combined with micro- or nano-patterning as it has been shown to significantly improve EC adhesion and proliferation (Cutingo et al., 2016; Ren et al., 2015).

Since considerable differences exist in the potential for endothelialization between humans (low) and animals (higher, e.g., canines), translation of results from animal studies can be problematic. A detailed discussion of this issue is presented by Zilla et al. (2007). With immobilizing adhesion peptide sequences, there is a concern that regions not covered by endothelial cells would lead to enhanced platelet and thrombus deposition, or that the attached endothelial cells might indeed be activated (see Box 1.4.3B.3).

• BOX 1.4.3B.3 Associated Facts: Endothelial Cell Activation on Vascular Grafts

When endothelial cells (ECs) are expected to adhere onto vascular grafts (or any cardiovascular material) to provide a nonthrombogenic surface, it is required that the cells express a nonactivated, nonthrombogenic phenotype, such that leukocytes and platelets do not bind to them and the endothelial cells are able to inhibit coagulation and platelet activation. While many investigators measure endothelial cell adhesion to a substrate, few characterize the actual phenotype of the adherent cells (McGuigan and Sefton, 2007). It is not a simple matter to determine adherent EC thrombogenicity in vitro, since cell seeding density, the cell origin (e.g., adipose tissue vs. umbilical vein), shear rate, and culture conditions (serum vs. no serum, human vs. bovine serum) seem to affect the expression of ICAM-1, VCAM-1 (leukocyte adhesion receptors), PECAM-1, and E-selectin (platelet adhesion receptors), and the effects are material dependent. Differences in the in vivo endothelialization process between humans and animals (e.g., canines) further complicate matters (Zilla et al., 2007).

Strategies to Lower the Thrombogenicity of Metals

While polymers represent the principal class of materials used in the cardiovascular setting, metallic surfaces are also used in mechanical heart valves and stents. Most metals are highly thrombogenic and life-long anticoagulant and antiplatelet therapies are required with the use of mechanical heart valves, while the optimum therapy for stented patients is a much discussed topic, especially with drug-eluting stents (see Box 1.4.3B.4).

To reduce the thrombogenicity of the materials used in prosthetic heart valves, three approaches for surface

[3] EPC are circulating bone-derived progenitor cells. They circulate in blood at low concentration and share some similarities with monocytes.

modification have been explored: coating whereby a layer of metal oxide is deposited on the metal (plasma deposition); oxidation of the metal; and ceramic or polymer coating. Deposition of tantalum-doped titanium oxide films significantly reduced platelet activation and fibrin deposition in an in vivo dog model (Huang et al., 2003). Coating with oxynitrites on stainless steel also improved overall in vitro and in vivo biocompatibility (Chen et al., 2003). A layer of oxide on titanium has also been prepared by oxidation in a solution of H_2O_2, and this reduced platelet adhesion in vitro (Takemoto et al., 2004). Diamond-like carbon (DLC) (Mikhalovska et al., 2004) and apatite composite (Muramatsu et al., 2003) have also been coated on various metals, and both a reduction in fibrinogen adsorption and platelet adhesion have been observed in vitro. More recent approaches focus on coatings with multilayers of collagen and sulfated chitosan (Li et al., 2008), or covalently attaching a phosphorylcholine-containing polymer (see Fig. 1.4.3B.13; Ye et al., 2009). Despite these efforts, low-temperature isotropic pyrolytic carbon remains the choice for heart valves (see Chapter 2.5.2A).

Coatings for the metals currently used (stainless steel, cobalt chromium, tantalum, and Nitinol) in bare metal stents were sought as a means of reducing the thrombogenicity of such stents (Van Belle et al., 2007), and to at least indirectly influence restenosis. Due to its inertness, gold was deposited on stents, but increased restenosis rates were observed (Hara et al., 2006). Randomized clinical trials of heparin-coated tantalum stents (Blezer et al., 1998) showed that there was no significant improvement in restenosis or clinical outcomes compared to uncoated stents (Wohrle et al., 2001). Other efforts to reduce thrombogenicity included coating tantalum stents with polymers such as polyetherurethane and parylene to reduce platelet adhesion density (Fontaine et al., 1996) and radiation grafting N-vinyl-pyrrolidone (NVP) onto plasma-treated stainless steel stents (Seeger et al., 1995). Hyaluronic acid coating also reduced platelet thrombus formation on stainless steel stents and tubes in a primate

• BOX 1.4.3B.4 Area of Further Interest: A Benefit of "Poor" Material Blood Compatibility

While metallic stents are being modified to reduce their potential thrombogenicity, thrombogenicity may be beneficial to the promotion of osteogenesis with orthopedic implants. Upon implantation, osteogenic cells interact first with the blood clot that occupies the wound site, and platelet activation releases growth factors, such as PDGF, and cytokines, such as TGFβ (both contained in platelet's α granules), that are recognized to stimulate bone growth. As such, platelet concentrates are currently being used during surgery to improve bone regeneration. More generally, thrombogenicity is a special case of inflammation (Gorbet and Sefton, 2005b), and enhancing thrombogenicity may be a strategy for creating materials with improved healing characteristics in situations such as in orthopedics.

Covalent surface modification of a titanium alloy with a phosphorylcholine-containing copolymer for reduced thrombogenicity in cardiovascular devices. J. Biomed. Mater. Res. A. 91 (1), 18–28.))

• BOX 1.4.3B.5 Clinical Correlations: Drug-Eluting Stent-Induced Thrombosis

Drug-eluting stents (DEs) have significantly reduced the rates of restenosis. However, clinical data, albeit not without dispute, suggest that DES increase the risk of late thrombosis (>30 days after implantation). While changes to the antithrombotic and anticoagulant regimen have resolved some of the concerns, ongoing animal and in vitro research (Lüscher et al., 2007) has suggested that in addition to preventing neointima formation (the intended use of the therapeutic agent being delivered), paclitaxel and sirolimus inhibit reendothelialization and induce tissue factor, thus creating a prothrombotic environment at the local site of stent implantation. The proprietary nondegradable polymers used in these stents have also been reported to be linked to inflammatory reactions at the site of implantation, although it is not clear whether these are different from what is seen with metals. A chronic inflammatory reaction would further contribute to a prothrombotic state around the stent. The clinical concerns have driven a resurgence in stent endothelialization strategies as well as a different strategy where balloons are now being considered to deliver some of the therapeutic components.

thrombosis model (Verheye et al., 2000). In another study, metal/polymer composite stents loaded (40% by weight) with a potent antiplatelet agent (GPIIb/IIIa antagonist; >90% elution in 89 h) reduced, by almost a factor of 2, platelet adhesion in dogs 2 h after stent deployment (Santos et al., 1998). r-Hirudin has also been immobilized on Nitinol stents coated with functionalized paracyclophanes (Lahann et al., 2001). As with vascular grafts, a phosphorylcholine coating has also been explored to improve stent endothelialization, however, it did not show significant improvement compared to bare metal stents in clinical trials (Abizaid et al., 2007). The relationship between thrombogenicity and clinical outcomes such as restenosis remains a hypothesis.

The early work on reducing stent thrombosis has been supplanted by drug-eluting stents (DES) to reduce restenosis rates. Rapamycin- or sirolimus-eluting stents in which the therapeutic agent is blended in a nonerodible polymer and coated onto the surface of the stent have the dramatic effect of eliminating in-stent restenosis for at least 6 months after deployment (Morice et al., 2002). Paclitaxel is an antineoplastic agent used in chemotherapies. However, the concern that DES appear to have higher risk of late thrombosis (Box 1.4.3B.5) renewed interest in developing surface strategies to lower stent thrombogenicity. Also, because of late thrombosis, there has been an interest in biodegradable stent materials with both polymeric and metallic stent systems entering clinical trials in recent years.

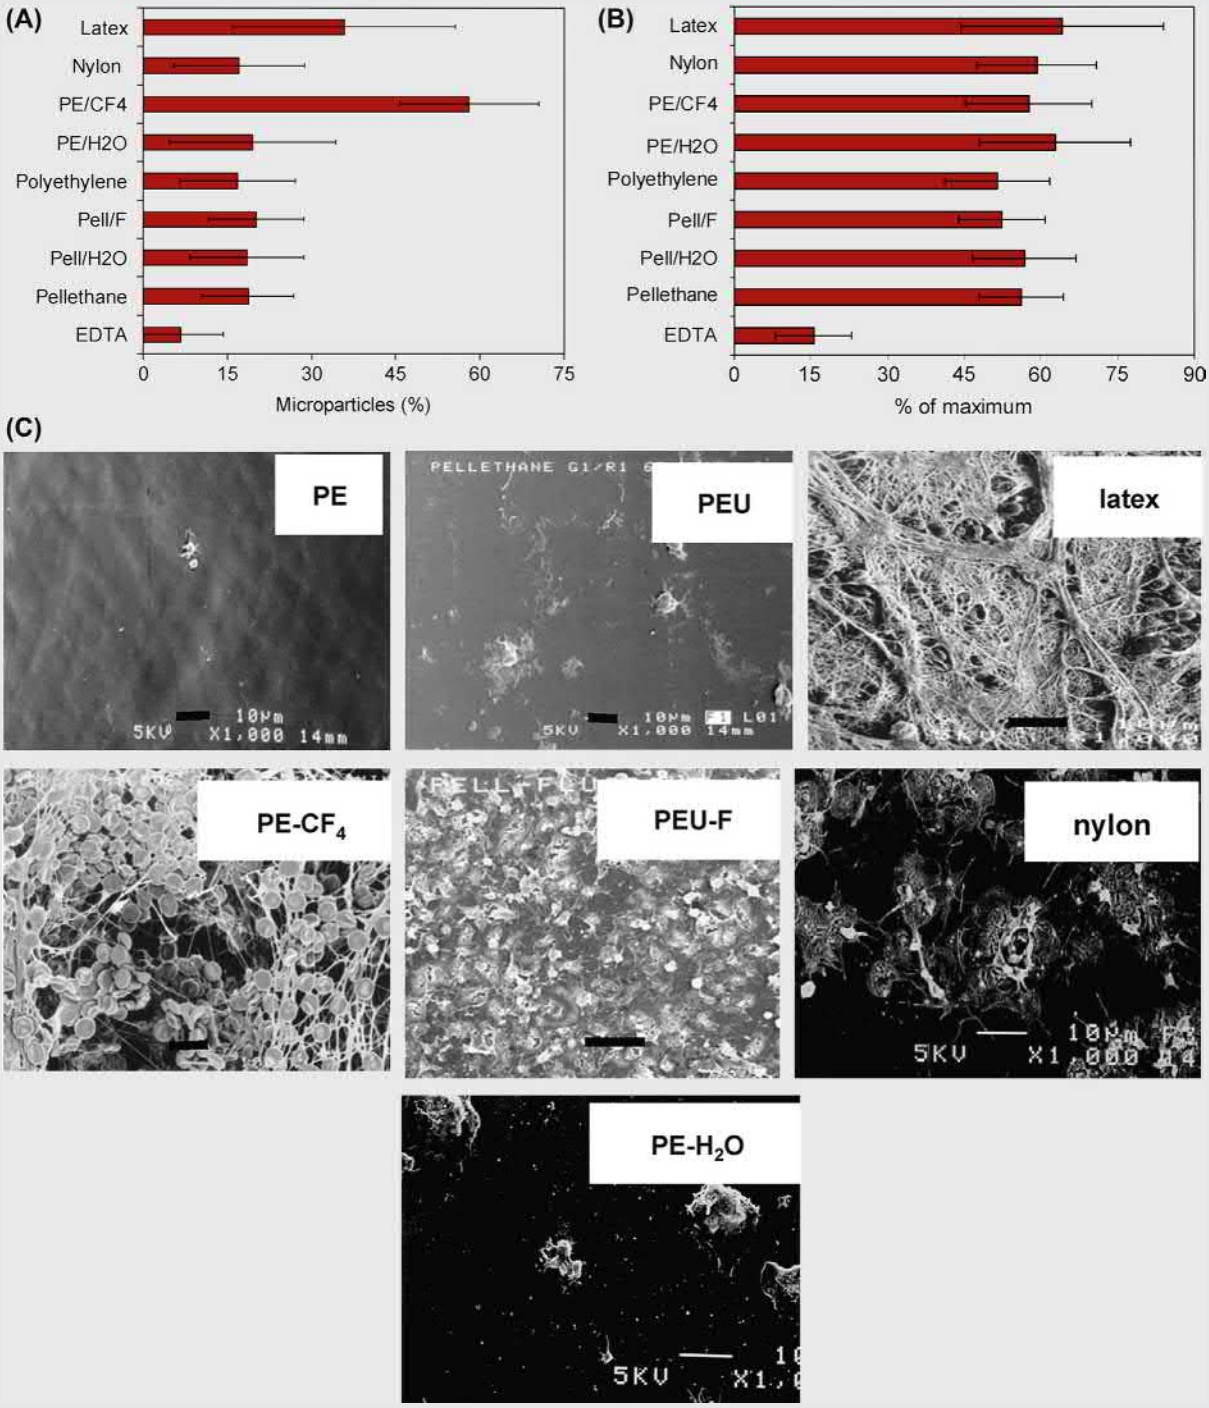
Summary

It is an axiom that the interactions between materials and blood are complex. Hence, it is no surprise that developing low thrombogenicity materials (let alone ones with zero thrombogenicity) is challenging. Medical device manufacturers relying on elegant device designs and systemic pharmacological agents have significantly improved existing materials. Adverse effects are minimized and existing devices, if not risk-free, provide sufficient benefit to outweigh the risks. The focus of research in biomaterials is to make better materials that have fewer risks and greater benefits. Stents that "actively" prevent restenosis are a great example of how modifying a material can have a dramatic clinical effect. Inert materials, such as those with immobilized PEG, can resist protein and platelet deposition, but these may only be at best surrogate markers for thromboembolic phenomena. On the other hand, incorporating anticoagulants such as heparin can be an effective means of reducing thrombin production rates below critical values, but this may not be sufficient to prevent platelet activation and consumption. Many strategies for lowering thrombogenicity have been identified, and they all show a beneficial effect in at least one assay of thrombogenicity. Moreover, some have made the transition from a one-parameter benefit to multiple benefits, or from in vitro to clinical use. These issues are discussed more fully in Chapters 2.2.6 and 2.3.5.

Which approaches will ultimately be successful is impossible to predict. Certainly there is much activity in biomembrane mimicry and PEG immobilization. There are many new anticoagulants and antithrombotics under development, but few have yet to be incorporated into material surfaces. In recent years, combining strategies such as reducing both protein adsorption and thrombin production while also promoting endothelialization have become prevalent and have shown promising results in small animal in vivo short-term studies (Bastijanic et al., 2016; Choi et al., 2016). The commercial Trillium coating is an example of the benefit of combining various approaches. Finally, as new hypotheses are developed to understand cardiovascular material failure, new approaches will be identified for inhibiting undesired pathways. The failure to produce the ideal nonthrombogenic material, despite over 40 years of research, merely reflects our limited understanding of blood–material interactions (Jaffer and Weitz, 2019; Brash et al., 2019; Gorbet et al., 2019; Maitz et al., 2019; Ratner, 2007). A recent approach has been to consider the anticoagulant regimen that a patient is subjected to: two studies have shown that surface modification combined with single anticoagulant therapy (rather than the double anticoagulant and antiplatelet therapies) resulted in a significant improvement in blood compatibility (Yau et al., 2012; Deidre et al., 2019). Perhaps the right strategy for producing a nonthrombogenic material will have little to do with controlling platelets or thrombin, but will be directed toward leukocytes, endothelial cells, or complement (Gemmell, 1998; Wetterö et al., 2003). Ongoing research is expected to improve the blood interactions of materials used in medicine to address important clinical needs.

ISO10993-4, Biological Evaluation of Medical Devices Part 4: The Effects on Blood (AAMI, 1995), which manufacturers of medical devices need to use as guidance to register their products, includes thrombosis and coagulation among the tests that need to be done. However, specific test methods are not detailed. With a view to clarifying this question, a series of plasma-modified tubes (along with an unmodified control and other commercially available tubing) were prepared, surface characterized, and exposed to heparinized whole blood (1 U/mL heparin) for 1 hour at 37°C (Sefton et al., 2001). The surface modifications included several different plasma vapors (H_2O, CF_4, and fluorine). The 1.5-mm ID tubing was incubated with whole blood on a rocking platform to gently agitate the blood and keep the cells from overtly settling. This system does not probe the effect of shear on cell activation; rather the agitation and long incubation time are thought sufficient to create "well-mixed" conditions.

Some of the results from this study are shown in Fig. 1.4.3B.14 and Table 1.4.3B.1. One of the conclusions from this



• **Figure 1.4.3B.14** Cell activation and SEM (scanning electron microscope) results after 60 min contact with whole blood (1 U/mL heparin) at 37°C in rocking platform. Flow cytometry results are mean ± SD. (A) Microparticle levels (percentage of platelet events); (B) Leukocyte CD11b upregulation (expressed relative to the maximum upregulation obtained with a phorbol ester). (C) SEM. Scale bar is 10 μm in all. Modified materials are designated with the name of base materials and gas introduced into plasma (H_2O, NH_4, CF_4, or F). Presented data are a subset of those studied and figures are adapted from those published (Sefton et al., 2001). PE, polyethylene; PEU, Pellethane.

CASE STUDY—CONT'D

Nonthrombogenic Materials and Strategies

TABLE 1.4.3B.1 Most Biomaterials Are the Same

Parameter	EDTA Control (or Equivalent)	Value For Most Materials
Platelet count loss (%)	0 (by definition)	25–35
P-selectin (% positive)	6.4	~8–9
Platelet–leukocyte aggregates (Fluorescent intensity)	46	~200–250
CD11b upregulation (% of maximum)	15	~50–60
L-selectin shedding	11	~70–90

study is that the materials with the lowest levels of platelet and leukocyte activation (microparticle formation, CD11b upregulation) were the unmodified materials (polyethylene, Pellethane, a polyurethane), and that the surface modifications tested here had either no effect or only made things worse from the perspective of platelet and leukocyte activation. The scanning electron micrographs showing little cellular deposit on the polyethylene or Pellethane were consistent with the flow cytometry findings. Except for those materials that were worse, the other materials expressed similar levels of activation for platelets, leukocytes, and the other markers tested; i.e., the majority of the "inert" materials (in the absence of bioactive components like heparin) appear to have a similar nonspecific effect on blood.

The results from this study contrast sharply with other studies (many of them cited in this chapter) showing large differences in blood interactions between different biomaterials. This highlights the lack of consensus about blood–materials interactions. Reasons for this lack of consensus are discussed in Chapter 2.3.5.

Introduction

Biomolecules such as enzymes, antibodies, affinity proteins, cell receptor ligands, and drugs of all kinds have been immobilized on and within biomaterial surfaces for a wide range of therapeutic, diagnostic, tissue regeneration, separation, and bioprocess applications. Immobilization of heparin on polymer surfaces is one of the earliest examples of a surface-modified, biologically functional biomaterial (Gott et al., 1963). Living cells may also be combined with biomaterials, especially when their surfaces contain cell adhesion peptides or proteins, and the fields of cell culture, artificial organs, and tissue engineering include important examples of cell–surface interactions. These "hybrid" combinations of natural and synthetic materials confer "biological functionality" to the synthetic biomaterial. Many sections and chapters in this textbook cover various aspects of this topic, including adsorption of proteins and adhesion of cells and bacteria on biomaterial surfaces, nonfouling surfaces, cell culture, tissue engineering, artificial organs, drug delivery, and others. This chapter will focus on the methodology involving physical adsorption and chemical immobilization of biomolecules on biomaterial surfaces, especially for applications requiring bioactivity of the immobilized biomolecule.

Among the different classes of biomaterials that could be biologically modified, synthetic polymers are especially interesting because their surfaces may contain reactive groups such as –OH, –COOH, or NH_2 groups, or they may be readily modified with other reactive groups such as azide, alkyne, and SH groups. All of these groups can be used to covalently link biomolecules.

Another advantage of polymers as supports for biomolecules is that the polymers may be fabricated in many forms, including films, membranes, tubes, fibers, fabrics, particles, capsules, and porous structures. Furthermore, macromolecular structures can also vary substantially. The latter can include homopolymers, random, alternating, block, and graft copolymers, and hyperbranched (comb-like) and star-shaped structures (see Chapter 1.3.2 on polymers).

Living anionic polymerization techniques, along with newer methods of living free-radical polymerizations, now provide fine control of molecular weights with narrow distributions. The molecular forms of solid polymers include noncross-linked chains that are insoluble at physiologic conditions, cross-linked networks, physical blends, and interpenetrating networks (e.g., Piskin and Hoffman, 1986; see also Chapter 1.3.2). "Smart" polymers are sharply responsive in solubility behavior to stimuli, such as temperature, pH, and salt concentration (see Chapter 1.3.2G on "smart" polymers).

For surfaces of metals, metal oxides, inorganic glasses, or ceramics, biological functionality can sometimes be added via a chemically immobilized or physically adsorbed polymeric or surfactant adlayer, or by use of techniques such as plasma gas discharge, corona discharge in air, or ozone to modify polymer surface compositions with functional groups (see also Chapter 1.4.2). Several researchers have applied mussel adhesive chemistry based on self-condensation of dopamine to form tight bonding layers of polydopamine on a variety of surfaces, including metals, metal oxides, and glasses (Lee et al., 2007; Ku et al., 2010). The amine groups in these polymers may be further functionalized with biomolecules.

Patterned Surface Compositions

(See also Chapter 1.4.5).

Biomaterial surfaces may also be functionalized in geometric patterns (Bernard et al., 1998; Blawas and Reichert, 1998; James et al., 1998; Ito, 1999; Kane et al., 1999; Folch and Toner, 2000). Sometimes the patterned surfaces will

have regions that are nonbinding to proteins (so-called "nonfouling" compositions), while others may contain covalently linked cell receptor ligands (Neff et al., 1999; Alsberg et al., 2002; Csucs et al., 2003; VandeVondele et al., 2003), or may have physically adsorbed cell adhesion proteins (McDevitt et al., 2002; Ostuni et al., 2003). A huge industry has also evolved based on "biochips" that contain microarrays of immobilized, single-stranded DNA (for genomic assays) or peptides or proteins (for proteomic assays) (Houseman and Mrksich, 2002; Lee and Mrksich, 2002). The majority of these microarrays utilize inorganic silica chips rather than polymer substrates directly, but it is possible to incorporate functionality through chemical modification with silane

chemistries (Puleo, 1997) or adsorption of a polymeric adlayer (Scotchford et al., 2003; Winkelmann et al., 2003).

A variety of methods have been used for the production of these patterned biochips, including photoinitiated synthesis through patterned masks (Ellman and Gallop, 1998; Folch and Toner, 2000), microfluidic fluid exposure (Ismagilov et al., 2001), and protection with adhesive organic protecting layers that are lifted off after exposure to the biomolecular treatment (Jackman et al., 1999).

Immobilized Biomolecules and Their Uses

Many different biologically functional molecules can be chemically or physically immobilized on polymeric supports (Table 1.4.4.1) (Laskin, 1985; Tomlinson and Davis, 1986). Examples of applications of these immobilized biological species are listed in Table 1.4.4.2. When hydrophilic, molecularly cross-linked, or entangled solids are water swollen above about 15%–25% water content, they become hydrogels and biomolecules may be immobilized on the outer gel surface, as well as within the water-containing regions ("meshes") of the swollen polymer gel network. It can be seen that there are many diverse uses of such biofunctional systems in both the medical and biotechnology fields. For example, a number of immobilized enzyme supports and reactor systems (Table 1.4.4.3) have been developed for therapeutic uses in the clinic (Table 1.4.4.4) (De Myttenaere et al., 1967; Kolff, 1979; Sparks et al., 1969; Chang, 1972; Nose et al., 1983, 1984; Schmer et al., 1981; Callegaro and Denri, 1983; Lavin et al., 1985; Sung et al., 1986). Advantages and disadvantages of immobilized enzymes are listed in Table 1.4.4.5.

[a]A large number of receptor-binding peptide domains have been identified in numerous adhesion proteins that are able to recapitulate some of the binding character of the entire protein. Only a small selection of widely studied peptides is listed here.

Immobilized Cell Ligands and Cells

Cell interactions with foreign materials are usually mediated by a biological intermediate, such as adsorbed proteins, as described in Chapter 2.1.2. An approach using biologically functionalized materials can be much more direct, by adsorbing or covalently grafting ligands for cell–surface adhesion receptors, such as integrins, to the material surface (Lutolf and Hubbell, 2005; Patterson et al., 2010) (Table 1.4.4.6).

This has been accomplished with peptides grafted randomly over a material surface (Massia and Hubbell, 1991), as well as with peptides presented in a preclustered manner (Irvine et al., 2001). The latter has important advantages. Cells normally cluster their adhesion receptors into nanoscopic assemblies referred to as "focal contacts" (Geiger et al., 2009), in which both adhesion ligands and receptors are coclustered. This clustering plays an important role in both cell adhesion mechanics (Ward and Hammer, 1993) and cell signaling (Maheshwari et al., 2000; Geiger et al., 2009). In fact, Miyamoto et al. (1995) found that integrin receptors must be clustered by adhesive ligands to function as they would in a natural environment. This discovery is supported by the fact that many components of the extracellular matrix (ECM) exist as multivalent ligands. Other studies have further elucidated the impact of the multivalent presentation of adhesive ligands on cellular activity.

For instance, Boontheekul et al. (2008) found that the number of bonds between the integrin receptors of a cell and synthetic adhesion peptide ligands correlated with cell proliferation. Studies like these have influenced the use of multivalent adhesive ligands that cause integrin clustering in the design of synthetic biomaterial scaffolds. In addition to peptides, saccharides have also been grafted to polymer surfaces to confer biological functionality (Griffith and Lopina, 1998; Chang and Hammer, 2000). Other investigations of the migration- and differentiation-inducing influences of different cell adhesion molecules have used self-assembling monolayers for the defined presentation of adhesion ligands (Mrksich, 2009).

Nanotechnology methods of ligand immobilization have been used extensively to achieve very precise control of ligand immobilization density, ligand clustering, and arrangement, and even ligand exposure from a previously hidden state or hiding after an exposed state. For example, nanopatterning methods have been used to show that cells are capable of sensing and responding to clustering on the length scale of 70 nm of the arginylglycylaspartic acid (RGD) peptide, which binds to integrins such as $\alpha_v\beta_3$ (Huang et al., 2009). At longer length scales, the cell is unable to sense clustering. In another study that examined how nanoscale ligand clustering can affect cell activity, Petrie et al. (2010) developed a flexible assembly of multimeric recombinant fibronectin fragments that were covalently immobilized onto a polymer brush system that had been coated onto titanium. The researchers were able to show that this multivalent display of fibronectin clustered integrin receptors for enhanced cellular adhesion, signaling, and differentiation when compared to the presentation of monomeric fibronectin fragments. Furthermore, the functionalization of titanium with the multimeric fibronectin fragments allowed for the improved integration of a titanium implant into bone.

Specific biomolecules can be immobilized to control cellular interactions. One important class of such functionalizations is the polypeptide growth factor. Such molecules can be immobilized and retain their ability to provide biological cues that signal specific cellular behavior, such as support of liver-specific function of hepatocytes (Kuhl and Griffith-Cima, 1996), induction of neurite extension in neurons (Sakiyama-Elbert et al., 2001), induction of angiogenesis (Zisch et al., 2001), or the differentiation of mesenchymal stem cells into bone-forming osteoblasts (Lutolf et al., 2003a,b; Martino et al., 2009). It is important to understand that these effects are not merely induced by the mechanics of adhesion, i.e., what matters are the details of which adhesion ligand is displayed, and thus which adhesion receptor is ligated and what downstream signaling is activated. For example, stimulation of mesenchymal stem cells with a ligand for integrin $\alpha_5\beta_1$ stimulated osteogenesis, whereas stimulation with a ligand for integrin $\alpha_v\beta_3$ did not. Another example of a specific biomolecule that can be conjugated to a biomaterial scaffold to control cell behavior is Sonic Hedgehog (Shh), which naturally assembles into multimers after secretion by cells and plays a role in embryonic development. Vazin et al. (2014) immobilized Shh onto linear hyaluronic acid polymers and examined the effect of its valency on the specification of human embryonic stem cells. They found that when compared to monovalent Shh, the multivalent Shh constructs could be used to more effectively drive specification of human embryonic stem cells into cell types that could be used in cell replacement therapies for Parkinson's disease or epileptic disorders. Kaur et al. (2010) also demonstrated the ability to control cell differentiation using a multivalent display of a specific immobilized ligand. These researchers created a two-dimensional biomaterial scaffold using tobacco mosaic virus with phosphate ligands conjugated to each capsid coat protein of the virus. The phosphate ligands induced mineralization of the scaffold through calcium incorporation, which served to upregulate osteospecific genes in bone marrow stem cells. Other molecules may be immobilized that can take part in enzymatic reactions at the surface. McClung et al. (2001, 2003) immobilized lysines, whose ε-amino groups may interact with preadsorbed tissue plasminogen activator during coagulation, to enhance fibrin clot dissolution at that surface.

The foregoing paragraphs generally deal with biomaterial surfaces as though they are two dimensional. In some devices, this is indeed the case; however, biomaterials have been developed to display their surfaces in three-dimensional situations, even with triggering by cellular remodeling. For example, biomaterial gels have been developed, consisting of cross-linked poly(ethylene glycol) (PEG) chains, where the cross-linker is sensitive to proteases, such as plasmin or matrix metalloproteinases, that are activated by cells as they migrate (Lutolf et al., 2003a,b). In this way, as cells migrate in a material and remodel it, they can expose new surfaces and be stimulated by those new surfaces. Using such materials as tools, a number of regenerative medical applications have been targeted, where the biomaterial surface displays both adhesion ligands and polypeptide growth factors (Lutolf and Hubbell, 2005). Such materials, through careful selection of adhesion ligand composition, can control very specific biological processes, such as embryonic stem cell self-renewal (Lee et al., 2010). Materials have been developed that allow for very precise control of the adhesion ligand display and cross-linked nature of the three-dimensional material, e.g., through locally controlled photochemical manipulation (Kloxin et al., 2009, 2010).

Immobilization Methods

There are three major methods for immobilizing biomolecules: physical adsorption, physical "entrapment," and covalent attachment (Stark, 1971; Zaborsky, 1973; Dunlap, 1974). Physical adsorption includes: (1) van der Waals interactions; (2) electrostatic interactions; and (3) affinity recognition. Once adsorbed, the molecules may be further cross-linked to each other. Physical "entrapment" systems include: (1) microcapsules; (2) hydrogels; and (3) physical mixtures such as matrix drug delivery systems. Covalent attachment includes: (1) soluble polymer conjugates; (2) conjugates on solid surfaces; or (3) conjugates within hydrogels.

It is clear that the first two are physically based, while the third is based on covalent or "chemical" attachment to the support molecules. However, sometimes the physical attachment process may involve pairs of molecules with very strong affinity interactions, verging on covalent force levels, such as biotin with streptavidin. Thus it is important to note that the term "immobilization" can refer to a short-term, long-term, or "permanent" localization of the biomolecule on or within a support. In the case of a drug delivery system, the immobilized drug is supposed to be released from the support, either over a short period or over a longer term, while an immobilized enzyme or cell adhesion peptide or protein in an artificial organ is designed to remain attached to or entrapped within the support over the duration of use. Either physical or chemical immobilization can lead to relatively long-term or "permanent" retention on or within a solid support, especially if the immobilized biomolecule is large.

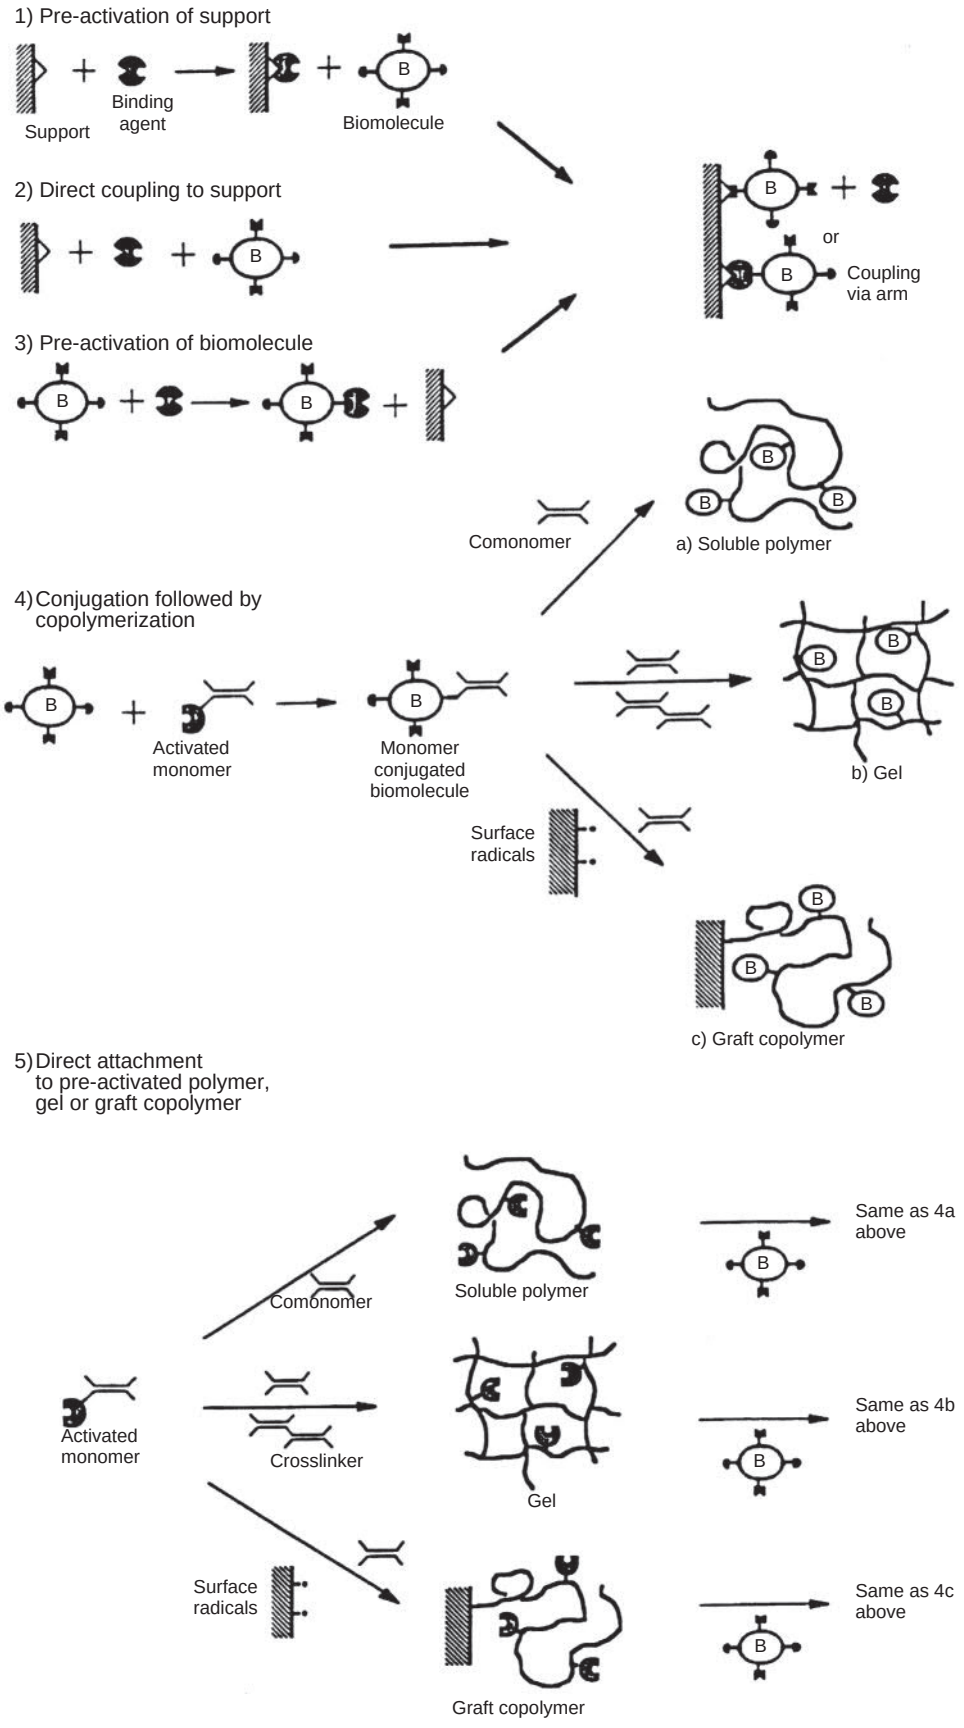
If the polymer support is biodegradable, then the chemically immobilized biomolecule will be released as the matrix erodes or degrades away. Many researchers have chemically immobilized cell adhesion peptides such as RGD onto biodegradable matrices such as poly(lactic-*co*-glycolic acid) for use as tissue-engineering scaffolds. The cells will have the time to bind and regenerate tissue if the support is slowly degrading. If the support degrades more rapidly than the cells' ability to reach and bind to the adhesion peptides, then the matrix will not function in the intended way. The immobilized biomolecule may also be susceptible to enzymatic degradation in vivo, and this remains an interesting aspect that has received relatively little attention.

A large and diverse group of methods has been developed for covalent binding of biomolecules to soluble or solid polymeric supports (Weetall, 1975; Carr and Bowers, 1980; Dean et al., 1985; Gombotz and Hoffman, 1986; Shoemaker et al., 1987; Park and Hoffman, 1990; Yang et al., 1990; Schense and Hubbell, 1999; Lutolf et al., 2003b). Many of these methods are schematically illustrated in Fig. 1.4.4.1. The same biomolecule may be immobilized by many different methods; specific examples of the most common chemical reactions utilized are shown in Fig. 1.4.4.2. The reader is referred to Hermansson (2008) for many useful details on numerous conjugation chemistries.

Click chemistry refers to a particular set of covalent reactions often used for biomolecule immobilization. Click reactions are modular, quick, selective, and deliver a high yield under mild reaction conditions (Kolb et al., 2001). In recent years, there has been an interest in bioorthogonal click chemistries, which occur under conditions that are tolerable to cells and do not interfere with the functional groups found in cells or their media. Common bioorthogonal click chemistries include Michael addition, thiol-ene coupling, and azide-alkyne cycloaddition, among others. Examples of these reactions are shown schematically in Fig. 1.4.4.3. Many diverse applications of bioorthogonal click chemistries exist, and a particularly relevant application for the immobilization and display of biomolecules is the formation of synthetic hydrogels. Hydrogels are hydrated networks of polymers that are often used as cell culture scaffolds due to their ability to mimic the ECM of natural tissues. Biomolecules such as adhesion ligands and growth factors can be immobilized within a hydrogel's polymeric network to further emulate the natural ECM. Both the synthesis of the hydrogel's polymeric network and the addition of immobilized biomolecules can be accomplished using bioorthogonal click chemistry. For example, Lutolf et al. (2003c) used base-catalyzed Michael additions to add monocysteine adhesion peptides (RGDS) in stoichiometric deficit to 4-arm-PEG tetravinyl sulfones, then cross-linked the resulting product with bis-cysteine matrix metalloproteinase-degradable peptides to form the hydrogel's polymeric network. More complex patterning of biomolecules on hydrogels is also possible using photoresponsive click chemistry, such as the thiol-ene reaction. Grim et al. (2018) created hydrogels in which visible light could be used to initiate the reversible and repeatable conjugation of thiol-containing biomolecules to pendant allyl sulfide moieties present in the hydrogel's polymeric matrix. This ability to spatiotemporally alter the immobilization of biomolecules within the hydrogel using photoresponsive click chemistry is important given the dynamic nature of the ECM and allows researchers to better study how a cell's environment affects its function and behavior. While the immobilization and display of biomolecules in hydrogels is one common application of click chemistry, many other applications exist. For example, click reactions have been used to immobilize redox proteins on electrode surfaces for use in bioelectrochemical reactions (Zhang et al., 2016), anchor nucleic acids to substrates for use as biosensors (Jiménez-Meneses et al., 2018), and tether peptides to drug-encapsulating nanoparticles for targeted drug delivery (Han et al., 2015).

For covalent binding to an inert solid polymer surface such as polyethylene or silicone rubber, the surface must first be chemically modified to provide reactive groups for the subsequent immobilization step. If the "inert" polymer support does not contain such groups, then it is necessary to modify it to permit covalent immobilization of biomolecules to the surface. A wide number of solid surface modification techniques have been used, including ionizing radiation-initiated graft copolymerization, plasma gas discharge, photochemical grafting, chemical modification (e.g., ozone grafting), and chemical derivatization (Hoffman et al., 1972, 1986; Gombotz and Hoffman, 1986, 1987; Hoffman, 1987, 1988) (see also Chapter 1.4.2 on surface modification techniques).

A covalently immobilized biomolecule may also be attached via a spacer group, sometimes called an "arm" or a "tether" (Cuatrecasas and Anfinsen, 1971; Hoffman et al., 1972; Hoffman, 1987). One of the most popular tethers is a PEG molecule that has been derivatized with different



Note : Ⓑ may be immobilized with or without a "tether" arm in any of the above

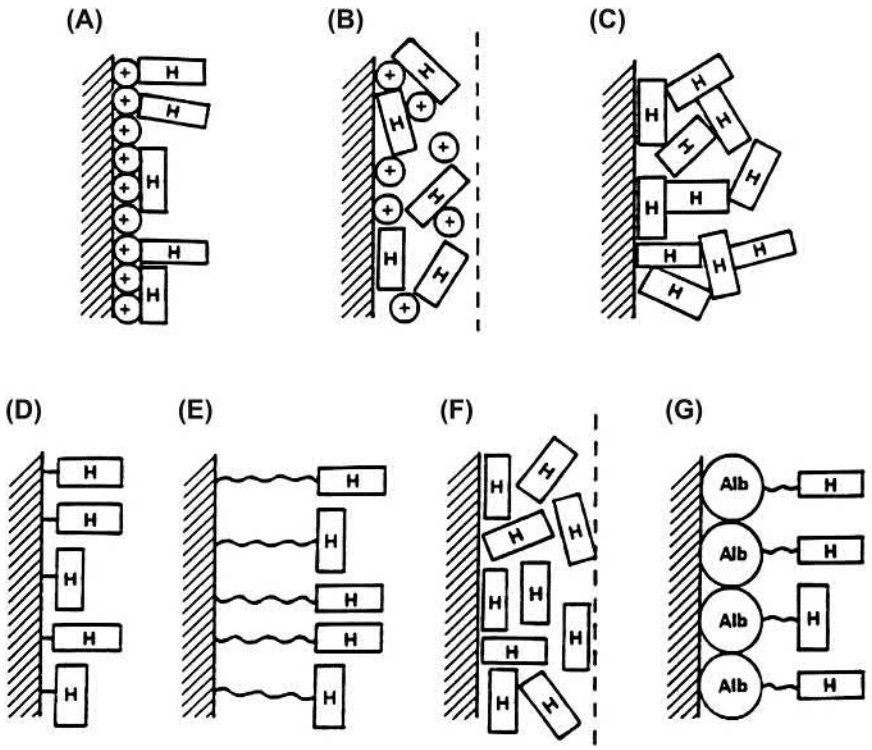
reactive end groups (e.g., Kim and Feijen, 1985), and several companies currently offer a variety of homo- or heterobifunctional PEGs with end group chemistries such as *N*-hydroxysuccinimide, maleimide, pyridyl disulfide, thiol, vinyl sulfone, alkyne, and azide. Such spacers can provide greater steric freedom, and thus greater specific activity for the immobilized biomolecule. The spacer arm may also be either hydrolytically or enzymatically degradable, and therefore will release the immobilized biomolecule as it degrades (Kopecek, 1977; Hern and Hubbell, 1998).

Inert surfaces, whether polymeric, metal, or ceramic, can also be functionalized through modification of a polymeric adlayer. Such physically adsorbed or chemisorbed polymers can be bound to the surface via electrostatic interactions (VandeVondele et al., 2003), hydrophobic interactions (Neff et al., 1999), or specific chemical interactions, such as that between gold and sulfur atoms (Harder et al., 1998; Bearinger et al., 2003). Metal or ceramic surfaces may also be derivatized with functional groups using silane chemistry, such as with functionalized triethoxysilanes (Massia and Hubbell, 1991; Puleo, 1997) or dopamine polymer chemistry, as described earlier. Plasma gas discharge has been used to deposit polymeric amino groups for conjugation of hyaluronic acid to a metal surface (Verheye et al., 2000).

As noted earlier, hydrophobic interactions have been used to functionalize hydrophobic surfaces, utilizing biomolecules such as ligands attached to hydrophobic sequences (e.g., Ista et al., 1999; Nath and Chilkoti, 2003). Surfaces with hydrophobic gradients have also been prepared for this purpose (Detrait et al., 1999). An interesting surface-active product was developed several years ago that was designed to convert a hydrophobic surface to a cell adhesion surface by hydrophobic adsorption; it had an RGD cell adhesion peptide coupled at one end to a hydrophobic peptide sequence.

Sometimes more than one biomolecule may be immobilized to the same support. For example, a soluble polymer designed to "target" a drug molecule may have separately conjugated to it a targeting moiety such as an antibody, along with the drug molecule, which may be attached to the polymer backbone via a biodegradable spacer group (Ringsdorf, 1975; Kopecek, 1977; Goldberg, 1983). For some nucleic acid drugs, sometimes a "nuclear localization signal" is added to enhance intracellular delivery to the nucleus (e.g., Nair et al., 2003). In another example, the wells in an immunodiagnostic microtiter plate will usually be coated first with an antibody, and then with albumin or casein (to block nonspecific adsorption during the assay); each is physically adsorbed to the well surface. In the case of affinity chromatography supports, the affinity ligand may be covalently coupled to the solid packing, and a "blocking" protein such as albumin or casein may be similarly added to block nonspecific adsorption to the support.

In certain instances, it may be important to consider the manner of presentation, or orientation, of an immobilized biomolecule. Several methods of site-specific biomolecule

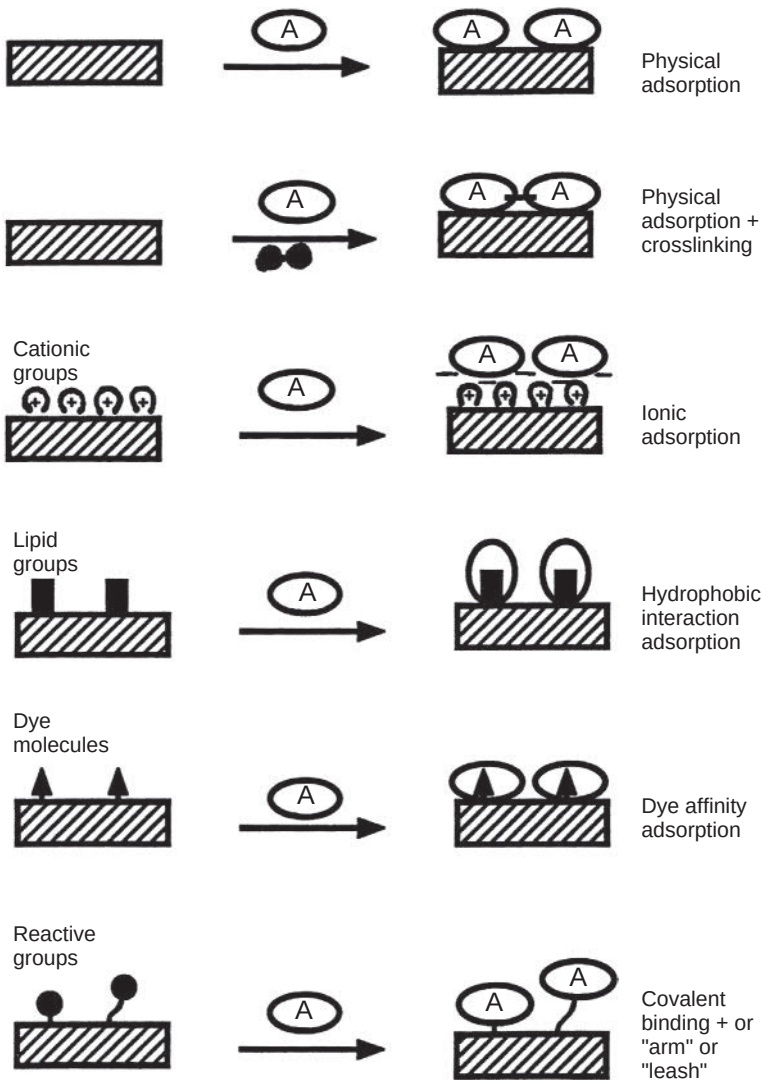


• **Figure 1.4.4.4** Various methods for heparinization of surfaces: (A) heparin bound ionically on a positively charged surface; (B) heparin ionically complexed to a cationic polymer, physically coated on a surface; (C) heparin physically coated and self-cross-linked on a surface; (D) heparin covalently linked to a surface; (E) heparin covalently immobilized via spacer arms; (F) heparin dispersed into a hydrophobic polymer; (G) heparin–albumin conjugate immobilized on a surface (Kim and Feijen, 1985).

immobilization have been developed for this purpose, some of which involve the incorporation of a single amino acid into the biomolecule to be immobilized. For example, Torrance et al. (2006) expressed single chain variable fragment (scFv) molecules with an added cysteine residue at the C-terminus such that the scFv could be oriented uniformly by covalent attachment to a gold surface presenting maleimide groups. This mode of attachment allowed the scFvs to be oriented such that they could sense antigen. In another example, Lee et al. (2009) developed a polydopamine-coated surface and synthesized a model peptide that contained histidine at the N-terminus and lysine at the C-terminus. These researchers demonstrated the ability to control the orientation of their model peptide on the polydopamine surface, as the peptide could be immobilized by either the lysine residue at low pH or the histidine residue at high pH. The addition of an unnatural amino acid can also achieve site-specific biomolecule immobilization. Wu et al. (2015) introduced an unnatural amino acid (*p*-propargylphenylalanine) into the enzyme T4 lysozyme such that the enzyme could be covalently immobilized onto beads presenting an azide group via the Huisgen 1,3-dipolar cycloaddition reaction. The ability to control the enzyme's orientation allowed for enhanced activity and stability when compared to random immobilization. The orientation of an immobilized protein can also be controlled through the incorporation of a peptide tag at a specific site in the protein. For instance, SpyTag forms an isopeptide bond with the protein SpyCatcher (Zakeri et al., 2012). The SpyTag-SpyCatcher system has been used for the presentation of antigens from the surfaces of virus-like particles for use in a malaria vaccine (Brune et al., 2016). Another application of peptide tags used for biomolecule immobilization are the tags used in Sortase A-mediated ligation, where proteins with an "LPXTG" tag are covalently linked to pentaglycine in the presence of Sortase A. Ito et al. (2010) used Sortase A-mediated ligation to covalently attach the C-terminus of glycosyltransferases, which aid in the process of glycosylation, onto a support to enhance the stability and activity of the glycosyltransferases. In addition to controlling the orientation of immobilized proteins, it can also be desirable to control their density. To accomplish this, Hodneland et al. (2002) controlled the density of phosphonate-terminated "capture ligands" that were incorporated into self-assembled monolayers. Since these capture ligands were capable of forming a covalent adduct bond with cutinase, this system enabled the controlled immobilization of any protein fused with cutinase.

It is evident that there are many different ways in which the same biomolecule can be immobilized to a polymeric support. Heparin and albumin are two common biomolecules that have been immobilized by a number of widely differing methods. These are illustrated schematically in Figs. 1.4.4.4 and 1.4.4.5.

Some of the major features of the different immobilization techniques are compared and contrasted in Table 1.4.4.7. The important molecular criteria for



• **Figure 1.4.4.5** Schematic of various ways that albumin may be immobilized on a surface. Albumin is often used as a "passivating" protein to minimize adsorption of other proteins to a surface.

TABLE 1.4.4.7 Biomolecule Immobilization Methods

Method	Physical and Electrostatic Adsorption	Cross-Linking (After Physical Adsorption)	Entrapment	Covalent Binding
Ease	High	Moderate	Moderate to low	Low
Loading level possible	Low (unless high S/V)	Low (unless high S/V)	High	(Depends on S/V and site density)
Leakage (loss)	Relatively high (sensitive to ΔpH salts)	Relatively low	Low to none[a]	Low to none
Cost	Low	Low to moderate	Moderate	High

S/V, Surface area/Volume.
[a]Except for drug delivery systems.

successful immobilization of a biomolecule are that a large fraction of the available biomolecules should be immobilized, and a large fraction of those immobilized biomolecules should retain an acceptable level of bioactivity over an economically and/or clinically appropriate time period.

Conclusions

It can be seen that there is a wide and diverse range of materials and methods available for immobilization of biomolecules and cells on or within biomaterial supports. Combined with the great variety of possible biomedical and biotechnological applications, this represents a very exciting and fertile field for applied research in biomaterials.

Introduction

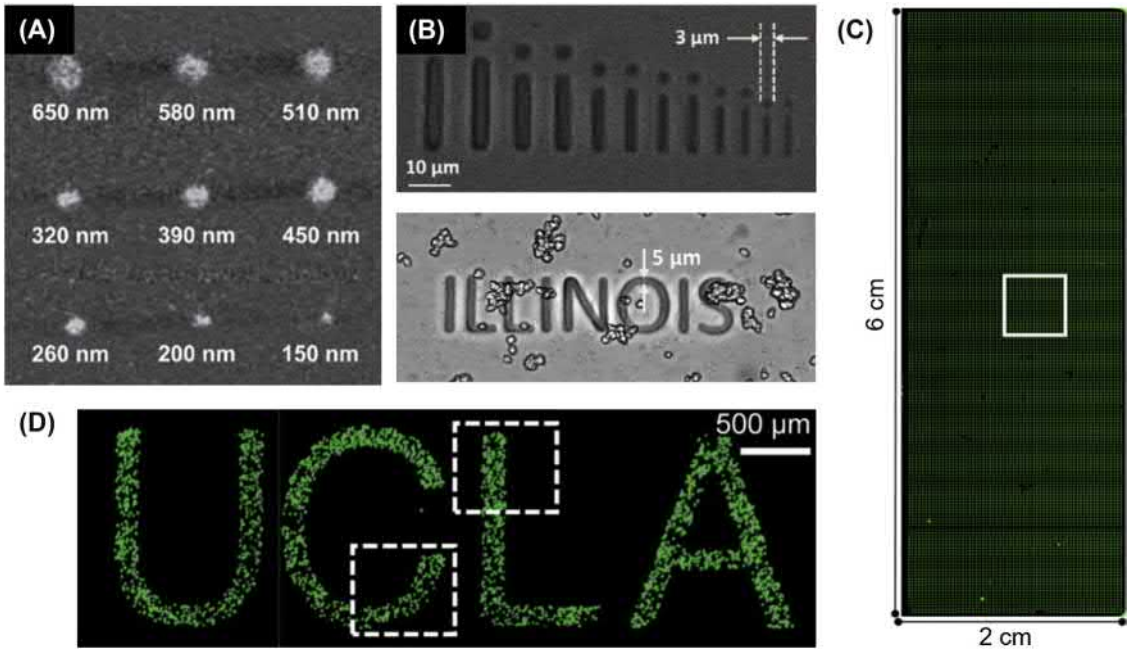
Surface patterning is the use of surface modification methods to create chemically or physically demarcated regions on a surface. The art of patterning surfaces has a long history; the recent antecedent methods to pattern biomolecules are derived, in part, from the microelectronics industry (Geissler and Xia, 2004; Whitesides et al., 2001). As hand-wiring small, complex electronic devices became increasingly difficult, new methods were developed to pattern substrates such that many electrical components and interconnects between the different components of these devices could be created on the surface of a relatively large substrate in a batch process. These processes that have been instrumental to the development of all modern electronic devices have been driven by a set of technologies to create micro- and nanoscale features on the surface of semiconductors that are collectively and somewhat loosely termed "photolithography." Seen from this broader perspective, it might be argued that the conceptual origins of many of the techniques used to pattern biomolecules and cells on surfaces extend back to the preindustrial era, to techniques that were developed to print on paper and textiles, such as block printing, screen printing, lithography, and batik.

This chapter focuses on surface patterning in the realm of biomedical research. Many surface patterning techniques, especially photolithography, have become important tools for biomedical research. The unique demands of biomedical research— for example, soft hydrated materials such as proteins and hydrogels in an aqueous environment—impose a special set of requirements and constraints on patterning methods. The goal of this chapter is to familiarize the reader with various surface patterning techniques, and how these techniques can be applied for biomedical research. First, we discuss important figure-of-merit of patterning methods that allow various methods to be compared with each other, and allow a user to identify which patterning method is most appropriate for a specific application. We then discuss various types of patterning techniques, and follow up with a brief conclusion.

Some chapters in this textbook that provide background information for this chapter include Surface Properties and Surface Characterization (Chapter 1.2.4), Non-fouling Surfaces (Chapter 1.4.3A), and Physico-chemical Surface Modification of Materials Used in Medicine (Chapter 1.4.2). However, as will quickly become apparent, this chapter has implications for many other chapters in the book.

Common Concerns In Biomolecular Surface Patterning

Surface patterning is carried out for a wide variety of reasons and, in turn, the ultimate goal of the patterned substrate defines a set of constraints or concerns that dictate how the fabrication process should be carried out. Surface patterning within the scope of biomaterials research is largely focused on the patterning of biomolecules or cells. Listed below are important figures-of-merit (FOMs) and concerns that typically need to be considered in patterning biomolecules or cells. We also briefly discuss how the selection of an appropriate patterning methodology for a particular application is not usually influenced by a single FOM, but is dictated by the technique that offers the best combination of several FOMs.



• **Figure 1.4.5.1** Examples of resolution and contrast in surface patterning. (A, B) Features of different sizes created with (A) a submicron high-resolution patterning technique (Lee et al., 2006) and (B) a relatively lower-resolution technique (Raman et al., 2016). (C) An example of a high-throughput process, enabling the patterned protein deposition on the whole glass slide (Foncy et al., 2018). (D) High-contrast cell patterning with nearly zero background defects (Wu et al., 2018).

Resolution

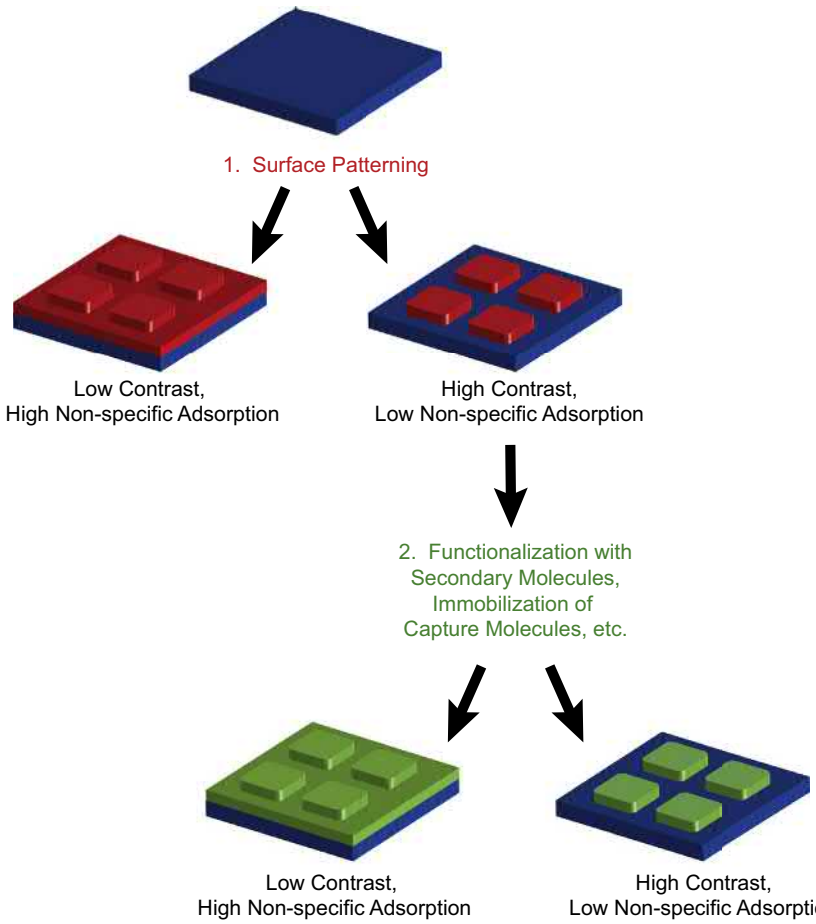
Resolution refers to the smallest feature size that can be reliably created by a patterning technique. Although the resolution of new techniques is constantly pushed toward smaller feature sizes and finer control, it is also beneficial to know what range of feature sizes a particular technique is capable of producing. Fig. 1.4.5.1A and B show examples of different size patterns created with a high-resolution technique, as well as patterns created with a lower-resolution technique that is capable of generating a wider range of feature sizes. The highest resolution is not necessarily better, as the desired resolution depends upon the application. Thus, in order to pattern cells whose dimension is at least several micrometers, a technique with a relatively low resolution in the micrometers range is likely adequate, as long as it can pattern a large enough area, i.e., has a high enough throughput, which is discussed next.

Throughput

While resolution refers to the smallest possible feature size that can be created by a patterning technique, throughput is a measure of the surface area that can be patterned in a given time. Therefore, the throughput of a patterning technique is especially important for its use in device manufacturing because scalable production is largely dependent on the length and time scale on which the patterned substrates can be manufactured (Fig. 1.4.5.1C). Although the different types of patterning techniques are discussed later in this chapter, here we briefly discuss a few patterning methods to illustrate throughput considerations. Direct-write or "on-the-fly" types of patterning methods are those that use a stylus and ink to pattern a surface. These techniques usually provide precise control over the patterning process and finer feature sizes—often sub-100 nm—than some other printing methods, such as microcontact printing, and can often create arbitrary feature shapes. Rapid patterning over large areas (i.e., greater than hundreds of square micrometers), however, is challenging for most variants of this type of patterning. On the other hand, techniques based on printing using a mask or master can readily pattern large areas of a surface quickly (in the order of seconds to minutes), but may only be able to access certain shapes of features (e.g., circles, lines, or squares), and may have limited resolution (i.e., on the micrometer scale or greater).

Contrast

Contrast is the degree to which the patterned subjects are distinguishable from the background substrate (Fig. 1.4.5.1D). In patterning biomolecules, contrast is generally defined as the surface density of the patterned biomolecule of interest relative to biomolecules that might adventitiously be bound outside of the pattern as a consequence of the patterning process and use. Contrast in patterns of biologically active molecules, such as enzymes, cytokines, or antibodies, can be assessed by measuring the activity of the patterned molecules. For example, the pattern of biomolecules can be visualized by another molecule having a high affinity to patterned biomolecules and a fluorescent, radioactive, or plasmonic tag. Biomolecular patterning often involves



• **Figure 1.4.5.2** Contrast and nonspecific adsorption. Maintaining contrast during patterning of biomolecules often requires that: (1) the patterned materials have low nonspecific adsorption to the background substrate; and (2) any molecules used in subsequent steps (functionalization of pattern with secondary, reporter molecules, immobilization of antigens or capture molecules from solutions, etc.) also have low nonspecific adsorption to the background.

molecules with a functional activity or activity that is difficult to assess in biochemical methods. In these cases, pattern contrast is often visualized by employing a secondary processing step for pattern visualization. For example, contrast in patterned peptides that act as cues for cell adhesion can be visualized by exposing the pattern to cells in culture, and the degree of cell confinement in patterned region is an indirect measure of the fidelity and contrast of the pattern.

Contrast in biomolecular patterning is heavily dependent on surface properties of not only the pattern itself, but also of the background. Biomolecular patterns are often exposed to solutions that can contain complex mixtures of proteins and other molecules in the course of their use, and most surfaces are particularly prone to nonspecific and irreversible adsorption of poorly defined proteins. Thus, maintaining contrast in biomolecular patterning usually involves some sort of passivation step to prevent two sets of undesirable events: (1) adsorption of the molecule to be patterned on the unpatterned background regions; (2) adsorption of biomolecules—that are to be subsequently exposed to the patterned surface—onto the patterned features or the background regions of the surface (Fig. 1.4.5.2).

Nonspecific adsorption should be minimized to ensure high specificity and can be reduced by methods of varying degrees of complexity. Perhaps the most common and simplest way to reduce nonspecific adsorption is to block the background surface by absorbing known proteins, such as bovine serum albumin (BSA), under the assumption that deposition of a known protein will prevent further nonspecific adsorption of unknown, undefined biomolecules to the substrate. However, it has been shown that proteins can adsorb onto a BSA layer (Hyun et al., 2001), so that this strategy, despite its widespread use, is of limited utility. A more effective way of reducing nonspecific adsorption is to create a "nonfouling" surface. Nonfouling surfaces are typically defined as surfaces that are resistant to the protein adsorption and cell adhesion. A widely used method to create a nonfouling surface is to generate a dense layer of polyethylene glycol (PEG) on the surface. The layer of PEG molecules effectively creates a hydrated steric barrier on the surface and interferes with protein adsorption to the surface. Since the degree of protein resistance is correlated to the density, length, and molecular architecture of PEG molecules on the surface (Kingshott et al., 2002; Li et al., 2005;

Michel et al., 2005), various synthetic strategies for creating PEG nonfouling surface have been developed (Elbert and Hubbell, 1998; Herrwerth et al., 2003; Huang et al., 2001; Hucknall et al., 2009b; López et al., 1992; Ma et al., 2004), which is discussed in detail in Chapter 1.4.3A Non-fouling Surfaces.

Bioactivity

Preserving the biological activity of a biomolecule during the patterning process is a significant and nontrivial concern. Many patterning processes, especially those that are adapted from the semiconductor processing industry, can involve exposure of the surface to extreme environments, such as high vacuum, extreme temperatures, and nonaqueous conditions, which can denature or degrade biomolecules. Methods that are compatible with aqueous conditions and ambient temperature are hence preferable when deciding upon a method to pattern a biomolecule—especially proteins—on surfaces, as they are especially prone to denaturation compared to other biomolecules, such as peptides and oligonucleotides.

Shelf-Life and Durability

The shelf-life and durability of the pattern over time is another consideration when choosing a patterning methodology. This is particularly important in the case where patterns are intended for use in diagnostic or point-of-care devices. The ultimate convenience in such a situation would be one where a fully functional pattern can be stored in ambient conditions for an unspecified period of time until used. When "soft-wet" materials—including hydrated polymers, proteins, and cells—are patterned, the exposure of these materials to vacuum, high temperature, or extremes of pH becomes a critical and often limiting issue, because many of them are easily degraded, destroyed, or irreversibly denatured under such conditions. For this reason, special care is needed to ensure that all biological components involved in the patterning process are maintained in a functional state. Ensuring this may involve strategies, such as sealing the devices in a hydrated environment or an inert atmosphere during storage, taking preconditioning steps to prepare the surface prior to analysis, or integrating rinsing steps into the analysis scheme. In some instances, it may be necessary to create the patterned substrates that act as a template for patterning biomolecules, and then functionalize the pattern with the biomolecule of interest, on demand, immediately prior to its use.

In addition, it is also useful to know how long a pattern will stay intact under the end-use conditions. This is especially important for substrates patterned for cell growth or for implantation into the body that need to retain functionality for extended periods of time. For this reason, researchers often report an FOM that alludes to the life of the pattern by stating, for example, how long the cells remain confined to the pattern in cell culture.

Patterning Techniques

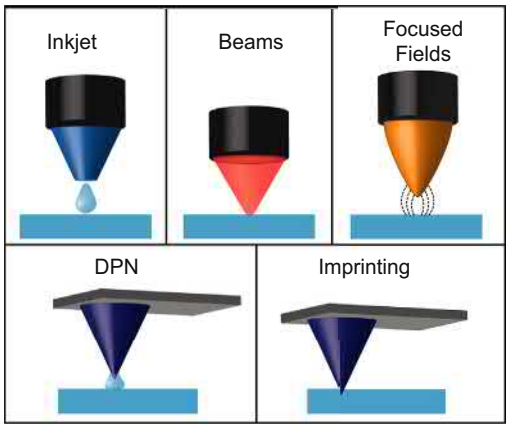
The number of surface patterning techniques is growing steadily, with new publications that present novel patterning schemes or variants of existing methodologies. This chapter seeks to provide a short discussion of the different categories of patterning techniques, and within each category points out some interesting examples; this chapter is not an exhaustive compendium of all patterning techniques. Although much of the overall organization or structure of this section owes an intellectual debt to the excellent and comprehensive review by Geissler and Xia (2004), the content of this section places greater emphasis on patterning for biomedical applications.

Direct-Write Patterning

In direct-write patterning techniques, patterns are fabricated by serially scanning a patterning element across a substrate. Direct-write patterning is a useful method because patterns of arbitrary feature shape and size—within the resolution limit of the technique—can be fabricated on-the-fly, in a process analogous to writing with a pen. In addition, direct-write patterning can generate extremely high-resolution features with great spatial accuracy. The drawbacks of direct-write patterning techniques are that they are typically slow, low-throughput, and not particularly suitable for large area patterning, because of the need to serially write the pattern. This limitation can be addressed, at the cost of greatly increased complexity of the instrumentation, by using independently actuated pens. Several direct-write techniques are described next and are grouped by the type of "pen" that is used to write the pattern (Fig. 1.4.5.3).

Writing With A Stylus

This section describes direct-write patterning techniques that use a rigid stylus as a writing tool. Inkjet printing, dip-pen nanolithography (DPN), and nanoshaving (also called nanoengraving) are typical examples of direct-write methods. DPN and nanoshaving can all produce very



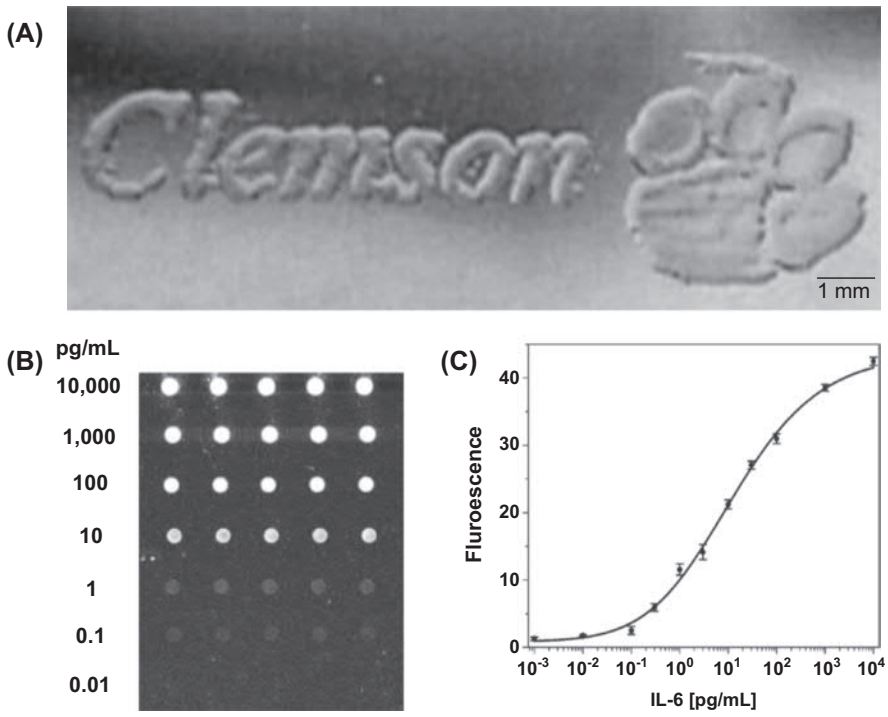
• **Figure 1.4.5.3** Types of direct-write patterning. Inkjet, beams, focused fields, dip-pen nanolithography (DPN), and imprinting.

high-resolution, sub-100 nm features, because they write patterns using very fine tips of an atomic force microscope (AFM) with nanometer-scale positional control. In contrast, inkjet printing produces coarser features, with the best lateral resolution of ~10 µm, and more often in the order of 100 µm. Inkjet systems, however, can be easily multiplexed, making them very attractive for patterning biomolecules in diagnostic devices, such as protein and DNA microarrays.

Printing With Inkjets, Quills, and Pins

Inkjet printing refers to any method where liquid is pumped through a nozzle and dispensed onto a substrate in a defined pattern. Inkjet printers deliver liquid solutions as small droplets (typically 10–20 pL) that are either electrostatically charged and guided via electric fields or generated on demand by thermally or piezoelectrically triggered pressure pulses (Derby, 2008). Inkjet nozzles are usually very small (20–30 µm in diameter), which enables them to be mounted on nozzle heads that can be interfaced with computers to control the fabrication of patterns. The resolution limit of inkjet printing is in the range of tens of micrometers, and is limited by the droplet volume, droplet spreading on the substrate (which varies depending on the ink and the surface), and other mechanical factors. Some useful features of inkjet printing are: (1) patterning is contact-free and can be performed under ambient conditions on a range of solid substrates; (2) the method has high positional accuracy; (3) multiplexed printing is easily accomplished by use of multiple nozzles and/or nozzle heads; and (4) high-throughput patterning over large surface areas can be accomplished by robotic automation.

Inkjet printing of biomolecules has gained popularity, in part due to the simplicity of the technique and the availability of inexpensive printers. Thomas Boland's research group demonstrated that low-cost consumer inkjet printers could be adapted to print "biological inks" with their demonstration of the inkjet printing of proteins (Pardo et al., 2002), cells (Cui et al., 2010), and bacterial colonies (Xu et al., 2004). Fig. 1.4.5.4A shows a "living advertisement"—a colony of bacteria printed in the shape of a university logo—created by Boland and co-workers. Automated robotic inkjet printing systems designed to print "biological inks" such as DNA (Bumgarner, 2013; Hughes et al., 2001), peptide (Lin et al., 2016), or proteins (Delaney et al., 2009; Weissenstein et al., 2006) are typically called microarray printers, which are much more sophisticated and expensive than consumer-grade inkjet printers. These systems are often self-contained in an environmentally controlled chamber, and can accommodate complex protocols involving delivery of multiple biological inks as well as rinsing steps. Since the advent of the human genome project and the rise of genomics, microarrays have migrated into other fields because they provide a convenient, high-throughput, and multiplexed methodology to characterize biomolecules in proteomics (Caiazzo et al., 2009; Nagaraj et al., 2008) and diagnostics (Delehanty and Ligler, 2002; Orchekowski et al., 2005). However, much of this work used arrays fabricated not by inkjet printers, but by pin-based arrayers in which pin arrays are dipped into solutions and then contact printed onto a surface, or else arrays that were fabricated by on-chip, photolithographic synthesis of spatially addressable arrays of



• **Figure 1.4.5.4** Inkjet printing. (A) Bacterial colonies printed in the shape of a university logo by a modified consumer-grade inkjet printer (Xu et al., 2004). (B, C) An inkjet-printed antibody microarray (Hucknall et al., 2009a). (B) An image of interleukin-6 (IL-6) antibody microarray on a nonfouling surface. (C) Dose–response curve for an IL-6 antibody microarray interrogated from whole blood.

oligonucleotide probes, such as the Affymetrix oligonucleotide array technology. For example, Ashutosh Chilkoti's group has used inkjet-printed microarrays of antibodies on a nonfouling polymer brush for the detection of multiple protein analytes from serum and blood with a femtomolar limit-of-detection (Figs. 1.4.5.4B and C) (Hucknall et al., 2009a).

Dip-Pen Nanolithography

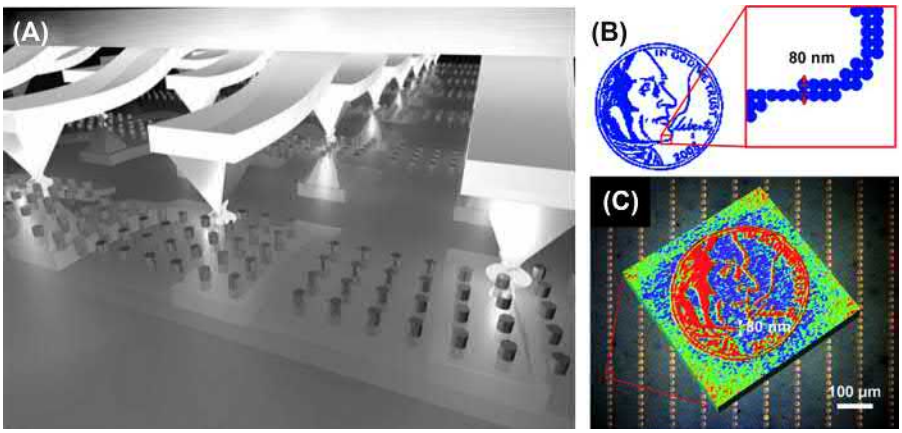
Dip-pen nanolithography (DPN) is the nanoscale equivalent of writing with a quill. In DPN, AFM probes are coated with a liquid-based ink and then scanned along a substrate to write a pattern of the ink. The ink solution on the tip forms a small meniscus at the interface between the tip of the probe and the substrate, and this meniscus provides a conduit for transport of biomolecules from the tip to the surface. In this approach, patterning can be achieved either by writing a substance of interest directly from the AFM tip or by patterning functional moieties on the substrate first using the AFM tip and then exposing to a substance of interest for selective attachment to the patterned regions. DPN has been used to pattern alkanethiols (Hong et al., 1999; Piner et al., 1999), as well as a range of biomolecules including DNA (Demers et al., 2002), proteins (Hyun et al., 2004; Lee et al., 2002; Wilson et al., 2001), viruses (Smith et al., 2003; Vega et al., 2005), lipids (Hirtz et al., 2013; Lenhert et al., 2010), and nanoparticles (Santra et al., 2015; Wang et al., 2008) on many different materials including gold, metal oxides, polymers, and graphene. The resolution limit of DPN is on the order of tens of nanometers, and this method can create patterns that extend over several hundred micrometers, which is the limit of most AFM scanners. Single-probe DPN patterning is also relatively low throughput, as it is a somewhat slow and serial patterning technique. For example, in an early report on DPN, 10 min were required to create a $1 \times 1\ \mu m$ feature (Piner et al., 1999). To improve throughput of conventional DPN, multiplexed DPN has been used, where parallel DPN tip arrays are scanned on the substrate simultaneously (Bullen et al., 2004; Lee et al., 2006; Ma et al., 2018). Perhaps the most impressive work to date in this regard is that of Chad Mirkin's group, where 55,000 DPN probes were inked with a thiol solution, and used simultaneously to generate massively high-throughput, high-resolution patterns on gold (Fig. 1.4.5.5A) (Salaita et al., 2006). In this demonstration, the face of Thomas Jefferson from a US five-cent coin was generated in 55,000 duplicates, with each face containing 470 million nanoscale features, in less than 30 min (Fig. 1.4.5.5B and C). See the reviews by Salaita et al. (2007) and Wu et al. (2011) for further information on DPN.

Nanoshaving and Nanografting

Nanoshaving or nanoengraving is a term used to describe the process of scratching patterns in thin molecular layers, such as SAMs, on a bulk substrate with a hard stylus (e.g., an AFM probe) (Liu et al., 2008). These techniques have similar advantages and limitations as DPN, as the patterning mechanism is very similar. Arbitrary patterns in the molecular layer are engraved by dragging the probe on the surface. A subsequent process can be used to functionalize the exposed, underlying substrate with a secondary molecule. For example, nanoshaving has been used to selectively scrape a protein-resistant SAM on the substrate, which is then exposed to a protein solution. Nanopatterns of proteins including antibodies and ECM proteins are formed on the surface as the proteins are adsorbed only to the scraped regions of the substrate that are no longer protein-resistant (El Zubir et al., 2013; Staii et al., 2009). Nanografting—a variant of nanoshaving—involves scratching the surface in the presence of a secondary molecule with high affinity to the underlying substrate, so that the secondary molecule fills in the regions that are already cleared away by the scanning probe. Nanografting has also been used to create nanopatterns of enzymes (Jang et al., 2002), antibodies (Bano et al., 2009; Hu et al., 2005; Wadu-Mesthrige et al., 2001), and DNA (Josephs and Ye, 2010; Liu et al., 2002).

Writing With Beams

This section describes patterning methods that scan an energetic beam over a surface to create a pattern. The spatial



• **Figure 1.4.5.5** High-throughput, high-resolution dip-pen nanolithography (Salaita et al., 2006). For details of figures, please see the text.

resolution of this class of patterning techniques is generally limited by the spot size of the beam. Beams of photons are used for patterning in direct-write photolithography, and thus the spot size (and hence, resolution limit) is set by the optical diffraction limit, which is ~200 nm. The diffraction limit can be overcome by using near-field methods, such as scanning nearfield lithography, to create features with the dimension down to several tens of nanometers. Direct-write photolithography is particularly conducive to patterning biomolecules, as it is compatible with aqueous conditions. Electron beam lithography and focused ion beam lithography represent two other methods in this class of patterning techniques that have higher spatial resolution than conventional far-field photolithography. Electron beam lithography and focused ion beam lithography, however, usually require high vacuum and dry samples, which can be a serious impediment to patterning biomolecules.

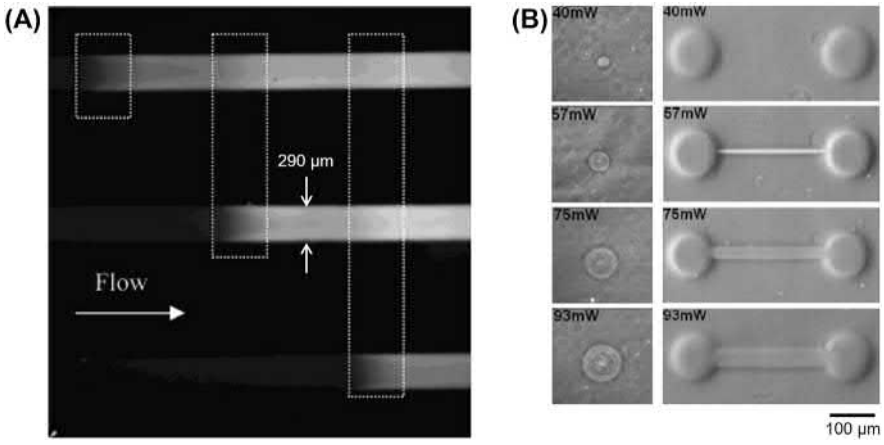
Direct-Write Photolithography

In direct-write photolithography, a beam of focused light is used to pattern a substrate directly. Light is focused into small spots using conventional light optics, and patterns are formed by photochemical or physical modification of the surface. The resolution of features that are patterned with conventionally focused light is governed by the optical diffraction limit, which is roughly half of the wavelength of the light used for excitation (Dunn, 1999). Thus, patterns formed by focused light typically have a minimum feature size of several hundred nanometers. Although broadband light sources can be used for direct-write photopatterning, lasers are more commonly used for this application, because they provide high-intensity beams of a single wavelength which allow precise control of specific photochemical reactions.

Patterning with light is generally performed using a photochemical mechanism—where the chemical reactivity of the substrate is altered by light—or a mechanism that locally induces a physical topological change on the underlying substrate. In direct-write patterning via photochemistry, light is used to locally activate photoactive molecules on the substrate either in the presence of a substance of interest to form a pattern simultaneously or followed by an additional step where a substance to be patterned is exposed to the substrate. Photochemical patterning with light has been widely used to create patterns of proteins on a substrate. For example, Holden and Cremer used a laser to pattern enzymes directly within flow channels (Fig. 1.4.5.6A), a methodology that can be applicable to lab-on-a-chip devices (Holden et al., 2004). In another patterning methodology using light, a laser is used to pattern substrates by physically altering a localized region of a substrate. This type of patterning is conceptually similar to engraving with AFM tips, with the only difference being that the substrate materials—polymers or resins—are ablated, melted, or deformed due to the high energy of the focused laser spot, instead of being physically excavated (Joglekar et al., 2003). For example, Nielson and Shear used a high-energy pulsed laser to ablate pores in a membrane where cells are cultured and which separates adjacent flow channels (Nielson and Shear, 2006). They showed that the pores created well-defined reagent streams and dosed cells with precisely located chemical gradients. In another example, Yasuda's group used a focused infrared laser beam to photothermally etch agarose microchambers stepwise for the controlled network formation of cardiomyocytes and neurites and for use in toxicity testing (Fig. 1.4.5.6B) (Kaneko et al., 2015, 2007; Suzuki et al., 2005; Suzuki and Yasuda, 2007).

Electron Beam Lithography

Direct-write electron beam lithography (EBL) uses similar patterning principles as that of patterning with focused light. However, in EBL, a focused electron beam (e-beam) is used as a stylus to write patterns on an e-beam-sensitive material. Since the e-beam radiation is of a much shorter wavelength than that used in direct-write photolithography, the spatial resolution of EBL is superior compared to direct-write



• **Figure 1.4.5.6** Direct-write photolithography. (A) Patches of enzymes (locations indicated by dashed boxes in the figure) patterned within flow channels produce fluorescent products when exposed to fluorogenic reagents (Holden et al., 2004). (B) Microstructures are created on the agar layer by photothermal etching using infrared focused laser beam (Kojima et al., 2003).

photolithography. For this reason, EBL is a very powerful technique for creating patterns at the nanoscale, with feature sizes of 10–100 nm (Ducker et al., 2008; Schmelmer et al., 2007; Steenackers et al., 2007). Although EBL has several limitations of low throughput, high cost, and limited applicability to biological molecules, EBL is considered useful largely as a method for high-resolution fabrication of nanoscale patterns over a small area. As biological molecules generally do not remain functional in high vacuum and are vulnerable to e-beam radiation, substrates are typically first patterned by EBL and then exposed to a biological molecule of interest for selective attachment to the patterned features (Rundqvist et al., 2006; Schlapak et al., 2012; Schmelmer et al., 2007; Steenackers et al., 2007). An elegant example of EBL patterning is the work done by Heather Maynard's group, where multicomponent protein patterns were fabricated by e-beam-induced cross-linking of functionalized PEG molecules. These functional PEG patterns were then used to immobilize proteins via specific binding interactions between the soluble proteins and the ligands presented by the PEG patterns (Fig. 1.4.5.7A) (Christman et al., 2009). In a more recent approach, they demonstrated a one-step protein patterning using a trehalose glycopolymer resist, which is cross-linked by the e-beam and protects the embedded proteins from denaturation during a high-vacuum, high-energy EBL process (Fig. 1.4.5.7B).

Focused Ion Beam Lithography

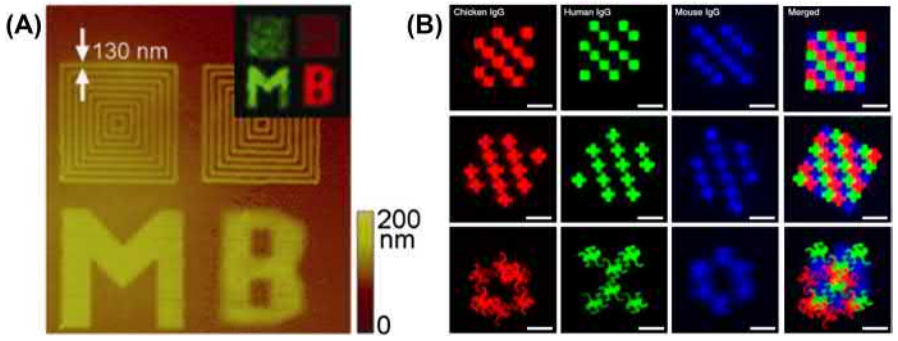
A focused ion beam (FIB) can also be used for direct-write patterning. FIB patterning is similar to EBL in its advantages and limitations; however, FIB patterning makes use of high-mass ions, such as gallium ions, as the energy carriers instead of electrons in EBL. FIB patterning is an inherently destructive process, as the bombardment of a surface with ions causes atomic sputtering from the surface. For this reason, FIB is typically used as a milling technique to engrave a surface with submicrometer size features. For example, Hill et al. used an FIB to selectively sever a metallized protein-based wire to eliminate current flow in microelectronics (Hill et al., 2005). FIB can also be used to sputter metals onto a surface, which makes FIB useful in repairing integrated circuits (Reetz et al., 1997).

Writing With Fields

Direct-write patterning with fields includes scanning electric and magnetic fields across a substrate to form a pattern. Features generated by direct-write electric field scanning typically have a lower spatial resolution than that attainable with other direct-write techniques. Similar to other scanning techniques, writing with fields is slow and unsuitable for large-area patterning. However, scanning electrodes allow one to perform extremely localized electrochemical reactions. Direct-write magnetic patterning is mostly geared toward data storage and, as it has not been used for sputtering biomolecules, only the underlying principle will be briefly described in this section.

Electric Field

Direct-write patterning with electric fields is accomplished by scanning an electrode near a surface to locally modify the surface using charge or current. Patterning is mediated through a variety of electrochemical processes, which include localized charging, ohmic heating, and redox reactions. Scanning electrochemical microscopy (SECM), which was developed by Allan Bard and co-workers, can be used in a patterning mode to perform localized redox reactions on a surface, resulting in the formation of microstructures (Bard et al., 1990). SECM patterning is performed with ultramicroelectrodes in electrolyte solutions, and has been used to pattern enzymes and SAMs on a surface (Shiku et al., 1997; Wittstock and Schuhmann, 1997). The feature sizes of patterns generated by SECM are typically larger than those created with other types of scanning probe techniques. Scanning tunneling microscopy (STM) and AFM can be used to generate higher resolution features. STM has the highest resolution of all proximal-probe lithography methods, as it can manipulate single atoms (Eigler and Schweizer, 1990; Manoharan et al., 2000), but as it must be operated under high vacuum to achieve atomic resolution, it is of limited utility for biomolecular patterning.



• **Figure 1.4.5.7** Electron beam lithography patterning of multicomponent patterning. Patterning is carried out by (A) two sequential reactions: local e-beam induces cross-linking of reactive PEG molecules and subsequent reaction with proteins (red: streptavidin, green: BSA) (Christman et al., 2009), and (B) one step process where an e-beam cross-linkable resist made of trehalose glycopolymer is used to protect proteins during direct-write patterning (Bat et al., 2015). Scale bars = 25 μm.

Magnetic Field

Direct-write patterning with magnetic fields has mostly been geared toward data storage applications to date, and thus this topic will not be covered in detail in this section other than to provide the reader a basic idea of its underlying physical principle. In direct-write magnetic patterning, an inductive element is scanned above a magnetizable material, such that localized regions of the surface become magnetized. These locally magnetized areas allow data to be recorded as bits, and can read the stored data using the same type of inductive element that is used to generate the patterns. For more information on magnetic direct-write patterning, see the review papers by Chou (1997).

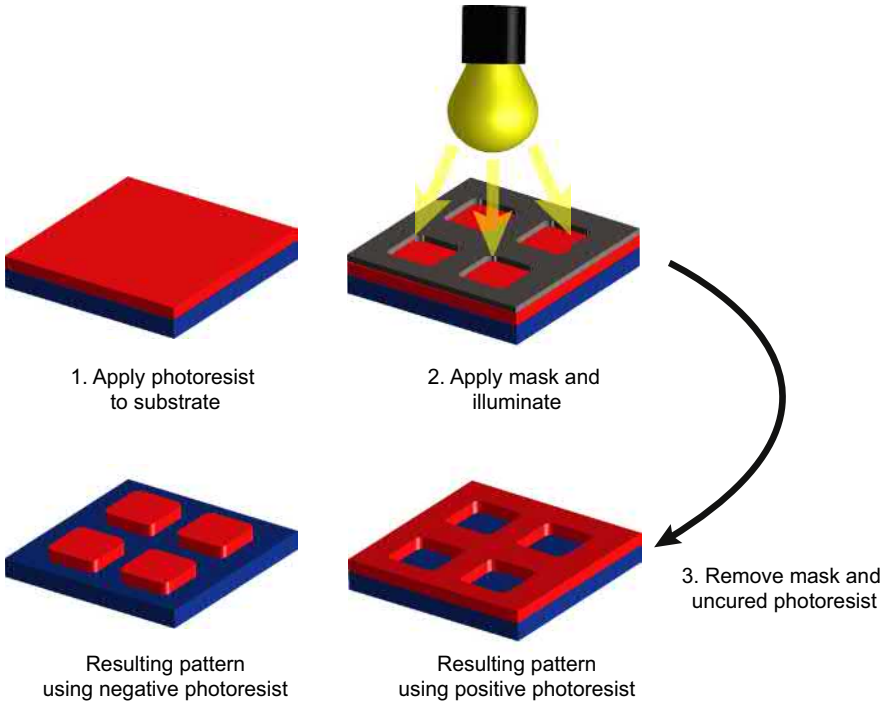
Patterning With Masks

Patterning with masks is a highly developed form of patterning, as it has been the core technology of the microelectronics industry. Because of its sophistication and maturity, it has also been extensively adapted for the patterning of biomolecules and cells. A mask is broadly defined as a template that can spatially modulate a field or beam radiation that passes through it, or a template that physically protects spatially defined regions of the underlying substrate from exposure to inks or etchants. Patterning with light, generally called photolithography, is the most common form of patterning using masks, even though photolithography can be performed in a maskless, direct-write manner, as described previously. Mask-based patterning can also be performed with radiation (other than light), liquid inks, or with chemical or biological etchants. Mask-based patterning is powerful and versatile for the following reasons: (1) large areas—typically 4–6-inch wafers—can be rapidly patterned in batch mode, which makes it a high-throughput patterning technique; (2) spatially intricate patterns can be fabricated, the limitation of which is the design of the mask; and (3) layered features can be fabricated by performing multiple patterning steps in succession, each with a different etching or deposition step. With advances in light sources and optics, the spatial resolution of mask-based approaches is in the sub-100 nm regime (Goodberlet, 2000; Totzeck et al., 2007).

Photolithography With Masks

In photolithography, a mask can be any material that has optically transparent and opaque regions. Masks can be rigid, such as those fabricated out of metal or printed on quartz glass, or they can be fabricated on flexible substrates such as transparencies. The critical requirement of a mask-based photolithographic patterning process is that light must pass through spatially defined regions of the mask and lead to the formation of a pattern that conforms to or is dictated by the pattern of the mask, on a substrate that is located below the mask. However, historically, the term photolithography encompasses a set of processes that were derived from the semiconductor industry, which involves more than simply using light and masks to fabricate patterns.

Patterning in photolithography is facilitated by a polymer photoresist that is spin-coated onto a silicon wafer or other substrate. The photoresist is regioselectively activated by light irradiated through a mask and then exposed to a developing solution (Fig. 1.4.5.8) to create a pattern of the photoresist, which is then subsequently processed to create a pattern in the underlying substrate. There are two types of photoresists. (1) For a positive photoresist, the areas that are



• **Figure 1.4.5.8** Mask-based photolithography.

exposed to light become soluble in the developing solution, while the unexposed regions of the photoresist are insoluble in the developing solution. (2) A negative photoresist works on the opposite principle; areas of the photoresist that are exposed to the light will become insoluble to the developing solution, so that incubation in the developing solution dissolves the unexposed regions of the photoresist. The photolithography process is completed by removing portions of photoresist that are soluble to the developing solution and exposing the underlying substrate in a pattern. Removal is usually followed by either an etching step in which the exposed thin metal/oxide films coated on a bulk substrate are dissolved or a deposition step in which metal or other materials are selectively deposited onto exposed regions.

Photolithography can be performed in three modes, depending on the location of a mask relative to the light source and substrate: contact mode, proximity mode, or projection mode. In contact mode, the mask is placed directly on the substrate. Contact mode photolithography produces patterned features at a size ratio of 1:1 relative to the features in the photomask, and thus resolution is limited by the feature size of the photomask. In contact mode, it is essential that the substrate and mask are free of particulate contaminants, as any trapped debris between the mask and substrate will contaminate the pattern and/or damage the mask or substrate. Proximity mode patterning is a variant of contact mode, in that the mask is slightly separated from the substrate along the propagating light axis. Proximity mode photolithography also produces features on the substrate with the almost same size as are patterned on the mask, but the presence of foreign contaminants is not as devastating as in contact mode. In projection mode photolithography, the mask is placed at an image plane that is well-separated from the surface of the substrate along the optical axis that is conjugate to the image plane at the surface to be patterned. Projection mode photolithography can produce a smaller feature size than the original feature in the mask, as optics can be used to project the mask pattern at a reduced dimension on the substrate. Projection mode photolithography also enables higher-throughput processing, as mask alignment can be done quickly and efficiently due to reduced risk of damaging the mask or the substrate.

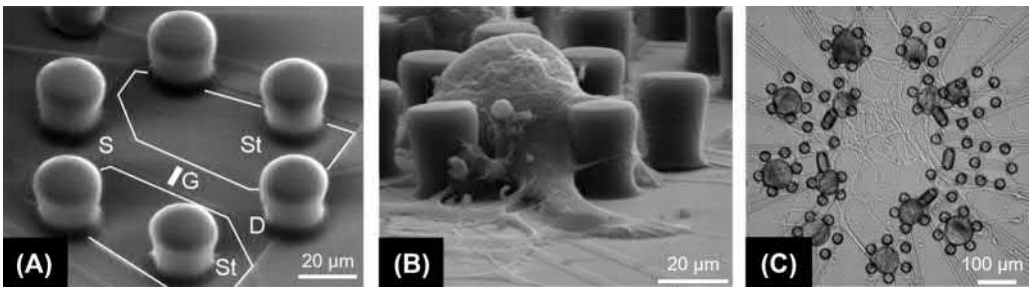
Mask-based patterning has been used to create hydrogel patterns having spatially controlled physicochemical properties, such as mechanical stiffness (Guvendiren et al., 2016; Kirschner et al., 2014; Tse and Engler, 2011), pattern geometry (Jamal et al., 2013; Thérien-Aubin et al., 2013), and type and density of chemical ligands (Azagarsamy et al., 2016; Gramlich et al., 2013). In these applications, light that is applied through the photomask can regioselectively modulate the material property by varying the degree of photochemical reaction, including cross-linking and covalent conjugation. For example, Rape et al. fabricated hyaluronic acid hydrogels using orthogonal light-induced chemistry to present mutually independent and spatially continuous gradients of substrate stiffness and density of biologically active ligand, which enabled the high-throughput study of the synergistic effects of multiple matrix parameters on cell phenotype (Rape et al., 2015).

Deposition/Etching With Masks

As mentioned above, mask-based deposition and etching is often a finishing step in a typical photolithography process. In fact, the actual photolithographic component of the process, as derived from the semiconductor/microelectronics industry, is the creation of a polymer-based mask on a substrate that is meant to protect specific parts of the underlying substrate from a subsequent deposition or etching process. However, it is beneficial to think of masked deposition and etching as standalone patterning techniques, because these techniques extend beyond the context of photolithography. Simply put, mask-based deposition is just like using a stencil to paint letters or graphics on paper, clothing, or any other material. However, other masks can be made of elastomeric polymers, such as poly(dimethyl siloxane) (PDMS), which provide the benefits of watertight seals with the substrate, compatibility with curved surfaces, and flexible peel-off (see Chapter 1.3.2B Silicones). In a deposition process, the mask is applied onto a substrate, the combination of which is then exposed to the material to be deposited. Once the mask is removed, areas protected by the mask remain free of the deposited material. In an etching process, the masked substrate is exposed to a form of radiation or an etching chemical, and the areas exposed through the mask are selectively etched.

Mask-based photolithographic patterning of biomolecules most likely started in the early 1990s with works such as Stephen Fodor's, where arrays of photoactive chemicals were patterned to create microarrays for peptide synthesis (Fodor et al., 1991). Around the same time, photolithographic processes were being used to create patterned surface chemistries to direct cell attachment and growth on substrates (Healy et al., 1994; Lom et al., 1993). This work was initiated by collaborative efforts from Kevin Healy's and Philip Hockberger's groups at Northwestern University. They combined photolithography and organosilane chemistry to produce materials with precise spatial control over presentation of surface chemistry. They went on to use these surfaces to study the mechanisms by which mammalian cells were distributed spatially when exposed to these micropatterned surfaces. These seminal studies established the utility of masked photolithography for biomolecular patterning as an important research tool in biomaterials.

An exciting biological application of mask-based photolithography combined with deposition and etching is the development of microelectronic interfaces for cells. Much work has been done creating electrode arrays and transistor arrays that can stimulate and record from cultures of neuronal cells in an attempt to elucidate brain activity on a single-cell level, as well as from controlled populations of networks of neurons (Fig. 1.4.5.9) (Patolsky et al., 2006; Zeck and Fromherz, 2001).



• **Figure 1.4.5.9** Mask-based photolithography and deposition/etching used to create microelectronics for interfacing with neurons (Zeck and Fromherz, 2001). Polymeric posts are used to confine neurons atop underlying transistors. The device is diagrammed in (A) indicating "stimulator wings" (St) and the transistor components (S, source; D, drain; G, gate). The device is shown with a single cell in (B). An array of devices is used to interface with a neuronal network (C).

Patterning With Masters

A master is a template that is used to replicate patterns, usually in a batch-type process. Rigid masters can be used directly to imprint or emboss patterns on substrates. However, the most widespread use of masters for patterning is to create a mold, typically made of an elastomeric polymer, which is subsequently used to replicate the patterns. Molds are generally fabricated by curing polymeric materials in the presence of the master, which embeds the features of the master into the mold. Once separated from the master, molds can be used for printing features on substrates using molecular inks that are first applied to ink the mold and then are transferred by contact of the protruding features of the mold with a substrate. Alternatively, they can be brought into contact with a substrate surface to create channels of the void features of the mold on a substrate, which can be used for patterning by a liquid ink flowing through the channel. Patterning with masters is a relatively cheap methodology to mass-produce features over large surface areas. In addition, the use of conformal molds allows patterning on curved surfaces (Jackman et al., 1995; Kang et al., 2013; Sun et al., 2015). Typically, patterning with masters does not offer as high spatial resolution as some direct-write patterning techniques.

Imprinting With a Master

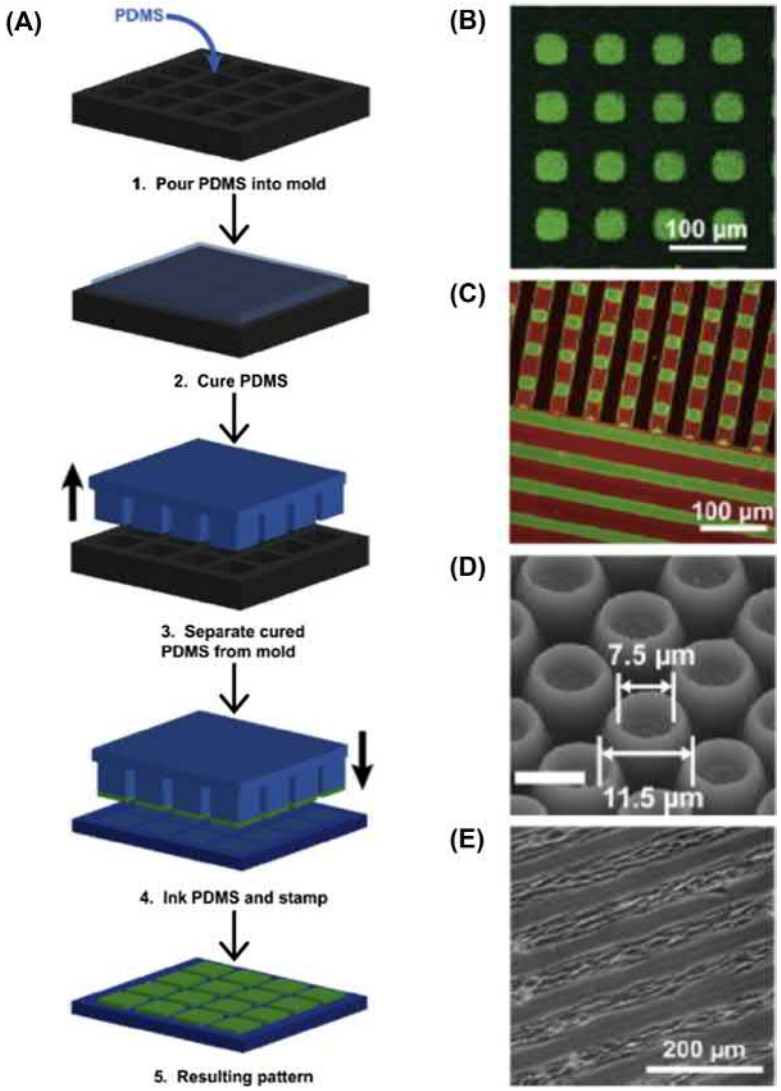
Imprinting or embossing with a master is essentially the same concept as imprinting with a stylus, as described above, except that a master is used to imprint multiple features at once, instead of serially imprinting or writing one feature at a time using a stylus. The master is fabricated from a relatively hard material such that it resists deformation when it is pressed against the substrate. The master contains a rigid relief pattern that molds the substrate into the shape which it is pressed into. Imprinting with a master is used often to pattern polymer films; however, other substrates can be used with the main requirement being that substrate must be soft enough to be deformed by the master (Amin et al., 2016; Yang et al., 2012). The resolution of features obtained from imprinting with a master is dictated by the durability of the master, the physical properties of the substrate, and the mechanical pressure applied during embossing. Feature sizes as small as 10 nm are attainable by imprinting with masters (Guo, 2007; Pandey et al., 2019).

Printing With a Stamp

Printing of patterns using molds is most widely done by soft lithography, a suite of related techniques that generally refers to the use of soft, elastomeric polymer molds to create patterns on substrates. Polymer molds are made by pouring liquid monomer onto a rigid master and then curing it. When separated from the master, the resulting polymer mold retains the topography of the original master. These topographical features are then transferred to the substrate for patterning. Masters can be created using photolithographic techniques, direct-write patterning, or even relatively low-tech methods such as gluing rigid objects together so that they create the desired topological features on the polymer constructs (Allen et al., 2005; Hill and Shear, 2006). The most widely used polymer as a mold in soft lithography is PDMS. PDMS has numerous advantageous qualities (Ruiz and Chen, 2007), some of which include low cost, flexibility, optical transparency, resistance to harsh chemicals (e.g., hydrofluoric acid, which is a popular glass etchant), permeability to biological gases, and tight liquid-sealing to various substrates. The elasticity and adherent nature of PDMS make it an extremely versatile mold, as PDMS molds can remain in close conformation with curved or otherwise nonuniform surfaces, which allows to pattern large surface areas (up to hundreds of square centimeters) with a single mold (Xia and Whitesides, 1998a). See the review from Whiteside and co-workers for the detailed process and applications of soft lithography including microcontact printing and microfluidic systems (Whitesides et al., 2001; Xia and Whitesides, 1998b).

Microcontact Printing: Use of Protruding Features of a Stamp

Printing in the context of soft lithography is commonly referred to as microcontact printing (Fig. 1.4.5.10), where an elastomeric stamp is used to transfer molecular inks from stamp to substrate only on the regions of contact. The feature sizes of patterns range from micrometers to nanometers,

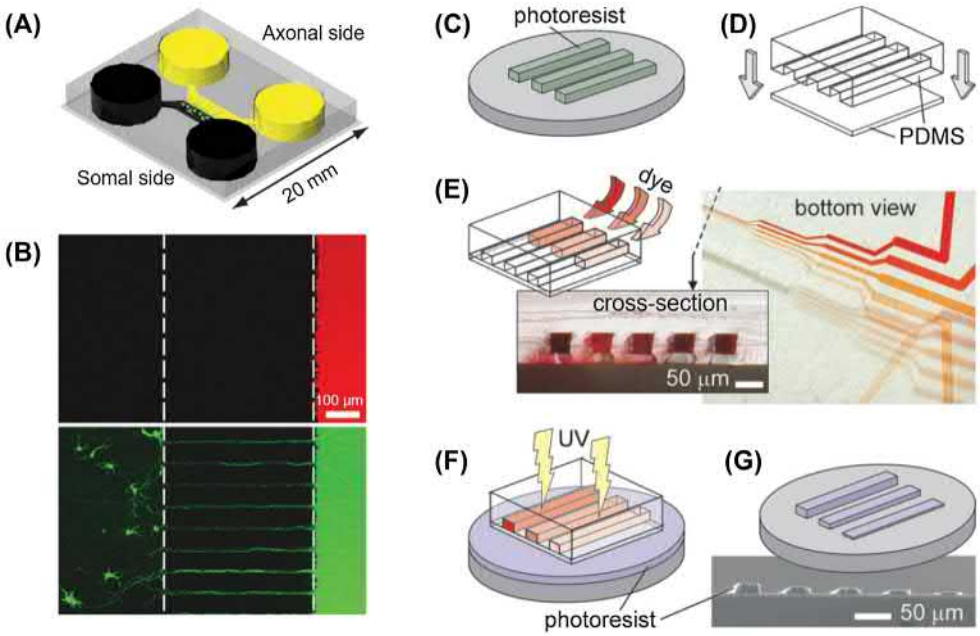


• **Figure 1.4.5.10** Microcontact printing. (A) The typical steps involved in microcontact printing. (B–E) Examples of patterns created using microcontact printing: (B) checkered pattern of fluorescent protein (Ma et al., 2006); (C) multicomponent polymer brush pattern (Zhou et al., 2006); (D) anemone-shaped patterns of stimulus-responsive polymer (Chen et al., 2009); (E) cell attachment on the fibronectin pattern (Hyun et al., 2003).

which are determined by the mechanical properties of the stamp, the deposition conditions (i.e., pressure and duration of application), and the leakiness or spreading properties of the molecular ink during the stamping process (Li et al., 2003; Whitesides et al., 2001; Xia et al., 1997).

Microcontact printing was first demonstrated in the early 1990s by George Whitesides' group at Harvard University (Kumar and Whitesides, 1993). It is benefitted from the fact that alkanethiols have a high affinity to gold and spontaneously form a dense monolayer when in contact with a gold surface. Thus, when a PDMS stamp that is inked with alkanethiol molecules comes into contact with a gold surface, alkanethiols dissociate from the PDMS stamp and self-assemble on the gold. Whitesides' group further demonstrated in the 1990s that the geometrical patterns created by microcontact printing could spatially control the adhesion and spreading of mammalian cells in culture and further direct their function and/or behavior (Lopez et al., 1993; Singhvi et al., 1994). This approach has been expanded to systematically investigate the effect of the size and shape of patterns on the lineage commitment of stem cells (Kilian et al., 2010; McBeath et al., 2004), which revealed the power of micropatterning on the length scale of the cell.

Microcontact printing has been used to include patterning of polymers (Chen et al., 2009; Zhou et al., 2006), proteins (including functional antibodies and enzymes) (Bernard et al., 2001, 2000; Buhl et al., 2015; Ma et al., 2006), DNA (Bernard et al., 2001, 2000; Buhl et al., 2015; Lange et al., 2004; Ma et al., 2006; Thibault et al., 2005), and cells (Foncy et al., 2018; Hyun et al., 2003; Kim et al., 2015) on various surfaces, including glass, silicon, graphene, and metals. In more recent efforts to extend the utility of microcontact printing, various approaches have been developed, including surface modification of PDMS stamps, new polymeric stamp



• **Figure 1.4.5.11** Microfluidic patterning. (A, B) A microfluidic cell culture platform (Taylor et al., 2005). (A) A culture chamber consisting of a PDMS mold containing a relief pattern of somal and axonal compartments, which can fluidically isolate axons of neurons without exogenous neurotrophic factors. (B, top) Fluidic isolation of a dye (shown in red) on the axonal side of the chamber. (B, bottom) Directional growth of axons (shown in green) from somal side to axonal side. (C–G) Use of microfluidic photomasks for photolithography (Chen et al., 2003). Flow channels are created using an elastomeric PDMS mold (D) developed from a photoresist micropattern (C). The channels are filled with fluids of varying concentration of UV-absorbing dye (E), which modulates the light exposure to the underlying photoresist (F) and hence creates patterns that vary in height (G).

materials, and a wide range of inks (Kaufmann and Ravoo, 2010; Perl et al., 2009). For example, polydopamine, which can self-polymerize and is highly adhesive in wet condition, has been used as an ink of stamps, and through secondary reaction created patterns of small molecules, proteins, cells, and nanoparticles on various substrates including silicon, glass, gold, polymers, and hydrogels (Beckwith and Sikorski, 2013; Chien et al., 2012; Lee et al., 2017).

Microfluidic Patterning: Use of Void Features of a Stamp

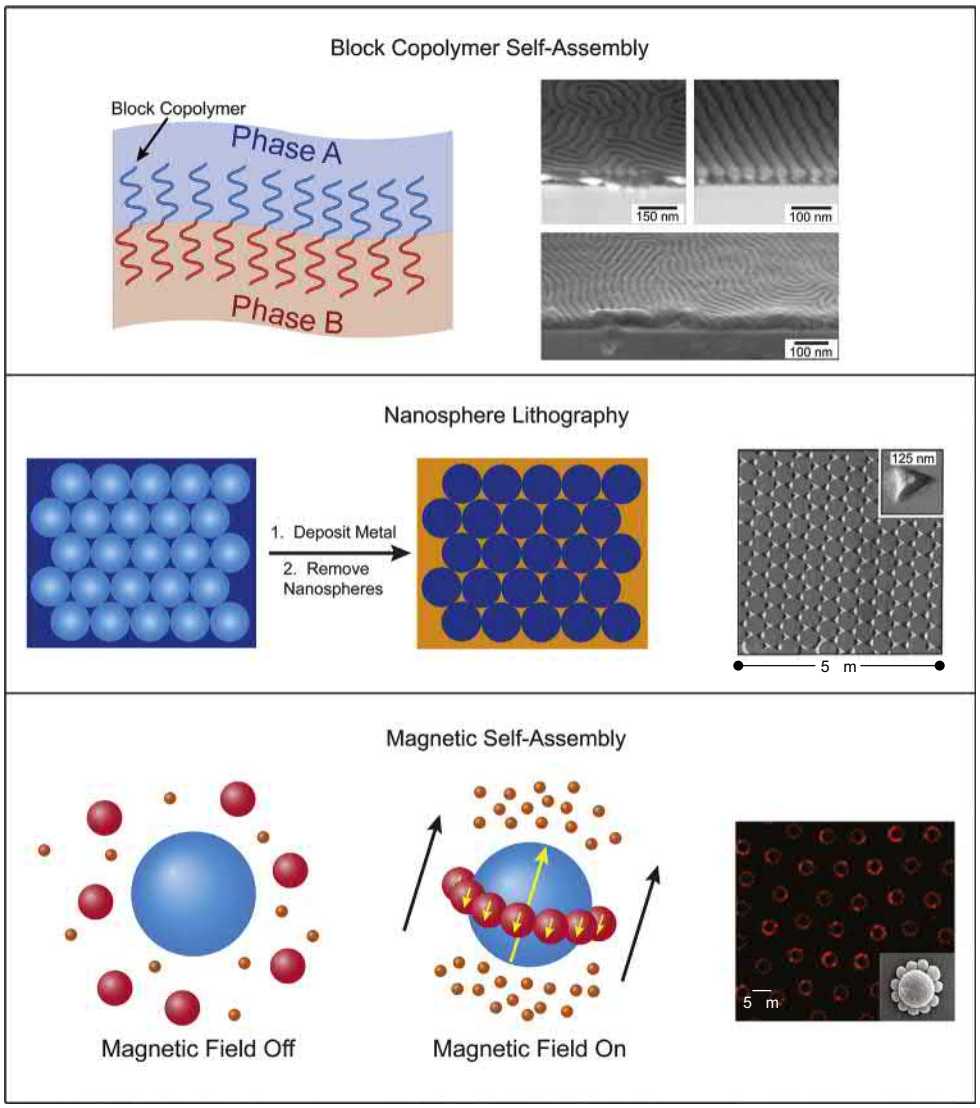
While microcontact printing makes use of the protruding features of a mold, a complementary set of patterning techniques utilizes the void features of the mold (Xia et al., 1997, 1996). When a mold with an engraved pattern is affixed to a substrate, the voids generated between the mold and substrate form empty features or channels that can be filled with liquid to create patterns. In microfluidic patterning, a network of channels is used to deliver liquids to specific locations on a substrate. The channels in a mold can be used to deliver reagents locally to microdevices on microfluidic chips (Fig. 1.4.5.11A and B) (Juncker et al., 2002; Taylor et al., 2005), to deposit biomolecules onto the surface through adsorption and in gradients (Bernard et al., 2001; Dertinger et al., 2002; Fosser and Nuzzo, 2003), to locally dissolve parts of the underlying substrate (Rodriguez et al., 2003), or to serve as a mask for photolithography (Figs. 1.4.5.11C–G) (Chen et al., 2003). Channels can also deliver a polymer solution to a surface in a spatially delimited manner, which is then hardened or cured. Subsequent removal of the elastomeric mold leaves microchannels behind. See the reviews by McDonald et al. (2000) and Sackmann et al. (2014) for a comprehensive review of microfluidic systems.

Patterning by Self-Assembly of Polymers and Colloids

Patterning by self-assembly of polymers and colloids is a powerful technique because, when properly executed, it requires minimal effort to produce the patterns. Self-assembled patterns are created by modulating experimental conditions where intermolecular or interparticle forces cause polymers or colloidal particles to phase separate or aggregate in a spatially defined pattern, driven by minimization of the free energy of the system. Self-assembled patterning can be used to pattern large surface areas with the feature resolution ranging from the nanoscale to the microscale. Three examples of patterning by self-assembly are highlighted in this section: block copolymer self-assembly; nanosphere lithography; and magnetic self-assembly (Fig. 1.4.5.12).

Block Copolymer Self-Assembly

Block copolymer self-assembly is an example of self-assembled patterning at the molecular level at 5–200 nm. A solution of the block copolymer having two or more blocks that are immiscible is deposited onto a surface where it undergoes phase separation as the solvent evaporates. This separation process is



• **Figure 1.4.5.12** Patterning by self-assembly. (Top) Block copolymer self-assembly where nanometer-scale patterns are created due to phase separation between the immiscible blocks of the polymer (Kim et al., 2003). (Middle) Nanosphere lithography where self-assembled, close-packed nanospheres are used as a mask for creating metallic patterns on surfaces (Haynes and Van Duyne, 2001). (Bottom) Magnetic self-assembly where magnetic fields can be used to pattern magnetically susceptible objects (Erb et al., 2009).

thermodynamically driven and then leads to the formation of highly ordered surface patterns with periods in the nanometer length scale that can readily cover large surface areas, although defects are a common problem on larger coverage areas. The nanometer-scale lateral resolution over a macroscopic surface area afforded by block copolymer self-assembly makes it a high-resolution, high-throughput patterning technique (Li and Ober, 2006). Patterns can be controlled by altering a number of variables: the sequence and length of the blocks, the degree of immiscibility of the blocks, the physicochemical properties of the solvent, the ambient conditions during thin film deposition, film thickness, and surface chemistry (Nie and Kumacheva, 2008). Patterned block copolymer films have been developed for the manufacture of integrated circuits and magnetic storage media (Ross and Cheng, 2008; Yang et al., 2013), and have also been used as photonic crystals, optical waveguides, and templates for the growth of inorganic materials (Kim et al., 2005; Shin et al., 2002; Valkama et al., 2004). In directed block copolymer self-assembly, biomolecules are patterned either by self-assembly of block copolymers having chemical ligands (Killops et al., 2012), or by physicochemical incorporation of biomolecules on the self-assembled block copolymer films (Frith et al., 2012; Lau et al., 2008; Shen et al., 2012). For examples of block copolymer patterning, as well as reviews, see references from Ji et al. and Li and Muller (Ji et al., 2016; Li and Müller, 2016).

Nanosphere Lithography

Nanosphere lithography exploits the self-assembly of nanoscale objects to create a periodic pattern or mask. In nanosphere lithography, a solution of relatively monodisperse nanospheres—usually composed of a polymer— is delivered

to a flat substrate. Under specific conditions, the nanospheres self-assemble into a hexagonal, close-packed monolayer as the solvent evaporates, which generates voids between the nanospheres where the underlying substrate is exposed. The nanosphere monolayer is then used as a mask to pattern the underlying substrate. Typically, nanosphere masks are used for selective deposition of substances of interest onto a substrate. After deposition, the nanospheres are removed from the surface, which leaves behind metal surfaces or pyramids in the regions corresponding to the void spaces between the nanospheres. Such selective deposition allows for spatial control over biomolecule incorporation (Li et al., 2013; Malmstro¨m et al., 2010; Valsesia et al., 2008). For a detailed review on nanosphere lithography, see the reviews by Ai et al. (2017) and Haynes and Van Duyne (2001).

Magnetic Self-Assembly

In magnetic self-assembly, nano- to microscale particles with a magnetic susceptibility align or orient themselves in a magnetic field. In one implementation of this approach, magnetic nanoparticles can be located in a pattern on the surfaces under magnetic field, which can then serve as a mask for deposition of proteins or other biological materials (Bardea and Naaman, 2009). Magnetic particles have been attached to cells to enable magnetism-directed cell patterning (Alsberg et al., 2006; Ino et al., 2007). Magnetic ferrofluid can also be used to template the self-assembly of nonmagnetic materials, such as microspheres and cells (Erb et al., 2009; He et al., 2013). In this case, nonmagnetic objects are spatially manipulated by the self-assembly of the magnetic medium surrounding them in response to the external magnetic field.

Dynamic Patterning

The discussion of patterning thus far has mostly related to the formation of static patterns, which offer little control after formation, and often are subject to deformation over time. An emerging field of surface patterning is focused on the creation of dynamic or "smart" patterns. These patterns are designed to respond to external cues in the local environment. Dynamic patterning more relevant to the focus of this chapter is to enable spatiotemporal control over interfaces used to study the cellular microenvironment in microfluidic devices, as well as those used in chip-based diagnostic and sensing devices. Dynamic patterning is particularly important, because most biological processes are triggered by temporal cues in the local environment. For example, intracellular signal cascades that are driven by ligand binding to receptors, clustering of receptors on cell membranes, and remodeling of the extracellular matrix due to mechanochemical stimuli, are all dynamic processes in biology. Engineered dynamic interfaces present a biologically inspired—although abiological—methodology to provide temporal control of biological interactions at artificial surfaces. For example, Milan Mrksich's group has created SAMs on gold that present ligands at the SAM–water interface that can be switched between an active or inactive state via electrochemical signals from underlying gold (Mrksich, 2009, 2002). They have used these surfaces to study the interactions between cell-adhesive ligands and cells during cell attachment to micropatterned surfaces (Yeo et al., 2003) and to pattern the attachment of two different cell populations, which allows for fundamental studies of heterotypic cell–cell interactions (Yousaf et al., 2001).

Three-Dimensional Printing

Three-dimensional printing is a set of rapid prototyping, additive manufacturing techniques, where three-dimensional objects are built by adding successive layers of materials ranging from polymers, metals, ceramics, to proteins and cells (Heinrich et al., 2019; Kyle et al., 2017). A major motivation for the development of three-dimensional patterning is the fact that cells exist in a three-dimensional environment in nature. However, cell-based experimentation in laboratories typically involves cell cultures growing on planar substrates, which is often irrelevant because they do not properly recapitulate the three-dimensional environment where the cells reside in the body. The benefits of three-dimensional patterning are also relevant for the design of biosensor and diagnostics, as control of an extra dimension in device fabrication will enable the design of new sensing architectures and transduction modalities with a potentially improved figure-of-merit. Three-dimensional control of patterning will yield better control over the design of microfluidic lab-on-a-chip devices. In addition, it facilitates rapid and on-demand generation of personalized tissues and organs for applications in tissue engineering and regenerative medicine. Many of the techniques described in the preceding sections can be used for three-dimensional patterning. Three-dimensional printing is a rapidly emerging area of growing interest, and is discussed in detail in Chapter 1.4.8.

Conclusions

Surface patterning has become an extremely important tool in biomedical research. The ability to precisely define the spatial location of biomolecules and/or cells on a surface or in three dimensions provides researchers with a powerful tool to examine the interplay between biomolecules, cells, and artificial materials in a highly controlled spatial environment. This chapter has reviewed a diverse set of patterning techniques, common concerns that need to be addressed in patterning biomolecules and cells, and important figures-of-merit of different patterning methods that should provide the reader with an intelligent stepping stone to sources in the primary literature for a deeper, in-depth investigation of this area of research. This chapter should also help the reader in making a rational decision about the choice of the patterning methodology that is suitable for a particular application. In conclusion, we hope that this chapter will serve as a beginner's guide for those who wish to delve deeper into the field of biomolecular and cellular patterning in two and three dimensions.

Introduction

Biotextiles, or medical textiles, are fibrous fabrics with defined structures generated from synthetic or natural materials that are used for the prevention, treatment, or diagnosis of injury or disease. They are used as biodurable or biodegradable components of implantable medical devices, as part of systems for ex vivo manipulation of media and cells, and for in vitro cell culture and testing. Civilizations dating as early as the ancient Egyptians used natural materials such as flax, silk, linen, and cotton to create sutures and bandages for wound healing. Some natural fibers are still in use today because of their intricate and versatile structures, favorable biocompatibility, and abundance. With advancements in fields such as chemistry, biomaterials, engineering, and manufacturing, it is now common to make synthetic fibers with tailored physical and biochemical properties. Specifically, improvements in spinning and fiber assembly methods and surface modification treatments have led to a rapid growth in new products and applications.

An important application is for surgical use, for example. Implantable and topical biotextiles have become readily available and offer a wide range of structural complexities and utilities. They can be designed to perform multiple functions, including maintenance of comfort and hygiene, prevention of injury and infection, treatment of injury and disease, and even replacement of injured tissues. Examples include vascular grafts, heart valves, ligaments, hernia meshes, and hemostatic wound dressings. Several commercially available biotextiles for surgical applications are listed in Table 1.4.6.1. These applications require careful considerations of biocompatibility and biostability.

The desired properties of biotextiles vary by application. Nonetheless, favorable attributes generally include high surface area, high porosity, lightness of weight, ability to fold, good flexibility, and tunable strength. A high surface area allows for more effective tissue interface, drug delivery, and cell attachment. Lightweight and foldable materials allow for minimally invasive implantation; strong and flexible materials can tolerate damage induced during implantation. On the other hand, thin and porous materials allow for better integration, as cells and surrounding tissue can readily interact with and grow into the material. Biodegradable or

TABLE 1.4.6.1 Examples of Commercial Biotextile Products and Their Clinical Applications

Clinical Application	Devices With Biotextile Component	Polymer	Fiber Structure	Fabric Structure	Resorption Time	Examples of Commercial Products
General surgery	Esophageal stent	PET	Monofilament	Braided	Permanent	Polyflex
		PDO	Monofilament	Braided	11–12 weeks	SX-ELLA
	Hernia repair mesh	PP	Microfiber	Nonwoven	Permanent	Surgimesh
		PP	Monofilament	Warp knit	Permanent	Sepramesh
		PTFE	Expanded film	ePTFE membrane	Permanent	Dualmesh, Dulex
		PGCL and PP	Monofilament	Warp, knit	Partially resorbable	Ultrapro
		PLA	Monofilament	Self-fixation, pile component	Partially resorbable	Parietex ProGrip
		P(GA-*co*-LA-*co*-TMC), P(LA-*co*-TMC)	Multifilament	Knit	3 years	TIGR Matrix
	Permanent suture	Nylon 6	Monofilament	–	Permanent	Ethilon
			Multifilament	Braided	Permanent	Nurolon
		PET	Monofilament	–	Permanent	Surgidac
			Multifilament	Braided	Permanent	Mersilene, Ethibond, Ticron
		PP	Monofilament	–	Permanent	Prolene, Surgipro
		PBT-TMEG	Monofilament	–	Permanent	Vascufil, Novafil
		PVDF-HFP	Monofilament	–	Permanent	Pronova
		Silk	Multifilament	Braided	Permanent	Perma-hand, Sofsilk
	Resorbable suture	Collagen (catgut)	Monofilament	–	70–90 days	Chromic/plain
		PDO	Monofilament	–	180–250 days	PDS
		PGCL	Monofilament	–	90–120 days	Monocryl
		PLGA	Monofilament Multifilament	– Braided	40–70 days	Vicryl Polysorb
		PGA-PCL-TMC-PLA	Monofilament	–	20–60 days	Caprosyn
		PGA-PDO-TMC	Monofilament	–	90–110 days	Biosyn
		P(GA-*co*-TMC)	Monofilament	–	60–180 days	Maxon
	Barbed suture	PDO	Monofilament	–	120–180 days	Quill
		P(GA-*co*-TMC)	Monofilament	–	180 days	V-Loc

bioresorbable textiles are important for devices that serve temporary functions such as injury repair. These properties are influenced by the biotextile manufacturing process, including the choice of material or polymer, as well as the structural design of the engineered textile. In this chapter, the techniques used for fiber and textile productions, which include steps involving polymer selection and fiber formation, fiber arrangement into various textile structures, finishing, and surface modification of the biotextile products, will be described. The effects of various design parameters on the final structures, properties, and performance of biotextiles will also be discussed. Lastly, several major biotextile applications in medicine and their future R&D directions will be examined.

Fiber-Forming Polymers

Characteristics of Fiber-Forming Polymers

The primary building blocks for biotextiles are the individual fibers produced in continuous yarns or fiber fragments. The biochemical nature of these fibers largely dictates their biocompatibility and biodegradation profiles. The basic requirement for polymer selection is the ability to form fibers, meaning the polymer chains need to share several common structural features, which include: (1) intermediate to high molecular weight (approximately 20–250 kDa) so the polymer melt or solution will have sufficient viscosity, (2) linear and ordered structure with absence of bulky side chains or cross-links to facilitate chain alignment and close packing, or crystalline phase formation when solidified from the melt or when precipitated from solution; and (3) interchain interactions that can stabilize closely packed chain segments and crystalline domains, allowing polymer chains to align and slide along the fiber axis during stretching or drawing. Fiber formation parameter requirements may also depend on the chemical structure of the polymers used. For example, a molecular weight ranging from 20 to 30 kDa is sufficient to generate fibers from polymers with strong interchain interactions such as nylon and PET, which can form hydrogen bonds and strong dipole–dipole interactions, whereas higher molecular weight is required for polymers with fewer interchain interactions, e.g., vinyl polymers and aliphatic polyesters. Polymers with a high

degree of crystallinity (e.g., silk, poly(tetrafluoroethylene) (PTFE), poly(vinylidene fluoride) (PVDF), polyethylene, and polydioxanone) typically have greater mechanical properties, and can form fibers more easily too.

The degradation of resorbable polymers in the body is driven by hydrolysis or enzymatic degradation. Biocompatible materials and implants should have nontoxic degradation by-products to minimize inflammatory response in the host. The mechanism of bioerosion and degradation for biotextiles occurs through surface or bulk degradation mechanism until the fiber has been totally resorbed. Examples of natural and synthetic fibers, including those that resorb into the biological environment postimplantation, and their relative resorption times, are provided in Table 1.4.6.2. Permanent synthetic polymers were originally developed for nonmedical applications, such as poly(ethylene-terephthalate) (PET), which was first used in apparel textile fibers. Any additives, stabilizers, and antioxidants that may be cytotoxic for biomedical applications require an extensive cleaning and removal process before being adopted for implantation (Fages et al., 1998; King, 1991).

Common nanofibrous polymers generated via electrospinning are poly(ε-caprolactone) (PCL), polyglycolide (PGA), poly(lactide-*co*-glycolide) (PLGA), and poly(*p*-dioxanone) (PDO), and are shown in Table 1.4.6.3. A wide range of polymers, both natural and synthetic polymers, can be processed into fibers by electrospinning, though most of the spinning conditions are optimized through empirical trial-and-error testing. Typical electrospinning parameters that influence fiber formation include molecular weight, architecture (branched vs. linear), viscosity, and conductivity, as well as other process parameters (temperature, humidity, electrical potential, and flow rate) (Frenot and Chronakis, 2003; Kai et al., 2014). More detailed discussion of the spinning process can be found in the section Electrospinning.

Natural and Synthetic Polymers for Biotextile Production

Natural polymers consist of protein materials such as collagen, elastin, and silk, and polysaccharides such as cellulose, chitosan, chitin, and alginate. These natural polymers, which are isolated from plants and animal tissues (Sionkowska, 2011), feature structural complexity with functional groups that allow for postspinning modifications. Many natural polymers contain functional moieties and bioactivities such as cell receptor binding, growth factor binding and enrichment, and thrombogenic activity, as well as enhanced biocompatibility and biodegradability.

Biopolymers have evolved naturally and are particularly well suited for medical applications. Polysaccharide-based fibers, such as cellulose fibers, have been used as wound dressings and hemostats due to their thrombogenicity. Alginates from algae, chitosan from crustacean shells, and dextran from bacterial fermentation have been used for fabricating surgical sutures and meshes. Proteins, such as collagen, elastin, fibrinogen, and silk have been spun to form fiber structures for tissue regeneration applications, notably for nerve repair and vascular repair.

Compared with natural polymers, synthetic polymers have good mechanical properties and thermal stability, and can be more easily processed into different forms with controlled batch-to-batch consistency during production. Depending on the application, synthetic polymers have high tunability of properties, such as strength, flexibility, degradation rate, resistivity, and chemical inertness. They tend to be cheaper to make into fibers and yarns. The degree of control over synthetic polymers offers great versatility for many different applications. On the other hand, biopolymers typically have better biofunctions and biodegradation property. In some applications, natural–synthetic blends are of interest, as they can combine the advantages of each polymer type while avoiding their disadvantages.

Medical Fibers and Production Methods

Introduction to Textile Fibers

The first step in creating a biotextile medical device is to generate textile fibers. Textile fiber is "a generic term for various types of matter that form the basic elements of fabrics and other textile structures. More specifically, a textile fiber is a unit of matter that is characterized by having an aspect ratio (length divided by width) of at least 100, and which can be spun into yarn or made into a fabric" (American Society for Testing and Mater, 1985).

Fibers can be spun in different ways to create either monofilaments or multifilament yarns, which can vary in length. Yarn size is usually measured in linear density, i.e., the mass in grams of a defined amount of material under standard conditions. In much of the world, the decitex (dtex) is used, which is the mass in grams of 10,000 m of fiber. In North America, linear density is measured in denier, which is the mass in grams of 9000 m of fiber. Linear density is a result of both the cross-sectional area of the fiber and its mass density. As such, it can be related to other properties such as strength and rigidity. For example, Unsealed Gelsoft, a polyester yarn for vascular prosthesis, has a reported linear density of 100 dtex. However, this yarn is a multifilament yarn made of 54 round filaments. Therefore each filament is only 1.9 dtex. Since each individual filament has a lower linear density and smaller diameter, the multifilament fiber is much more flexible than a single 100 dtex monofilament. Flexibility is critical in many medical textile applications, such as tissue scaffolds. Fig. 1.4.6.1 shows scanning electron microscopy (SEM) micrographs of mono- and multifilament woven sutures (Reinbold et al., 2017).

The spinning technique chosen to form fibers and yarns affects properties such as texture, cross-section shape, and size. For example, natural fibers typically have a cross-section

TABLE 1.4.6.2 Examples of Permanent and Resorbable Fiber-Forming Polymers

Polymer[a]	Chemical and Physical Parameters	Construction/Fiber Forms	Applications	Resorption Time
Nylon 6	Thermoplastic Hydrophobic T_m = 220°C T_g = 45°C Crystallinity 50% as spun	Melt spun into monofilaments and multifilament yarns	Sutures (Nurolon; Ethilon)	Permanent
Nylon 66	Thermoplastic Hydrophobic T_m = 265°C T_g = 50°C Crystallinity 50% as spun	Melt spun into monofilaments and multifilament yarns	Sutures (Monosof™; Dermalon™; surglion™)	Permanent
PE	High-density PE (HDPE) Hydrophobic T_m = 125°C Crystallinity up to 85%	Melt spun into fibers for polymer composite reinforcement	Orthopedic and craniofacial implants	Permanent
	Ultrahigh molecular weight PE Hydrophobic T_m = 140–150°C High crystallinity High tensile strength and modulus	Converted to very high tenacity yarn by gel spinning	Ligament prostheses and loadbearing orthopedic composites	
PET	Thermoplastic Hydrophobic T_m = 265°C T_g = 65–105°C 100% amorphous as spun, needs to be drawn and annealed to have crystallinity	Melt spun into monofilaments and multifilament yarns for weaving, knitting, and braiding	Sutures (Mersilene™; surgidac™; Ticron™); hernia repair meshes; anterior cruciate ligament prostheses; heart valve sewing rings; vascular and endovascular grafts	Permanent
PP	Predominantly isotactic Thermoplastic Hydrophobic T_m = 165–175°C Crystallinity 40%–46% Higher fracture toughness than HDPE susceptible to degradation from heat and radiation	Melt spun into monofilaments, hollow fibers or spunbonded and melt blown to nonwoven fabrics	Sutures (Prolene; surgipro); hernia repair meshes; blood filters (e.g., renal dialysis machines)	Permanent
PTFE	Thermoplastic Hydrophobic T_m = 325°C Crystallinity 50%–75% for processed fibers	Melt spun into monofilaments and multifilaments	Sutures; vascular and endovascular grafts; heart valve sewing rings; embolic vena cava filter; anterior cruciate ligaments	Permanent
PVDF	Thermoplastic Hydrophobic T_m = 165–175°C Crystallinity 52%–66%	Melt spun into monofilaments and multifilaments	Sutures (Pronova)	Permanent
Silk	Biocomponent fiber prepared from fibroin protein with sericin sheath Hydrophilic Crystallinity 70% Low elastic recovery	Spun by *Bombyx mori* silkworm with sericin coating; sericin is removed before processing	Sutures (Perm-Hand; sofsilk)	Classified as permanent but known to degrade in 1–2 years
Viscose rayon	First manufactured fiber in 1892 Hydrophobic Crystallinity 33% Decomposition begins at 250°C	Wet spun from alkali sodium cellulose xanthate solution into continuous multifilaments	Wound dressing	Permanent

TABLE 1.4.6.2 Examples of Permanent and Resorbable Fiber-Forming Polymers—cont'd

Polymer[a]	Chemical and Physical Parameters	Construction/Fiber Forms	Applications	Resorption Time
PCL	Thermoplastic Rubbery at room temperature T_m = 58–63°C T_g = –65°C	Melt spun into monofilaments and multifilament yarns; can be electrospun into nanofibers; can be copolymerized with other resorbable polymers	Used as scaffolds in tissue engineering	>24 months
PDO	Thermoplastic T_m = 110–115°C T_g = –10–0°C Crystallinity 55%		Sutures (PDS); intramedullar pins; ligating clips	6–9 months
PGA	Thermoplastic T_m = 225°C T_g = 40–45°C Crystallinity 45%–55% Simplest linear aliphatic polyester rigid		Sutures (Dexon); meshes (for defect repairs and periodontal inserts); used as scaffolds in tissue engineering	6–12 months
PLA	Thermoplastic T_m = 173–178°C T_g = 60–65°C		Stents; drug delivery devices; used as scaffolds in tissue engineering	>24 months
Polyglactin 910 10/90	Thermoplastic T_m = 205°C T_g = 43°C Crystallinity 40%	Multifilament yarns; for weaving, knitting, and braiding	Sutures (Vicryl; Polysorb); meshes	3 months
P(GA-*co*-CL)	Thermoplastic T_g = –43–18°C depending on the copolymer ratio and molecular weight	Monofilament	Sutures (Monocryl)	3–4 months
P(GA-*co*-TMC)	T_m = 206°C T_g = 20°C	Monofilament	Sutures (Maxon)	2–6 months

[a]For abbreviations see Table 1.4.6.1.

diameter of 10–50 µm. However, advancements in spinning methods have allowed for polymers to be spun to sizes below 1 µm, as shown in Fig. 1.4.6.2, thus allowing them to be better suited for more applications due to their high surface-to-volume ratio. In the following sections, various fiber-spinning techniques are described in greater detail.

Melt Extrusion

In melt spinning, or melt extrusion, the polymer is heated above its melting point then extruded through a spinneret. As the polymer resin is extruded, cold air is used to solidify the filaments. A yarn is immediately drawn, lubricated, twisted, and entangled before it is wound onto a bobbin. Yarns can also be texturized by blowing air through the filaments as they are drawn and twisted. A typical setup for the melt extrusion process is depicted in Fig. 1.4.6.3. A spin finish, which is scoured from the textile prior to use, is added as a lubricant to reduce friction and prepare the yarn for the next processes of texturing, weaving, and knitting.

Spinneret design, which includes the number, size, shape, and length of the spinneret's holes, affects fiber properties such as size, number of filaments, and cross-section shape. For example, a multifilament yarn made of 50 filaments can be produced by designing a spinneret with 50 holes. Alternatively, two (same or different) yarns made of 25 filaments each could be plied together to form the 50-filament final yarn. The shape of these spinneret holes determines the fiber's cross-section. A circular cross-section is the most common fiber shape but using other cross-sectional shapes has become more popular as they can change overall fiber properties without having to change the polymer used. Unique shapes such as stars, squares, and trilobes are frequently used to increase the filaments' ratio of surface area to volume. Cross-sectional shape also influences other properties such as strain, yield stress, bending rigidity, and shrinkage.

With melt spinning, the fabrication process is quick and does not require added solvents. However, melt spinning can only be used with thermoplastic polymers, or polymers that are not significantly affected by the melting process.

Wet/Gel Spinning

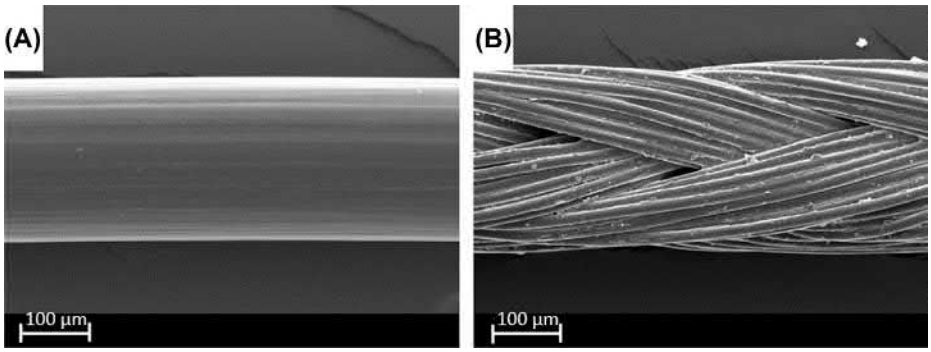
Wet spinning can be used to form fibers from soluble nonthermoplastic polymers or thermoplastic polymers that have

TABLE 1.4.6.3 Representative Polymers used for Electrospinning and Example Spinning Conditions

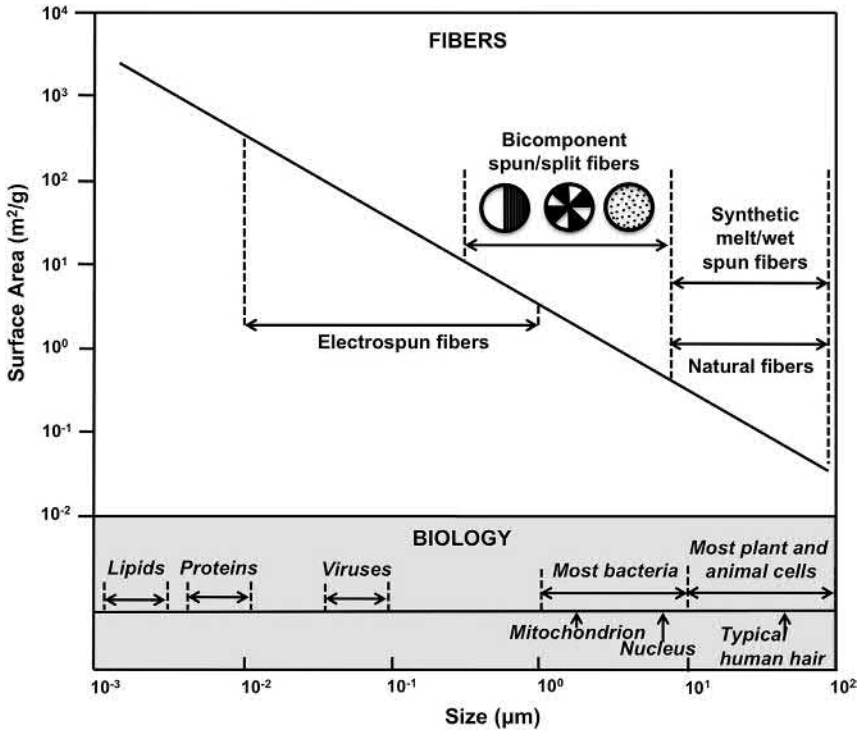
	Polymer	Solvent	Fiber Diameter	Highlight
Synthetic Polymers	PCL	THF/DMF (1:1, w/w); DMF/DCM (1:1)	100–1200 nm	As a semicrystalline polyester, PCL has slow biodegradation rate, high biocompatibility, and good drug permeability
	PLA	Acetone; DCM; chloroform; dioxane; THF; DMF; DMAc	210–1181 nm	
	PLGA	DCM; HFIP; THF; THF/DCM	500–1500 nm	Increasing the ratio of glycolide to lactide in the copolymer increased the rate of degradation
	PLA-*b*-PEG	Acetone	610–1010 nm	PLA-*b*-PEG displays good biocompatibility and increases hydrophilicity compared to pure PLA
	PEG-*b*-PCL	DMF/DCM (1:3, v/v)	350–400 nm	The hydrophilic PEG block increases the water wettability and degradation rate of PCL
	PS	DMF; THF; DMF/THF (1:1, w/w)	600–2760 nm	
	Polyanhydride	Chloroform	80–3200 nm	Polyanhydride undergoes surface erosion and gives steady degradation rate
	PU	HFIP	400–1400 nm	PU has high elasticity and low degradation rates
	PVA	Water; water/DMF (7:3, w/w)	50–1500 nm	PVA undergoes erosion in aqueous media. It has good physical and mechanical properties in dry and crystalline form.
	PVP	Water	190–1500 nm	
	PEO	Water		
Natural polymers	Collagen	HFIP	100–1200 nm	
	Gelatin	Transformation-enhancing activity; hot water	100–340 nm	
	Silk fibroin	Formic acid	30–120 nm	
	Spider silk protein	Formic acid		
	Chitosan	Formic acid		
	Alginate/PEO or PVA (coelectrospinning)	Water		Fiber swelling degree and mechanical property depend on the concentration and type of cross-linking agent used
	Fibrin	Water		Fibrin fiber is formed by cross-linking fibrinogen with thrombin in the presence of Ca ions
	Hyaluronic acid	Water		Hyaluronic acid fibers can be formed by different cross-linking methods

DCM, Dichloromethane; *DMAc*, dimethylacetamide; *DMF/THF*, dimethylformamide/tetrahydrofuran; *HFIP*, hexafluoroisopropanol; *PCL*, polycaprolactone; *PLA*, polylactide; *PLGA*, poly(lactide-*co*-glycolide); *PLA-b-PEG*, poly(lactide-*b*-ethylene glycol); *PEG*, polyethylene glycol; *PS*, polystyrene; *PU*, polyurethane; *PVA*, polyvinyl alcohol; *PVP*, polyvinylpyrrolidone; *PEO*, polyethylene oxide.

excessively high melt viscosity or melting temperature, which prevent use of melt extrusion equipment. The polymer is solubilized in either an organic or aqueous phase, extruded through a spinneret, like melt spinning, and then into a solution of opposite phase or into a cross-linking solution to precipitate fiber as shown in Fig. 1.4.6.4A (Mather and Wardman, 2011). Alternatively, the polymer solution can be introduced directly into the coagulation bath as shown in Fig. 1.4.6.4B. The wet/gel fiber spinning method is applicable for many synthetic and biological polymers, including PCL,



• **Figure 1.4.6.1** Scanning electron microscopy micrographs of (A) a monofilament suture (Resonlon, 75 cm USP 3/0, Resorba (Nürnberg, Germany)) and (B) a multifilament suture (Ethibond Excel, 75 cm, USP 3-0 from Ethicon (Johnson and Johnson Medical GmbH, Norderstedt, Germany)). (Modified from Reinbold, J., Uhde, A.K., Müller, I., Weindl, T., Geis-Gerstorfer, J., Schlensak, C., Krajewski, S., 2017. Preventing surgical site infections using a natural, biodegradable, antibacterial coating on surgical sutures. Molecules 22 (9), 1570.)

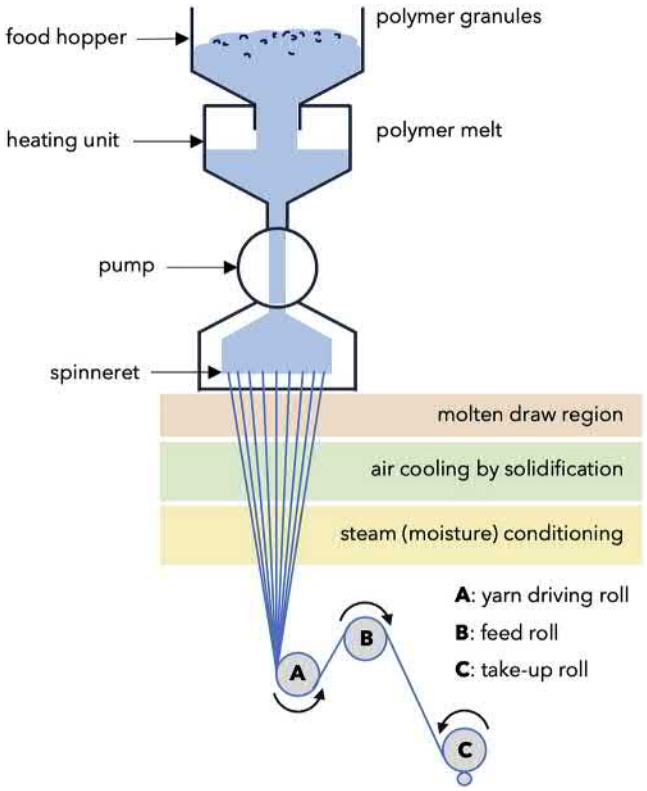


• **Figure 1.4.6.2** Relationship between fiber dimensions and surface area compared to a biological scale.

PLGA, cellulose, chitosan, alginate, cyclodextrin, fibrin, and collagen. For example, polylactide (PLA):PLGA may be solubilized in a chloroform solution and then extruded into an isopropanol solution, which it is not soluble in, to precipitate out a PLA:PLGA fiber (Razal et al., 2009). The resultant PLA:PLGA yarn can then be vacuum dried to remove residual solvent prior to use. In a similar manner, chitosan may be solubilized in acetic acid and wet spun into an ethyl alcohol or phosphate phthalate salt solution as a coagulation bath (Knaul et al., 1999). Fiber precipitation may also be induced through changes in other factors such as temperature or solution pH. Alginate fibers may be wet spun after the polysaccharide is solubilized in a sodium carbonate and caustic soda solution, via extrusion into a hydrochloric acid bath to precipitate fiber.

Electrospinning

Electrospinning is one of the most readily accessible and versatile techniques for producing ultrathin fibers with diameters on the order of hundreds of nanometers to several microns. The term "electrospinning" was coined in 1993 by Darrell H. Reneker for generating fibers from an electrically charged solution (Doshi and Reneker, 1995). Medical use of electrospun fiber mat was first developed as a wound dressing (Tucker et al., 2012). This technology has since been widely adopted for producing nanofiber structures due to its versatility, low cost, and ease of use. Although there are other approaches, such as mechanical drawing and melt blowing, which may be employed for the fabrication of nanofibers, electrospinning remains the most industrially



• **Figure 1.4.6.3** A schematic showing a typical process of melt extrusion for fiber production.

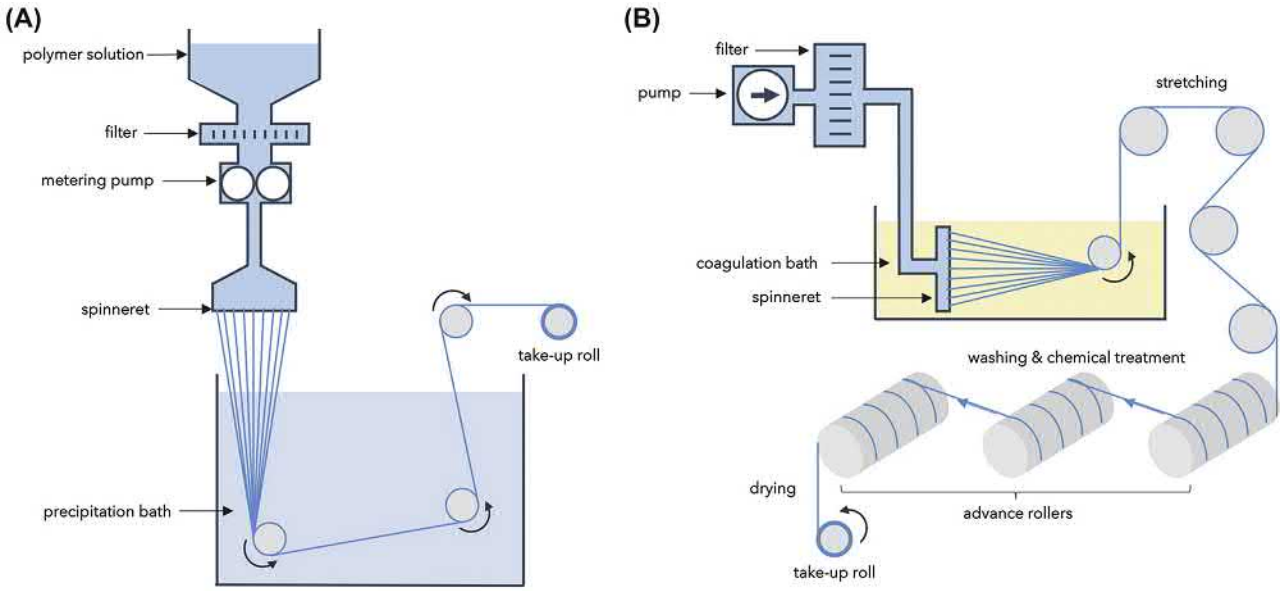
advanced as it is more suitable for producing ultrathin fibers with narrowly distributed diameters (Li and Xia, 2004).

Electrospinning Process and Spinning Parameter Optimization

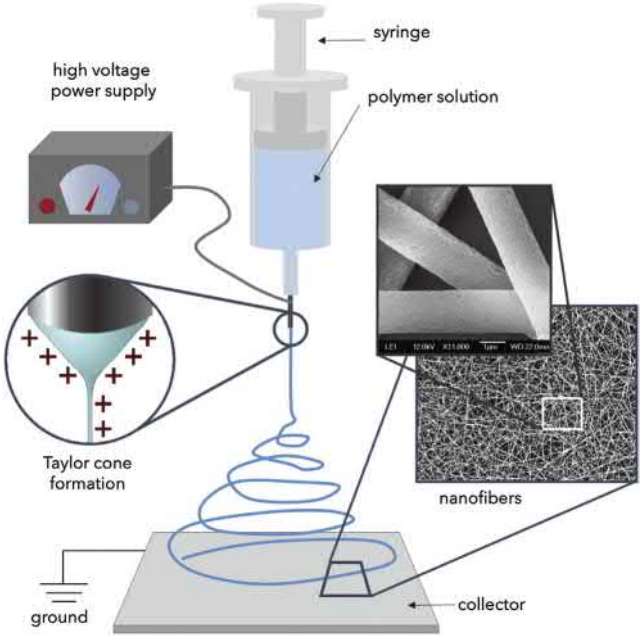
The setup for electrospinning consists of four main components: a high-voltage power supply, a syringe pump, a spinneret, and a grounded collector. When a high-voltage electrostatic field is applied to a dissolved polymer solution or melted polymer fluid with constant flow, a continuous splitting jet is ejected from the Taylor cone to form fibers, which are collected on a grounded, stationary target or rotating drum. The final fiber qualities, such as diameter, surface morphology, and alignment, can be precisely controlled by the properties of the spinning fluids and the parameters of the electrospinning process.

Exploring the formation of a Taylor cone, the most important mechanism of the electrospinning process, can help us understand how these parameters influence fiber quality. The Taylor cone is the critical condition where the shape of such a cone approaches the theoretical shape just before jet formation (Fig. 1.4.6.5) (Li and Xia, 2004; Ghorani and Tucker, 2015). To form a stable Taylor cone, the charged droplets should achieve a balance of surface tension against the electrostatic force. Therefore surface tension-related solution properties and electrostatic force-related parameters are important to consider when controlling fiber quality.

The electrospinning process is regulated by many parameters, broadly classified into solution parameters, process parameters, and ambient parameters. One example of a solution parameter is the viscosity of the spinning solution, which increases with increasing molecular weight of the



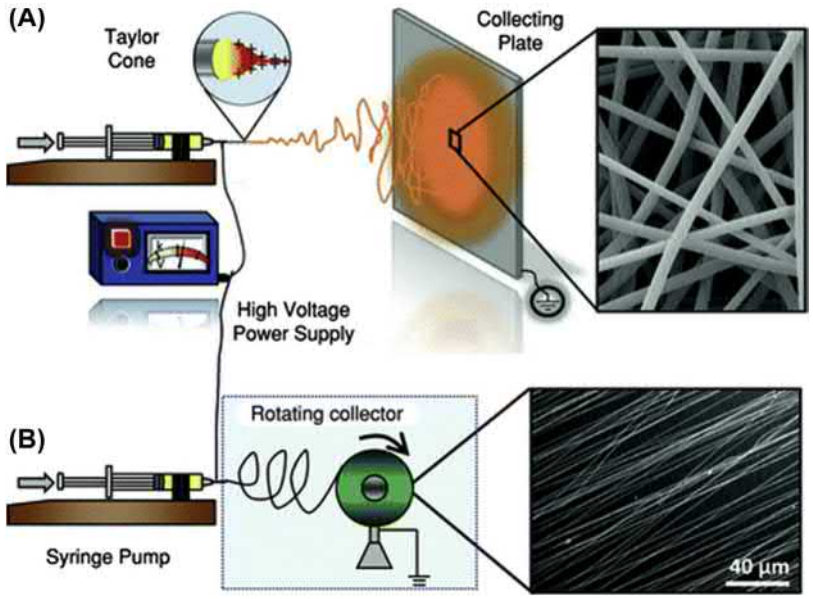
• **Figure 1.4.6.4** Examples of wet/gel spinning processes for fiber production. (A) A schematic showing a dry-jet-wet spinning process where a polymer solution is extruded out through an air gap into a precipitation bath. (B) A schematic showing a coagulation wet/gel spinning process where a polymer solution is extruded directly into a coagulation bath with a miscible but poor solvent for the polymer or with a cross-linking agent. ((A) Modified from Mather, R.R., Wardman, R.H., 2011. The Chemistry of Textile Fibers. R. Soc. Chem.)



• **Figure 1.4.6.5** Schematic illustration of a basic setup for electrospinning. The insets show a drawing of an electrified Taylor cone and a typical scanning electron microscopy image of the nonwoven mat of poly(ether sulfone) nanofibers deposited on a grounded collector. (Modified from Li, D., Xia, Y., 2004. Electrospinning of nanofibers: reinventing the wheel? Adv. Mater. 16 (14), 1151–1170.)

selected polymer or solution concentration and can increase the surface tension, thus leading to larger diameter nanofibers, while the electrostatic force will remain unchanged (Sill and von Recum, 2008). If the selected solvent possesses a higher conductivity, the electrostatic field force of the charged droplets will be greater, thus resulting in a finer jet and a thinner final fiber.

In terms of process parameters, several scaling and operational laws govern the electrospinning process, such as applied voltage, flow rate of solutions, collector distance, and shapes of spinneret and collector. Fiber diameters ranging from submicron to hundreds of nanometers have been reported (Bhardwaj and Kundu, 2010). Generally, a higher voltage results in greater stretching of the solution due to the larger coulombic forces in the jet as well as a stronger electric field. This leads to rapid evaporation of solvent from the fibers and thus reduction in the fiber diameter. Another important process parameter is flow rate. A lower flow rate is desired to get enough time to evaporate the solvent and reduce the fiber diameter. The collector distance also influences the time for solvent evaporation and fiber size distribution. The type of collector employed directly influences the fiber orientation on the collector (Fig. 1.4.6.6) (Lim and Mao, 2009; Mao et al., 2010). For example, if the collector is a roller that is rotating at high speed, the depositing fibers will be stretched, thus resulting in a highly oriented parallel fiber arrangement. Likewise, randomly oriented nanofibers can be acquired if the rotating speed is relatively slow or stationary. Additionally, collectors may be customized to obtain any needed fiber arrangement (Yee et al., 2008).



• **Figure 1.4.6.6** Two different modes of fiber collection in electrospinning, resulting in different nanofiber arrangements. (A) Randomly arranged fiber mat is produced from a polymer solution or melt when the electrospun jets are collected on a stationery grounded plate. (B) Highly aligned fibers are produced when polymer jets are collected on a wheel or frame rotating at a sufficiently high angular velocity. (Modified from (A) Mao, H.Q., Lim, S.H., Zhang, S., Christopherson, G., Kam, K., Fischer, S., 2010. The nanofiber matrix as an artificial stem cell niche. Biomater. Stem Cell Niche, Springer, Berlin, Heidelberg, pp. 89–118. (B) Lim, S.H., Mao, H.Q., 2009. Electrospun scaffolds for stem cell engineering. Adv. Drug Delivery Rev. 61 (12), 1084–1096.)

The dominant ambient parameters that can affect fiber quality during electrospinning are temperature and relative humidity (RH). After a stable polymer solution jet has been initiated from a Taylor cone, solvent evaporation and fiber deposition on the collector surface occur in ambient conditions. An increase in temperature and decrease in RH helps solvent evaporation, therefore decreasing fiber diameter. If the RH prevents solvent evaporation, the final fiber networks will be partially dissolved, thus compromising fiber quality and uniformity (Fashandi and Karimi, 2012; De Vrieze et al., 2009).

Materials Selection for Electrospinning

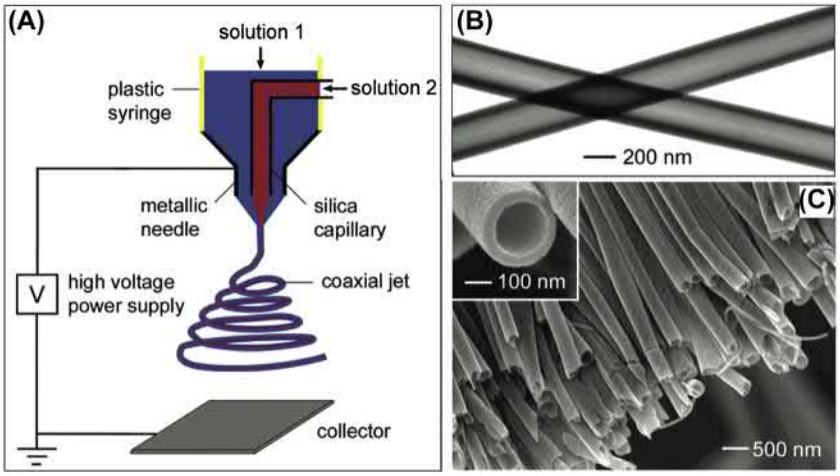
To date, numerous polymer materials have been fabricated into nanofibers through electrospinning. As the electrospinning technique advances, the range of materials that can be electrospun expands too. These materials include both synthetic and natural polymers, multicomponent composite polymers, and inorganic/organic composite materials. Table 1.4.6.3 summarizes the most commonly reported biomaterials used in electrospinning (Yang et al., 2018). Among them, electrospun fibers made from biodegradable polymers, including synthetic polyesters (PGA, PLA, PLGA, and PCL) and natural polymers (collagen, gelatin, silk fibroin, chitosan, and alginate), have garnered strong interests for their potential applications in regenerative medicine (Chong et al., 2007; Zhang et al., 2005). Their tunable degradation properties also allow for potential utilities in delivery of bioactive agents to control tissue regeneration or therapeutics. For example, a local anesthetic-eluting suture system, which combines the function and ubiquity of the suture with locally controlled release properties of a biodegradable polymeric matrix, was prepared by using PLGA fibers (Weldon et al., 2012). Fibrous electrospun scaffolds with distinct alignment topography may guide cell migration, topography, differentiation, and growth of seeded or recruited cells (Qian et al., 2018).

Coelectrospinning

Bicomponent or multicomponent electrospun fibers can be generated for special applications. Coaxial electrospinning has been developed for preparing fibers with a core–shell or hollow structure, and emulsion electrospinning can be utilized to fabricate fibers with an embedded second component with mismatch solvent compatibility. For core–shell spinning, a spinneret fabricated from two coaxial capillaries is required, where two spinning solutions are fed into the outer and inner capillary separately. If the viscosity of the outer solution is high enough to form a stable Taylor cone, then a core–shell nanofibrous structure will eventually form, regardless of the viscosity of the inner solution, as shown in Fig. 1.4.6.7 (Hudecki et al., 2017; Sun et al., 2003). If the core component contains a bioactive agent, this core–shell nanofiber structure is capable of delaying and extending its release duration (Jiang et al., 2005). It is also possible to generate bicomponent nanofibers by electrospinning an emulsion using a typical single-nozzle spinning setup. Due to the phase separation between the oil and water phases of the emulsion, nanofibers with discontinuous phases can be generated as a result of agglomeration of droplets in the emulsion jet (Yarin, 2011).

Centrifugal Electrospinning

Centrifugal electrospinning (CES) has been developed to overcome several limitations of the electrospinning method,



• **Figure 1.4.6.7** (A) Schematic illustration of a coaxial electrospinning setup for generating nanofibers having a core–sheath. The spinneret was fabricated from two coaxial capillaries, through which two feed solutions were simultaneously spun to form a continuous, coaxial jet. (B) Transmission electron microscopy image of two as-spun hollow fibers when a heavy mineral oil was used as a core solution and then extracted with octane after spinning. The walls of these tubes were made of a composite containing amorphous TiO_2 and polyvinylpyrrolidone. (C) Scanning electron microscopy image of a uniaxially aligned array of TiO_2 (anatase) hollow fibers. (Modified from Li, D., Xia, Y., 2004. Direct fabrication of composite and ceramic hollow nanofibers by electrospinning. Nano Lett. 4 (5), 933–938.)

such as low production yield and limited scalability in producing aligned fibers. Major equipment for CES includes a power rotation unit, high-voltage generator, spinning unit, and collection unit. The CES technique combines the centrifugal, electrostatic, gravitational, and auxiliary forces acting on the initial jet. When the combination breaks through the jet surface tension and viscous resistance, the jet is fully stretched out, forming ultrathin fibers. During the spinning, multiple formulations could be infused into the system and expelled via a rotating spinneret at a speed from the order of several hundred rpm to thousands of rpm (Mehta et al., 2019). Highly aligned PVDF, polyethylene, and chitosan fibers have been prepared by using a centrifugal electrospinning system (Edmondson et al., 2012).

Hydrogel Fiber Spinning

Hydrogels are particularly important biomaterials for cell delivery and growth, with highly porous and hydrated structures. A hydrogel can be chemically modified to incorporate cell-binding motifs and differentiation factors, while physical properties can be tuned through cross-linking type and density to provide a biomimetic microenvironment to support cell proliferation and differentiation (Hsieh et al., 2010).

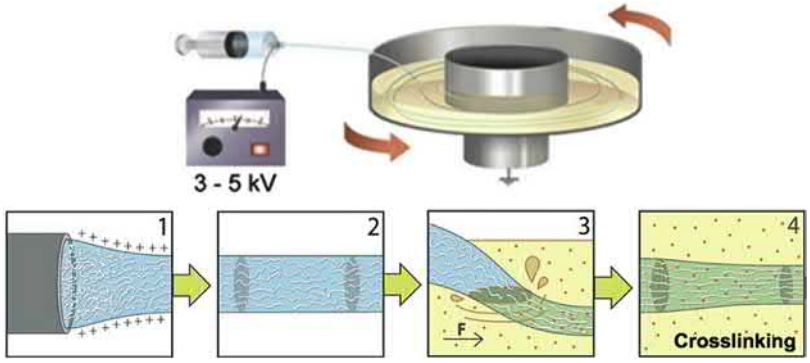
Hydrogel nanofibers can be generated via electrospinning through spinning of a highly hydrophilic polymer that is cross-linked into a swellable network. For example, gelatin methacrylate nanofibers can be electrospun and then cross-linked into a hydrogel network when exposed to ultraviolet light in the presence of a photoinitiator (Sun et al., 2017). Hydrogel nanofibers produce highly extracellular matrix (ECM)-like structures capable of supporting endothelial cell and dermal fibroblast adhesion, proliferation, and migration throughout scaffolds to facilitate improved vascularization (Benton et al., 2009).

Alternatively, wet-spun fiber can also be formed through a modified electrospinning technique to produce molecularly aligned hydrogel fibers (Fig. 1.4.6.8). The use of aqueous-based solutions enables incorporation of cells in situ during the fiber-forming process and induces alignment of cells on the fiber surface (Zhang et al., 2014). Biologically derived polymers, such as fibrin, alginate, or collagen, are used to generate fibers with this technique. Several methods of cross-linking are possible with this hydrogel fiber-forming method, including use of thrombin in the collection solution when forming fibrin fibers to mimic physiological blood coagulation or the use of calcium ions to rapidly induce ionic gelation of alginate to form fibers. Fibers produced with this method have been used to improve muscle regeneration in preclinical volumetric loss defect models (Gilbert-Honick et al., 2018a,b), while hydrated fibrin yarns have been used to study the effects of curvature on microvasculature formation and microvascular cell organization in vitro (Barreto-Ortiz et al., 2013, 2015).

Surface Functionalization

The surface chemistry of biomedical fibers plays a major role in affecting how well cells or proteins may bind to a fiber surface. Surface functionalization can be used to achieve a desired biological response or avoid an adverse response, such as increasing cell adhesion or decreasing complement deposition. Generally, surface functionalization methods can be divided into physical and chemical methods.

Physical vapor deposition (PVD) and plasma surface treatment are common physical methods used for modifying surface chemical compositions of polymer fibers. The most common PVD processes are sputtering and evaporation, which utilize a physical vapor to deposit a specific functional film onto the surface of the target substrate under a vacuum (Zussman et al., 2006). Plasma treatment is another commonly used physical surface functionalization method that employs a charged plasma to activate the target surface. For example, electrospun PCL nanofibers treated with O_2 and N_2 plasma at very low pressures will



• **Figure 1.4.6.8** Electrospinning of hydrogel fibers where biological polymer is solubilized in aqueous solution and dispensed from a syringe tip into an electric field (1). The electric field induces alignment of the polymer chains within the polymer jet (2), which is rapidly cross-linked as mechanical strain is applied upon landing in a rotating cross-linking bath (3), capturing the aligned polymer chains into a hydrogel fiber (4). (Modified from Zhang, S., Liu, X., Barreto-Ortiz, S.F., Yu, Y., Ginn, B.P., DeSantis, N.A., Gerecht, S., 2014. Creating polymer hydrogel microfibres with internal alignment via electrical and mechanical stretching. Biomaterials 35 (10), 3243–3251.)

have abundant hydrophilic functional groups that form on the surface, such as –OH, –COOH, and $–NH_2$ depending on the plasma selection (Formica et al., 2016).

There are many chemical methods for the surface functionalization fibers. For example, various types of cross-linkers and cross-linking techniques can be used based on the functional groups on the polymer and the extent of properties to be improved (Reddy et al., 2015). Glutaraldehyde is a widely used chemical cross linker, because of its high chemical reactivity of the aldehyde groups towards amino and hydroxyl groups found in natural polymers (Lai, 2014). Apart from glutaraldehyde, chemicals including carbodiimide, epichlorohydrin, and sodium metaphosphate, have also been used for surface functionalization (Hennink and van Nostrum, 2012). For polymers without reactive functional groups, surface-grafting methods can be adopted to modify the surface property of the fibers. For example, electrospun poly(ether sulfone) fibers can be surface grafted with poly(acrylic acid), which can then be converted to amino or hydroxyl groups through surface reactions. These surface functionalities have been shown to markedly influence hematopoietic stem cell phenotype maintenance during the expansion culture (Chua et al., 2006, 2007; Das et al., 2009).

Textile Structures

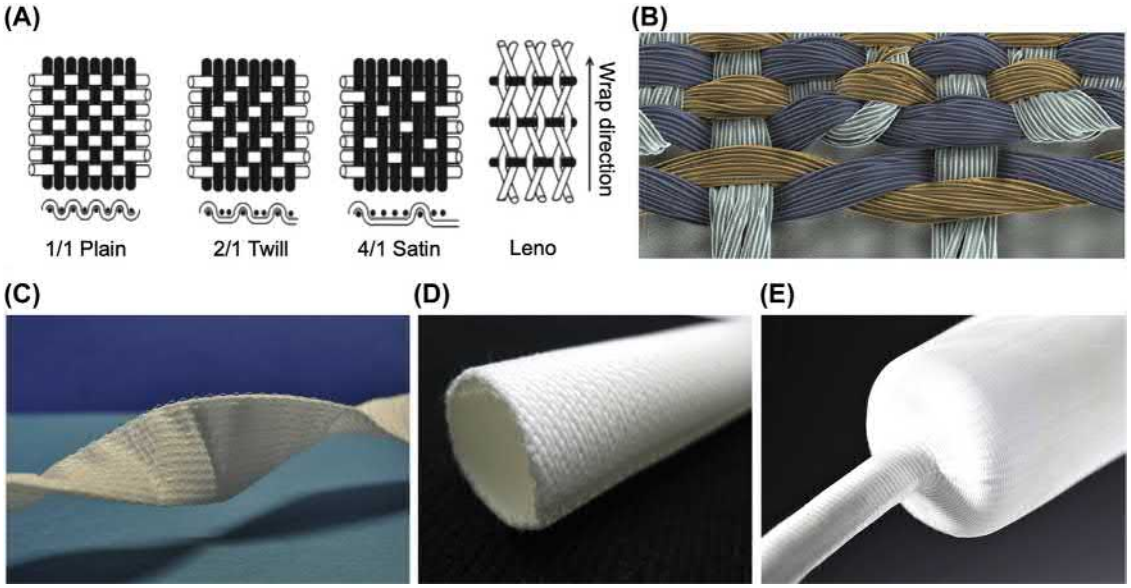
Once fibers or yarns are produced via spinning, they are fabricated into textiles using various techniques to give the final product its desired mechanical and biological properties. Structures typically used for medical textiles include weaves, knits, braids, and nonwovens. Material properties dictated by textile structure include strength, flexibility, porosity, permeability, handleability, and stability. Generally, woven fabrics are strong and dimensionally stable, and have low porosity and permeability. Knit fabrics are more permeable and have higher specific surface area for tissue integration. Braided fabrics hold together well under longitudinal loads but are unstable under torsional loads while also being moderately porous. Choosing a final structure requires balancing the advantages and disadvantages of each structure. The rest of this section describes each structure in greater detail and introduces their typical use in medical applications.

Woven Textiles

Woven structures are made by interlacing primary structural yarns at right angles in directions called warp and weft. Warp yarns are held in place by a loom, while the weft yarns are drawn through warp yarns by a shuttle as warp yarns are lifted up in particular patterns to form weave structures such as plain, twill, satin, and leno weaves (Fig. 1.4.6.9A, B). Woven structures have high breaking strength in both the warp and weft directions and display low elongation. Weaves are particularly adept for vascular grafts and dental ribbon fabrications. Examples of woven textiles include planar weaves used for dressings or tubes for a variety of grafts and tissue scaffolds (Fig. 1.4.6.9C, D). Advanced textile production methods allow for the development of even more complex structures, such as tapered tubular grafts for vascular prostheses (Fig. 1.4.6.9E).

Knitted Textiles

Knitted fabrics are made of continuous interconnected chains of yarn loops. Rows of loops are called wales and vertical columns are called courses. Two major variations of



• **Figure 1.4.6.9** Woven textile structures. (A) Schematic diagram of woven textile structures. (B) False-color scanning electron microscopy images of a multifilament woven poly(ethylene-terephthalate) (PET) textile microstructure. (C) Macro view of a woven PET textile sheet. (D) Macro view of a woven PET textile tubular graft. (E) Macro view of a tapered woven PET textile tubular vascular graft. ((B–E) Courtesy of Secant Group, LLC.)

knit fabrics are the weft knit and warp knit constructions. Weft knitting is simpler; one yarn forms courses in the fabric. In warp knitting, a series of yarns forms wales in the fabric. These structures are depicted in Fig. 1.4.6.10. Warp knits are more dimensionally stable, have less stretch, and unravel less when cut compared to weft knits. Warp knits, such as velour or pile knits, are generally more versatile as they can be additionally modified by adding extra yarn to the structure to add thickness, bulk, and surface texture.

Knitted structures are generally more flexible and compliant than woven structures. Knit fabrics have a much higher porosity than woven fabrics, with typical total porosity exceeding 65%. This porosity is beneficial for tissue ingrowth but results in unacceptable water permeability. To decrease permeability, for example when a knit structure is used as a vascular graft, knits must first be coated or impregnated with collagen or gelatin to avoid the need of preclotting. Knit fabrics are often subjected to heat setting, which shrinks the yarn and tightens the loop structures to improve the fabric strength, stretchiness, softness, and stability. The addition of pile yarn to warp knits makes the fabric softer and improves the thrombotic deposit from the initial blood contact to improve tissue ingrowth and healing (Fig. 1.4.6.11).

Braided Textiles

Braiding is the interweaving of three or more yarns in an angled overlapping pattern (Fig. 1.4.6.12). The structure is described by the horizontal repeat distance, called a line (l), the vertical repeat distance, called a stitch (s), the width (w) of the yarn, and the braid angle (θ) between the yarn and machine directions as seen in Fig. 1.4.6.8. Because of their inherent strength and flexibility, braided structures are the most used in surgical sutures. Advances in three-dimensional (3D) braiding have allowed for the formation of more complex structures, including "I" beams, hollow channels, and solid tubes (Chen, 2015). One application of a braided hollow tube is the vascular stent; due to the braid's low bending rigidity and ability to radially expand, the

((C–E) Courtesy of Secant Group, LLC.)

structure is ideal for keeping arteries open and preventing clots. Another common application of braided fabrics is in anterior cruciate ligament (ACL) prostheses. ACL prostheses must exhibit sufficient mechanical strength, as the ACL is subject to myriad forces, stresses, and strains. Braided structures for this application can be designed to have pore sizes that promote tissue infiltration while still maintaining mechanical integrity. One challenge associated with braided fabrics is securing the yarn at each end of the structure. This can be addressed with finishing techniques that fuse braid ends together, or more novel approaches such as constructing the braided structure from a single wire, as has been used for an esophageal stent (Polyflex) and for thoracic aortic aneurysm repair (Murgo et al., 1998).

Textile structures may also be a combination of the three structures we have discussed thus far, allowing for more complex mechanical properties. For example, to make the PET textile shown in Fig. 1.4.6.12F, yarns were knitted together, then the knit structures were braided.

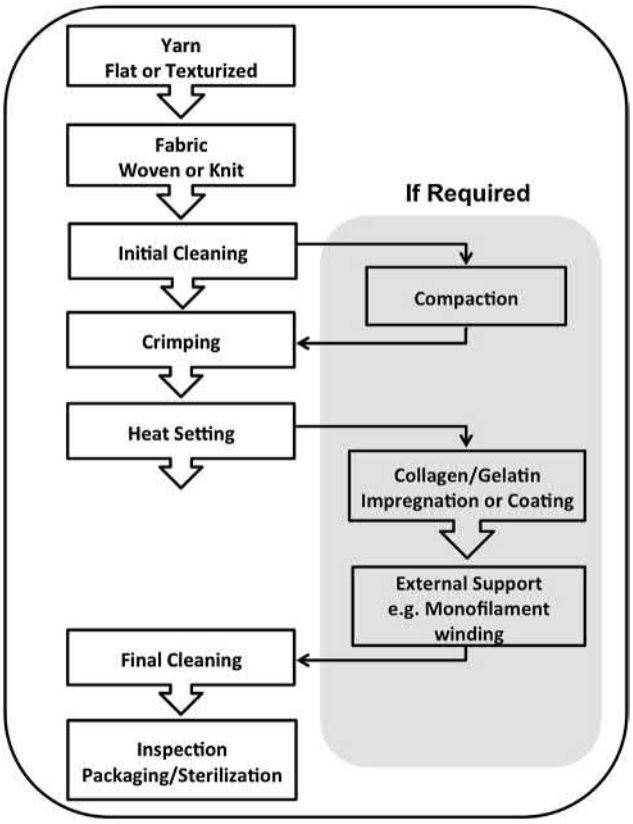
Nonwoven Textiles

Nonwoven fabrics are produced directly from fibers or fiber fragments without the intermediate step of yarn production. Nonwovens are produced by creating a porous uniform web, often by spun-laid, wet-laid, or melt-blown processes, that is then bonded or interlocked via mechanical, thermal, chemical, or solvent means. The fibers may be randomly oriented or preferentially oriented in one or more directions, depending on the production method. Total porosity, average pore size, and pore size distribution may be controlled by changing the density and orientation of the fibers, fiber diameter and length, and bonding method. Multiple nonwoven layers can be combined to further control the physical and mechanical properties of the textile such as permeability and strength. Nonwovens typically exhibit dimensional stability, strength, durability, and high porosity.

The properties of nonwovens are easily modified, making them highly versatile with wide-ranging applications. Nonwoven textiles are often used as bandages and wound dressings, as listed in Table 1.4.6.1, since they can be highly absorbent and gas permeable. Nonwoven wound dressings can also have release agents such as antimicrobial drugs incorporated in them for localized drug release (Giram et al., 2018). Since nonwovens can form multilayer meshes, they also work well as filters, for example, within regenerative tissue devices (Iwamoto et al., 2015) and for blood filtration (Sato et al., 2015). Nonwovens can also be implanted as tissue scaffolds for applications including nerve repair (Sarhane et al., 2019b), intestinal prosthesis (Liu et al., 2019), tendon grafts (Sensini and Cristofolini, 2018), and osseous tissue regeneration (Krucińska et al., 2017).

Finishing and Surface Coating

After polymers have been spun into fibers and yarns, and yarns have been fashioned into textile structures, there are



• **Figure 1.4.6.13** Typical vascular graft manufacturing operations.

several processing steps that must be done before the textile is ready to be used in a medical device. Finishing operations are based on the polymer choice, the fabrication process, and the medical application. However, all finishing operations are concerned with the same properties: cytotoxicity, sterility, surface modifications, and packaging. An example of the general workflow for textile finishing for a vascular graft is diagrammed in Fig. 1.4.6.13. Each of these processes, including cleaning, heat setting, bleaching, shrinking, inspection, packaging, and sterilization, affects the textile's final properties.

Additives and solvents are often employed during various phases of the textile production process. These additions can result in cytotoxicity and other adverse events when placed in a biological environment. Many surface finishes, such as yarn lubricants, can be easily removed with cleaning and scouring techniques. Other additives such as mineral oil or silicone based require special aqueous-based or organic-based washing procedures. After wash steps, the product must be thoroughly tested to ensure there are no more harmful additives or other chemicals from the product. Finally, the product is cleaned, packaged, and sterilized. Careful packaging is necessary to protect the textile from light degradation, bacterial contamination, moisture, and oxidative stress in certain cases. Sterilization can be achieved through heat, chemical treatment, irradiation, or pressure.

There has been increasing interest in more specialized finishing that enhances the biocompatibility or functionality of the textile. For example, with any wound dressing or implantation there is a chance of infection. Many researchers are developing antimicrobial coating agents that can be applied to textiles during production (El-Ola, 2008). Microencapsulation techniques can also be applied to medical textiles to deliver other drugs of interest through textile scaffolds or wound dressing. Other biological coatings such as collagen can be used to improve biocompatibility and promote tissue growth (Singh et al., 2015).

Applications of Medical Fibers and Biotextiles

Biotextiles of General Surgery

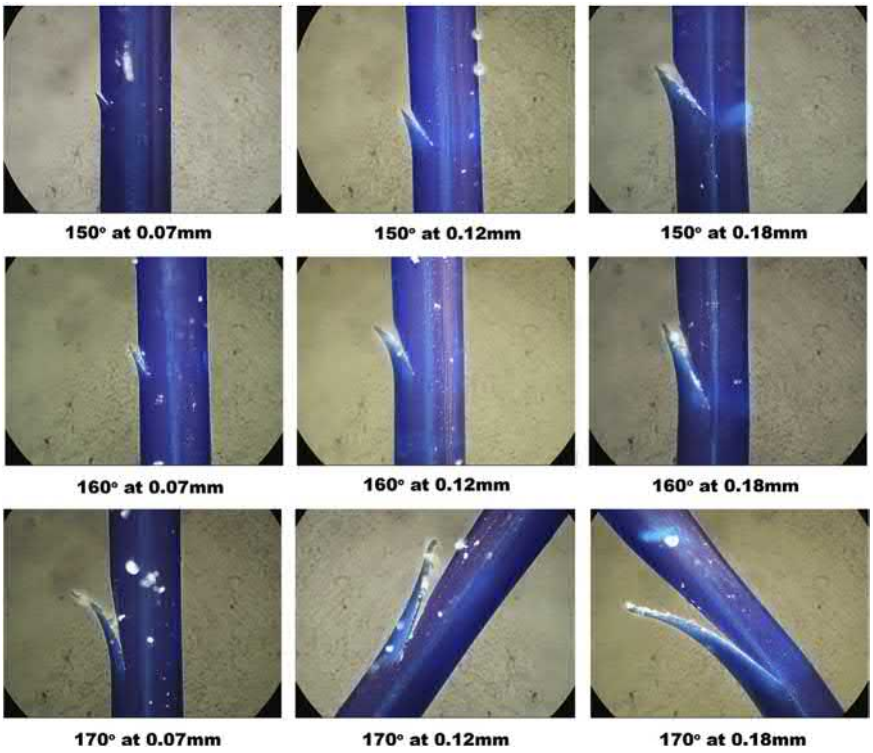
Surgical sutures and tissue repair meshes represent two of the most prominent applications of biotextiles in the general surgery field. A variety of porous mesh fabrics have been employed as a supportive material in hernia and prolapse repair, as well as in tissue patches, as listed in Table 1.4.6.1. Traditional constructions are warp knitted from polypropylene or polyester monofilaments or expanded polytetrafluoroethylene (ePTFE) membranes whose increased resistance to infection makes them preferable to multifilament yarns. More recently, 3D warp knits using polyester multifilament yarns have been found to possess increased flexibility and can be implanted endoscopically. Although the majority of these meshes are nondegradable, recent developments have included a resorbable component that allows for the promotion of a more acute inflammatory response and, ideally, faster healing.

Meshes and Sutures: Design and Materials

Sutures and meshes can be modified by a protein coating (collagen and/or gelatin) or a microporous PTFE layer applied to a single side, which reduces the risk of unwanted adhesion in vivo. As with other textile structures, specific characteristics may be engineered into the mesh to meet design goals such as added flexibility, increased strength, reduced thickness, improved handling, and a better suture-holding strength. Commercial sutures possess either a monofilament or braided multifilament structure and can be synthesized from natural materials such as silk or collagen (often referred to as "catgut," though it is actually derived from the submucosal layer of either bovine or sheep intestine), or synthetic materials, including nylon, polyester, polypropylene, and stainless steel, as listed in Table 1.4.6.1.

Barbed and Drug-Eluting Sutures

Among the more recent innovations in surgical sutures is the development of the barbed suture (Fig. 1.4.6.14), the structure of which allows for tissue anastomosis without the need for the surgeon to tie a knot. The design concept of the barbed suture mimics the quill of a porcupine, such that angled barbs protrude from the monofilament's surface and mechanically interlock with the surrounding tissue. Advantages of these self-anchoring barbed sutures include shorter suturing time given the elimination of the



• **Figure 1.4.6.14** Single barbed suture samples with various cut angles and lengths. (Modified from Ingle, N.P., King, M.W., 2010. Optimizing the tissue anchoring performance of barbed sutures in skin and tendon tissues. J. Biomech. 43 (2), 302–309.)

need to tie knots, as well as a more uniform distribution of holding forces, which reduces suture slippage, tissue distortion, and necrosis, allowing for improved cosmetic outcomes. Given the previously mentioned favorable characteristics, resorbable barbed sutures are a viable clinical option for patients seeking a less invasive facelift procedure, known as a "threadlift." However, recent studies have shown this to be a more temporary solution with results lasting between 1 and 9 years (Wu, 2019). Additionally, Wu noted that there was an increased complication rate associated with threadlifts performed using barbed sutures versus traditional and more invasive surgical facelifts performed using nonbarbed sutures. Meanwhile, a 5-year retrospective analysis found barbed sutures to be as safe as conventional sutures for the purpose of closing the gastric pouch–jejunal anastomosis in laparoscopic gastric bypass (Pennestri et al., 2018). These findings suggest that additional work is needed to identify optimal barb dimensions, frequency, and geometry for use with different types of tissues (Ingle et al., 2010). Examples of barbed sutures currently approved by the United States Food and Drug Administration (FDA) for commercial use are included in Table 1.4.6.1.

Drug-eluting sutures represent an exciting development in the field of surgery as they simultaneously serve both a mechanical and a pharmaceutical function. The active pharmaceutical ingredient can be incorporated into the suture either during manufacturing of the suture, or after the suture has been fabricated. Current applications of this technology include a wet-electrospun suture comprised of poly(L-lactide), polyethylene glycol, and levofloxacin as a means of providing local, postoperative delivery of antibiotics following ophthalmic procedures (Kashiwabuchi et al., 2017). Further optimization will continue to improve drug-eluting sutures, thus providing the field of surgery with encouraging prospects for decreased rates of postoperative infection.

Cardiovascular Applications of Biotextiles

Examples of biotextiles developed for cardiovascular use include heart valve sewing rings, annuloplasty rings that provide dimensional stability to incompetent cardiac heart valves, as well as vascular and endovascular stent grafts, as listed in Table 1.4.6.1. One of the most significant contributions of biotextiles to the field of cardiovascular surgery has been large (10–40 mm) diameter vascular grafts. As mentioned previously, polyester (e.g. PET) is the principal polymer used to construct vascular grafts.

Design Criteria for Vascular Prostheses

There are multiple design combinations that are possible for vascular grafts, including either a knitted or woven structure that can then be produced in a straight or bifurcated configuration. Ideally, the properties of a vascular prosthesis will meet all of the following criteria: available in different shapes and sizes, sterilizable, easy to handle and suture, cut edges that will not fray, ravel, or run,

hemostatic yet nonthrombogenic, biocompatible, low associated infection rate, capable of promoting rapid healing, dimensionally stable, and compliant (Edwards and Tapp, 1957). Although no single biomaterial has been found to meet all these requirements, textile structures designed to be flexible, porous, lightweight, and compliant are able to satisfy most of these criteria.

Woven Versus Knitted Structure

Design decisions and the goals that guide them carry significant consequences in the field of biomaterials. Woven structures can provide hemostasis and dimensional stability, whereas knitted devices are more compliant, easier to handle and suture, and promote more rapid healing. Conversely, warp knits are more dimensionally stable and do not ravel in comparison with weft knits, which are more compliant. Thus considering the key characteristics in relation to the implantation site or disease state is necessary prior to selecting the material and structure.

Examples of Cardiovascular Biotextiles

The field has a rich history of innovations that have addressed several physiological challenges, as was seen in the 1950s with Dr. Sterling Edwards' use of imparting radial folds prior to finishing, known as crimping, as a means to avoid kinking and to facilitate handling (Edwards and Tapp, 1957). Today, a substantial amount of effort is being devoted toward the development of a small vessel (<6 mm diameter) prosthesis for coronary artery bypass and tibial/popliteal artery replacement. However, high thrombogenicity, compliance mismatch of existing materials, and complications due to intimal hyperplasia have prevented the development of a successful commercial product to meet this market need. A recent study employing a cell layer-electrospun mesh composite demonstrated a construct capable of a similar J-shaped circumferential stress–strain response to that of native coronary artery, as well as an acceptable level of tensile strength. However, an extended pre-culture period and prolonged use of media additives present a significant barrier to its clinical translation (Erndt-Marino et al., 2016). In addition to the previously discussed challenges of meeting required compliance and mechanical properties, a translatable small diameter vascular graft would need its surface to be modified with an endothelial cell layer, or a specialized surface coating, growth factors, and other bioactive agents to prevent thrombosis and thromboembolic events. Thus another area of interest has been the development of biological grafts, surface-modified materials, and tissue-engineering constructs (Chung et al., 2010).

The first clinical application of an artificial vessel based on a synthetic scaffold was to reconstruct a low-pressure pulmonary outflow tract in pediatric patients with a cyanotic congenital defect (Shin'oka et al., 2005). In this approach, autologous bone marrow cells were seeded into tubes made from a copolymer of lactide and caprolactone and subsequently reinforced with a woven PGA sleeve. While the grafts were not suitable for high-pressure arterial implantation, this study demonstrated the feasibility of a tissue-engineered approach. At the most recent follow-up of a 25-patient cohort (range: 4.3–7.3 years, mean: 5.8 years), all grafts remained intact and patent (Fig. 1.4.6.15); however, there were four stenotic events and one thrombotic event that had occurred. Even though graft stenosis appeared to be the primary mode of graft failure and the mechanism of stenosis remains unclear, none of the grafts actually failed over the course of this study (Hibino et al., 2010).

• **Figure 1.4.6.15** Three-dimensional computed tomography scan at 1 year after tissue-engineered vascular graft implantation (indicated by *red arrows*). The graft is patent and there is no aneurysmal dilation. (Modified from Hibino, N., McGillicuddy, E., Matsumura, G., Ichihara, Y., Naito, Y., Breuer, C., Shinoka, T., 2010. Late-term results of tissue-engineered vascular grafts in humans. J. Thor. Cardiovas. Surg. 139 (2), 431–436.)

Endovascular Stent Grafts

Over the past 20 years, a sizable investment of resources has been dedicated to the development of endovascular stent grafts, which have utility in minimally invasive aortic aneurysm repair, occlusive disease, and vascular trauma (Powell and Kashyap, 2016; Hinchliffe and Hopkinson, 2007). The benefits of these grafts over open surgery include decreased patient trauma, blood loss, postoperative complications, infection risk, and exposure time to anesthesia. Additionally, the costs associated with hospitalization, patient care, and the time for recovery and rehabilitation are significantly lower than for open surgery. Endovascular prostheses, or stent grafts, are tubular biotextiles with either an internal or external stent comprised of nitinol or stainless-steel wire. Given that the stent graft must be collapsed and folded onto a balloon catheter and subsequently inserted through a distal artery, the structure needs to be thin, flexible, and hemostatic. To meet these specifications, either an ePTFE

membrane or a polyester tube tightly woven from fine (45 dtex or less) untextured multifilament yarns, which allows for minimization of overall wall thickness, may be employed (Guidoin et al., 2004). However, the long-term durability and fatigue resistance of such structures require further evaluation via in vitro testing and predictive modeling.

Knitted Textile Structures as Sewing Rings

Given their high suture retention strength and ability to tolerate damage during surgery, knitted textile structures have been used as sewing rings for aortic and mitral valves. More recently, heart valve leaflets have also been fashioned from textile-based structures due to their superior flexural fatigue properties using either permanent polyester or resorbable PCL multifilament yarns (Heim et al., 2008).

Orthopedic Applications of Biotextiles

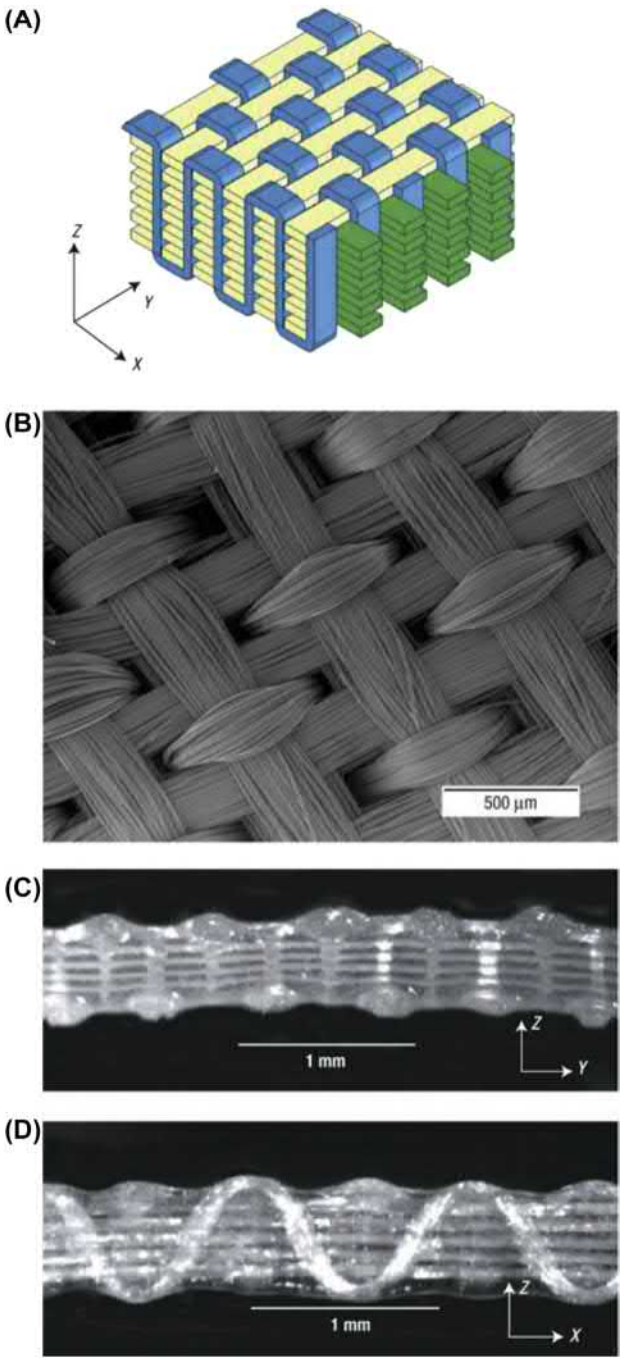
Ligament and Tendon Replacement With Woven and Braided Biotextiles

In the field of orthopedics, woven and braided textile devices have been used to construct replacement ligaments and tendons. However, issues such as abrasion and wear, inadequate strength, and poor bone attachment have been cited for premature clinical failures in ligament and tendon applications (Guidoin et al., 2000). For example, early failures in using a braided PTFE structure for ACL repair was attributed to creeping of the PTFE polymer, causing patients to experience increased knee instability over time (Roolker et al., 2000). More recently, 3D braided and woven scaffolds employing resorbable fibers spun from PGA, PLA, and their copolymers have been reported for ligament and cartilage replacement (Fig. 1.4.6.16) (Moutos et al., 2007). Although several artificial biomaterials have been brought to market to serve as ligament grafts for purposes such as repair of separated shoulder joints and ACLs, an ideal prosthesis capable of mimicking natural human tissue has yet to be found.

Another challenge for polyester implants in orthopedic surgery has been the host inflammatory response to the implanted biotextile. Coating the textile implants with antlerogenic stem cells or platelet-rich plasma (PRP) has been shown to significantly reduce inflammation and accelerate healing in a cranial cruciate ligament repair model in rabbits, leading to faster covering of the implant by host connective tissue and increased intertwining between recipient connective tissue and polyester fiber implant, highlighting the potential benefit of combining biological components with synthetic biotextiles (Przadka et al., 2017).

Fiber Reinforcement in Bone Graft Cement

Previously, loadbearing prostheses for orthopedic applications were fabricated primarily from metals and ceramics due to their high strength and modulus. However, advances in fiber spinning technologies have allowed for the production of fibers with superior mechanical performance, including fibers comprised of ultrahigh molecular weight polyethylene, carbon, and poly(arylamide) (Kevlar). Today, these fibers are predominantly employed as a reinforced composite structure for bone graft cement as well as for spinal support devices.



• **Figure 1.4.6.16** Fiber architecture of a three-dimensional (3D) orthogonally woven structure. (A) Schematic showing a 3D structure that is woven by interlocking multiple layers of two perpendicularly oriented sets of in-plane fibers (X- or warp direction, and Y- or weft direction) with a third set of fibers in the Z-direction; (B) Surface view of the X–Y plane (scanning electron microscope); (C) Cross-sectional view of the Y–Z plane; (D) Cross-sectional view of the X–Z plane. Biotextiles as Wound Dressings and Skin Grafts

Wound Dressings and Hemostats

Another common application of biotextiles and fiber technology is in the synthesis of wound dressings and hemostats. Wound dressings serve primarily as a physical barrier to prevent infection and promote moisture absorption and blood coagulation, while hemostats are used clinically to stop bleeding.

Traditionally, woven cotton gauze has been used as a wound dressing due to its superior moisture absorption and blood-clotting ability. However, since it is composed of short staple fibers of cellulose, woven cotton gauze tends to adhere to the wound, consequently leading to infection and trauma upon removal. Other materials such as polyester, polypropylene, nylon, and viscose rayon, as well as the addition of antibiotics, growth factors, and a barrier layer, have been combined with absorbent cellulose as a means of fabricating a more effective wound dressing. A typical example of a layered laminate structure includes a protective outer barrier of polyester or polypropylene accompanied by an inner layer comprised of absorbent cellulose. Collagen, chitosan, and cellulose derivatives can all serve this purpose in layered fibril, foam, and powdered forms, which have hemostatic properties. Other biomaterial applications for hemostasis that have been investigated in recent years include a hydrophilic absorbent layer of poly(acrylic acid) surrounded by a flexible outer layer of electrospun ethylene-vinyl acetate (EVAc) copolymer, as well as various polysaccharide polymers, including alginate, chitosan, and dextrin (Hickman et al., 2018). Additional examples of commercial products can be found in Table 1.4.6.1.

Skin Grafting for Burn Injuries

Patients suffering from severe burn injuries or chronic diabetic ulcers require a temporary skin graft to provide protection against infection as well as maintenance of hydration prior to receiving an autologous dermal transplant. To meet this need, the first commercial skin graft product that was introduced to the market was Epicel, which is an aseptically grown wound dressing prepared from autologous keratinocytes grown ex vivo on a petrolatum gauze dressing in the presence of proliferation-arrested, murine fibroblasts (Wright et al., 1998). Although biocompatible, this graft consisted exclusively of biological components and consequently lacked mechanical integrity, in addition to being difficult to handle and transport. As a means of overcoming these limitations, subsequent skin graft products have been developed to incorporate both biological components, such as porcine collagen and allogenic fibroblasts, with a synthetic textile layer to provide improved mechanical stability as listed in Table 1.4.6.1.

Applications of Electrospun Fibers

Wound Dressing

Electrospun nanofiber membranes have attracted a great deal of attention as wound dressings due to their high specific surface area, high porosity, and small-sized pores, among other characteristics. The high specific surface area enhances fluid absorption and high porosity facilitates the exchange of oxygen, water, and nutrients, as well as the removal of metabolic wastes. Additionally, the small-sized pores reduce penetration by microorganisms (Gautam et al., 2013).

Musculoskeletal Tissue Engineering

Cellular orientation and biomechanical stress on musculoskeletal tissue plays an important role in ECM deposition, neo-tissue formation, and cell phenotype maintenance. The electrospun fiber matrix can be constructed to mimic the orientation and architecture of native ECM collagen fibrils and its porous nature, and therefore suitable for muscle cell adhesion and proliferation (Abbah et al., 2015). Aligned electrospun fibers can withstand cell adhesion stress, direct cellular orientation, and maintain elasticity of the overall cell-scaffold structure. For bone reconstruction, electrospun nanofibers can be constructed to encapsulate or surface-immobilize osteo-inductive agents such as bone morphogenetic protein-2 (BMP-2) (Li et al., 2015; Perikamana et al, 2015). These functionalized nanofiber scaffolds have been shown to accelerate cranial bone regeneration by facilitating cell adhesion and growth and locally releasing osteo-inductive cues. Nanofibers also promote osteogenic differentiation and mineralization (Li et al., 2015) and guiding collagen deposition (Perikamana et al, 2015).

Neural Tissue Engineering

Electrospun fibrous scaffolds in wrap and conduit forms have been developed for neural tissue engineering due to its high porosity, small pore size, and flexibility. Alignment topography can also be incorporated inside the conduits or wraps serving as the guidance cue for Schwann cell migration and axonal re-growth. The ability to guide cell migration and maturation by aligned fibers is illustrated in a study by comparing human fetal tissue-derived Schwann cells cultured on aligned and random electrospun poly(ε-caprolactone) (PCL) fibers. Cell cytoskeleton and nuclei elongated along the fiber axes, emulating the structure of the bands of Büngner, which is formed during nerve repair by activated Schwann cells to guide growing axons. The aligned fibers can also condition Schwann cells into a myelinating phenotype with lowered expression of neurotrophic factors and up-regulation of an early myelination marker, myelin-associated glycoprotein. These functions may facilitate peripheral nerve regeneration. Additional functions such as local release of neurotrophic factors and immune conditioning can also be incorporated into the scaffold to promote tissue regeneration or modulating the tissue repair microenvironment. For example, nerve conduits prepared from the biodegradable poly(ε-caprolactone-co-ethyl ethylene phosphate) (PCLEEP) fibers with encapsulated glial cell-derived neurotrophic factor (GDNF) offer a combination of biochemical and topographical cues to facilitate peripheral nerve regeneration (Chew et al., 2008). By controlling the pore size of the electrospun fiber conduit, thus entrapping

the infiltrating macrophages, a microporous PCL nanofiber wrap creates an environment conducive to nerve repair and improves functional recovery (Sarhane et al., 2019a).

Nanofibers for Cardiovascular Repair

Electrospinning can be used to generate nanofibrous structures with various shapes and sizes to recapitulate specific architectures and functions in repairing different cardiovascular tissues, such as vascular grafts to replace blood vessels, heart valves, myocardial patches, etc. Similar to other tissue engineering applications, the multiscale topography and anisotropy, high porosity, and mechanical property make electrospun fibrous scaffolds a suitable choice (Capulli et al., 2016). Aligned fiber arrangement not only can improve the strength and elasticity of the grafts, but also can guide the organization of the endothelial cells and cardiomyocytes and the deposition of ECM molecules. Fibers with tunable degradation rates, together with the use of porogenic techniques and cell seeding methods, can be employed to facilitate cell infiltration and organization (Woods and Flanagan, 2014). Functionalization of scaffolds can be tailored for different design features of a specific product. For example, anti-thrombogenic agents can be conjugated to the surface of nanofibers to extend the patency of a small diameter vascular graft. Adhesion ligands can be conjugated to the luminal surface of the fibrous conduit to recruit endothelial cell progenitors or pre-seed autologous endothelial cells. An electrospun small-diameter vascular graft prepared with fibrin fiber tube encased in a thin sheath composed of PCL nanofiber membrane provided sufficient suture retention strength, overall mechanical property, vascular remodeling and enabled long-term graft survival (Elliott et al., 2019). The fibrin fiber tube allows successful endothelization, remodeling of the tunica intima and media layers, abundant ECM deposition particularly collagen layers and elastin lamellae, and reduced calcification; whereas the PCL fiber sheath improves the mechanical properties that withstands the reperfusion burst pressure and maintains the integrity of the graft following implantation. Such an approach has high translational potential for generating small diameter arterial grafts for bypass surgery (Elliott et al., 2019).

Electrospun fibers prepared from elastomeric polymers such as polyurethanes (PUs) and cross-linkable polyesters have excellent elasticity, which is ideal to serve as a scaffold to generate cell populated patches to repair the myocardial tissue damaged by a heart attack. A tri-component elastomeric patch was generated from electrospun poly(carbonate-co-urethane) (PCU, Bionate®) and PLGA nanofibers using a knitted polyester fabric as a template. This approach imparted anisotropic structure to guide local cell alignment and organization, improved the overall mechanical properties of the cell-grown patch construct, and sustained the spontaneous synchronous contractility at a physiologically relevant frequency (Şenel Ayaz et al, 2014). In a different study, an elastomeric polyester poly(glycerol sebacate) (PGS) prepolymer was mixed with PCL and the mixture solution was electrospun into a nanofiber mesh with improved mechanical properties. The PGS component allowed for direct conjugation of vascular endothelial growth factor (VEGF) to fiber surface. The functionalized nanofiber mesh permits the adhesion and proliferation of myogenic and angiogenic progenitor cells, and thus potentially improve the integration of the patch with host tissue after implantation (Rai et al, 2015). This polymer blend approach can be applied to generating fibers from a mixture solution containing synthetic and natural polymers (PGS, silk fibroin, and collagen; PFC fibers). The collagen-embedded PFC fiber mesh showed superior mechanical properties and promoted the adhesion of endothelial cells (Wang et al., 2015).

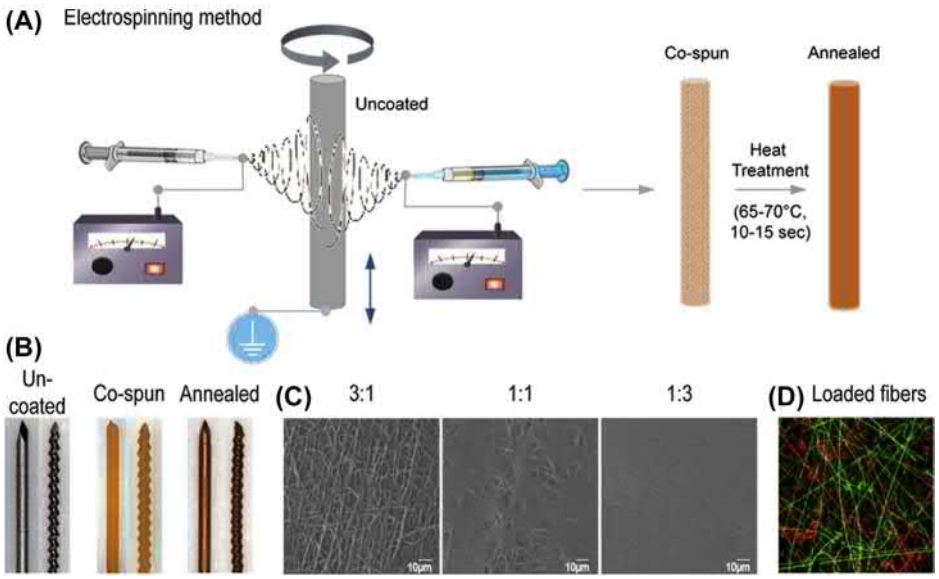
Nanofibers for Local Drug Delivery

The electrospun nanofiber structure can be used as a drug loading system to achieve controlled release of drugs locally at the site of implantation. Bioactive agents such as growth factors and cytokines can be locally delivered to influence tissue regeneration, angiogenesis, and inflammation. A wide range of bioactive agents and drugs can be loaded into the nanofibers during the electrospinning process if the agents can be dissolved or suspended in the polymer solution, or conjugated to the surface of the nanofibers through either chemical linkage or physical entrapment. Since multiple sets of fibers can be used to generate a single fibrous mesh or membrane, codelivery of multiple agents can be achieved by incorporating different drugs in different set of fibers. The release rate of each agent in one set of fibers can be independently tuned by varying the polymer-drug combination, independent of other fibers in the same fibrous mesh. This delivery feature can also be achieved by incorporating different drug-loaded nanoparticles into one set of electrospun fibers or loading different drugs into the inner or outer layer of a composite fibers with a core-shell structure through the co-axial spinning technique.

Such an approach has been applied to generate an electrospun fiber-based coating on an orthopedic prosthetic device to prevent biofilm-associated chronic infections particularly in cases involving antibiotic-resistant bacteria. A composite fiber membrane prepared from PLGA and PCL nanofibers, each loaded with a different antibiotic during electrospinning, was shown to effectively co-deliver a combination of antibiotics locally from the implant surface. The relative antibiotic release rate and duration can be adjusted by tuning drug loading and weight ratio of PLGA and PCL fibers. As tested in a mouse model for prosthetic joint infection, this conformal nanofiber coating effectively cleared bacterial infection from the implant surface and surrounding tissue without affecting osseointegration (Fig. 1.4.6.17) (Ashbaugh et al., 2016) This tunable nanofiber composite membrane or coating can be extended to other types of devices for a range of therapeutic applications.

Future Directions

The future of biotextiles development is driven by the clinical need for less-invasive and resorbable materials that do



• **Figure 1.4.6.17** Poly(lactide-*co*-glycolide) (PLGA)/poly(ε-caprolactone) (PCL) composite implant coating loaded with combinatorial antibiotics. (A) Antibiotic-loaded PLGA and PCL fibers are coelectrospun onto titanium implants to form a conformal PCL film with embedded PLGA fibers. (Modified from Ashbaugh, A.G., Jiang, X., Zheng, J., Tsai, A.S., Kim, W.S., Thompson, J.M., Ordonez, A.A., 2016. Polymeric nanofiber coating with tunable combinatorial antibiotic delivery prevents biofilm-associated infection in vivo. Proc. Nat. Acad. Sci. USA 113 (45), E6919–E6928.)

not require explantation, as well as the emphasis on pro-regenerative features of implanted materials to promote natural growth of viable tissue. As biotextiles are developed to become thinner, lighter, stronger, and more tunable in terms of flexibility, porosity, and functionalization, they are showing their versatility over traditional materials such as metals and ceramics. Current work is moving from permanent materials to not only resorbable materials, but also functional bioresorbable materials (Gajjar and King, 2014). The development of smart devices that rely on shape-memory, electroactivity, and self-healing properties that can respond to environmental changes in temperature, pH, and strain can serve as more than just scaffolding for biomedical applications (Lendlein and Langer, 2002). These smart devices such as biosensors, actuators, and drug delivery systems offer new ways for responsive biomaterials to improve therapeutic potential. Bioactive fiber coatings with slow release of antibacterial agents are being used to address infections resulting from implantation surgeries (Ashbaugh et al., 2016). Bioactive sutures have been developed for drug delivery, growth factor delivery, and cell delivery through surface modification and coating techniques (Alshomer et al., 2017). The growth of these new biotextiles also introduces new challenges in extrusion and sterilization practices while maintaining key functionality and structural integrity.

Prevalence in 3D printing technologies has enabled the generation of unique architectures using computer-aided designs. While these are primarily limited to microextrusion of polymer materials, progress in this area has expanded the range of temperatures and fiber diameters to better mimic the microstructure of biological tissue (Pedde et al., 2017).

New spinning techniques and improvements in electrospinning, bicomponent spinning, and materials improvements have also expanded the range of fiber diameters ranging from sub-50 nm to 10 μm, while also introducing new cross-sectional geometries. These enhancements facilitate the development of new therapeutic strategies as the effects of microenvironment architecture and cellular biomechanics are better understood. Moreover, new techniques to manipulate biotextiles, such as flocking, tufting, and embroidery, can create complex 3D structures (Pereira et al., 2007; Rentsch et al., 2009; Walther et al., 2007; Wollenweber et al., 2006). Additionally, techniques to improve foaming in electrospun fibers can further introduce new mechanical properties and increase porosity in these biotextile materials. These technologies contribute to the development of thicker tissue-engineered scaffolds to improve cell migration and tissue regeneration throughout the construct. As such, biotextiles and fiber-based tissue-engineering scaffolds will soon be considered as standardized "off-the-shelf" products that can be scaled up to be fabricated in large quantities for commercialization to meet growing clinical demand. The use of medical fibers and biotextiles in medicine will continue to grow as new synthetic polymers and genetically engineered biopolymers, fiber spinning technologies, 3D constructions, coatings, and surface modification processes are developed.

Chapter Study Questions

1. What are the general selection criteria for polymeric materials for medical fiber production?
2. Describe the main advantages and disadvantages of synthetic and natural materials as a source for producing medical fibers.
3. Give three examples each of synthetic and natural polymers and list examples of biotextile products generated from each polymer.
4. Name one clinical challenge that biotextiles have provided a solution for, and explain what specific structural features and properties are critical to accomplishing the particular tasks or serving the unique functions.
5. Consider a fiber that is 2 m long and weighs 3 g.
   a. If the fiber is a monofilament fiber, what is the linear density of the fiber in denier and dtex?
   b. If the fiber is a multifilament yarn made with 60 filaments, what is the linear density of each fiber in denier and dtex?
   c. Contrast the advantages and disadvantages of monofilaments and multifilament fibers.
6. Assume that you are given a 260-denier monofilament PET yarn to prepare a vascular graft.
   a. What is the diameter of the yarn used for this graft?
   b. What are the advantages and disadvantages for each of the following structures for this vascular graft: woven, knit, and braided textiles?
   c. Pick one of the three structures and describe how you could improve upon the disadvantages, which you have described, by altering the textile or yarn properties.
7. Pick a natural polymer, for example, from this list: chitosan, collagen, gelatin, alginate, and hyaluronic acid. Research and briefly describe its endogenous bioactivities and its functions in a current or potential biotextile. What properties of the biopolymer made it ideal for this application? What are the potential disadvantages of the biopolymer in this application?
8. The concept of combining naturally occurring biologic elements with artificially manufactured biotextiles has been observed with multiple products discussed in this chapter, including hybrid textiles intended for use as small vessel stent grafts and stem cell-coated polyester implants for orthopedic surgery. What are some of the advantages of products that combine textiles with biologic elements? What are some potential shortcomings of a hybrid textile compared with either the textile or biologic element alone?
9. Consider the process of producing electrospun polymer nanofibers.
   a. Describe the basic principle of electrospinning for preparing polymeric nanofiber mesh; use a sketch or schematic to aid your description.
   b. Explain how polymer solution properties and electrical potential applied may influence the fiber diameter.
   c. Discuss approaches to control fiber alignment. Give two examples each for electrospun fiber products with either ordered or random alignment.
   d. Propose one method each for encapsulating a hydrophobic drug (e.g., vancomycin) and a water-soluble drug (e.g., bone morphogenetic protein-2) into electrospun fibers.

1.4.7

Textured and Porous Biomaterials

W. BENTON SWANSON, PETER X. MA

Department of Biologic and Materials Science, School of Dentistry, University of Michigan, Ann Arbor, MI, United States

Introduction

Porous and textured biomaterial features have played an important role in the success of a myriad biomedical applications. Both the short- and long-term utility of biomaterials in medicine relies on their ability to interface with the body and deliver functionality without causing harmful complications. Biomaterial properties, including texture and porosity, are not only advantageous but necessary to facilitate successful biologic integration and influence cell adhesion, infiltration, proliferation, and nutrient and waste mass transfer. The culmination of favorable cellular responses at the tissue–material interface leads to organogenesis and accelerated healing. Biomaterial architectures at various size scales are key engineering and design considerations which require innovative fabrication strategies to impart favorable biologic compatibility to material constructs without compromising mechanical and other properties in application-specific uses.

In the past three decades there have been explosive advances and interest in porous and textured biomaterials due to new fabrication methods, particularly due to advances in the field of tissue engineering (Ma, 2008; Langer and Vacanti, 1993). As early as the 1940s, textured and porous features of successful medical devices serve as early examples of tissue engineering-like approaches to biomaterials fabrication. Biomaterial surfaces serve as critical interfaces between host and implant to coordinate many biologic processes. As demonstrated in recent literature and commercial medical products (Fig. 1.4.7.1), there is a strong appreciation for biomaterial architectural features, including surface texture and porosity, as advantageous design criteria. Hence, reliable and tunable fabrication methods are critical to the advancement of biomaterials science. Not intended to exhaustively review all textured and porous biomaterials, this chapter will focus on synthetic biomaterials and their tunable nano-, micro-, and macroscale architectures covering the following areas: (1) porous and textured synthetic matrices currently used in medical devices, (2) a comparison of the breadth of fabrication methods for biomimetic features to achieve desirable properties, and (3) a discussion of novel processing technologies and recent advances in combining multiple fabrication technologies, with more examples from recent advances such as in tissue engineering applications.

Importance of Texture and Porosity in Facilitating Biomaterial Integration

Historically, materials with textured and porous morphologies have higher success rates than smooth constructs. The extent of a construct's success is heavily related to its ability to facilitate tissue ingrowth, prevent fibrosis, and promote angiogenesis of surrounding tissue. Of these three, tissue ingrowth—physical integration of the material into the host—is the most important. A host's natural response is to encapsulate an implant with a fibrous capsule to compartmentalize it from the rest of the body, which is minimized by textured implants and open pore architectures, leading to the formation of a thinner foreign-body capsule (Salzmann et al., 1997). Numerous materials can be textured or rendered porous, including metals, ceramics, and natural and synthetic polymers. We will discuss specific examples of successful biomedical devices and their material features.

Textured Devices Promote Healing and Restore Organ Function

Dental implants, made of titanium and metal alloys as well as soft material constructs, benefit from textured surfaces. Their success in restoring normal mastication is directly related to their ability to integrate with craniofacial bone through the process of osseointegration. Branemark et al. defined osseointegration as the direct structural and functional connection between ordered living bone and the surface of a load-bearing implanted construct (Branemark, 1983). Mechanical interlocking between a synthetic prothesis (titanium dental implant) and the living bone is critically important and can be facilitated by intentional surface texture (Esposito et al., 2005). This idea launched the

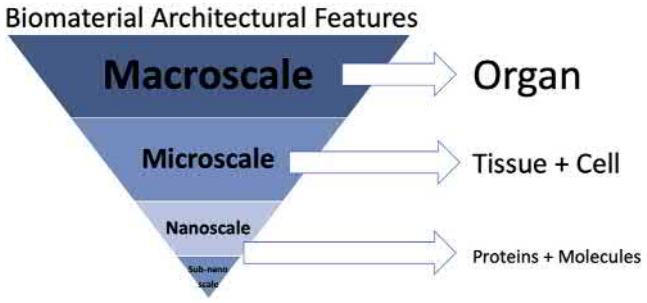
development of surface-modified implants to increase the osteoinductive potential of their surfaces (Dohan Ehrenfest et al., 2010). Macrotopography of implants can be designed in a variety of ways, strategically interfacing with local neotissue to facilitate implant integration. Additional visible geometries such as ledges, flutes, indentations, and grooves influence integration and are shown to increase implant stability and long-term success. These morphologies are primarily created by milling processes (Buser et al., 2012).

Microscale structures may also enhance the process of bone healing. Increased surface roughness has been shown to increase success by influencing cell and tissue integration. It also enhances interfacial and shear strength, important for dental implants to withstand the forces of the oral cavity over time (Strietzel et al., 2004; Wennerberg and Albrektsson, 2000). Increasing the surface area of the implant, through texture and roughness, allows greater space for cells to attach and facilitate tissue neogenesis around the implant. Microscale structures are influenced by techniques including acid etching, anodization, sandblasting, and grit blasting to mechanically impart features (Dohan Ehrenfest et al., 2010). More recently, laser micromachining has been used to modify dental implant surfaces (Nevins et al., 2010). Buser et al. evaluated the outcomes of 511 sandblasted, large grit, acid-etched dental implants (Straumann) in 303 patients over 10 years, and reported a success rate of 97%, with 98.8% of implants surviving 10 years without complication. For patients, advances in dental implant design allow for more rapid loading and return to normal lifestyle.

Breast augmentation surgeries are one of the most common cosmetic surgical procedures in the United States (Benediktsson and Perbeck, 2006; Gampper et al., 2007); 15%–25% of breast implant procedures are complicated by fibrous capsular contraction and result in long-term contracture, due to the body's natural response to *any* foreign object (Taraballi et al., 2018). Fibrous capsule contracts in the months following implantation leading to patient discomfort and disfigurement, and ultimately implant failure. Implant surface texture (smooth vs. textured) is known to be a key factor influencing success (Howard, 1999; Burkhardt, 1984; Burkhardt et al., 1986).

Orbital implants (Fig. 1.4.7.2) compensate for lost tissue when the eye is enucleated due to severe trauma, intraocular cancer, or removal of a blind and painful eye (Chalasani et al., 2007; Sami et al., 2007). Key engineering considerations include fit, motility, and minimized long-term complications such as extrusion, migration, and infection (Goldberg et al., 1994). A variety of materials, including glasses, silicones, and acrylics, have been used in orbital implants; recently, porous materials such as hydroxyapatite (HAP) and polyethylene (PE) have shown increasing popularity. Their textured structure roughly resembles native surrounding trabecular bone, and thus encourages fibrovascularization of the implant within a few weeks compared to implants with smooth surfaces (Chalasani et al., 2007; Sami et al., 2007). These advantages influence patient outcomes by increasing healing rate and decreasing infection, leading to therapeutic success in compensating for lost tissue.

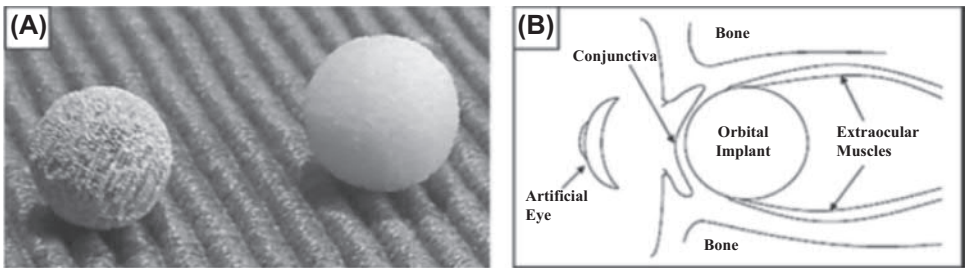
The cellular mechanisms of texture are not completely understood. Evidence suggests that texturing influences collagen arrangement of the surrounding extracellular matrix. Irregularly arranged collagen fibers at the textured surface may be less likely to create cooperative contractile forces and are more susceptible to collagenase degradation (Pennisi, 1990). Textured implants also show increased local macrophage number, which may degrade the capsule as it forms (Taylor and Gibbons, 1983). Additionally, texture minimizes micromotion and reduces chronic inflammation. In the case of breast implants, factors including the type of texturing, pore size, or implant material do not appear to be as important as simply disrupting surface smoothness (Caffee, 1994; Danino et al., 2001).



• **Figure 1.4.7.1** Biomaterial architectural scales at multiple levels are important considerations for developing fabrication methods.

Porosity to Promote Tissue Ingrowth

Synthetic vascular grafts used to repair damaged or occluded blood vessels are a good example of necessary

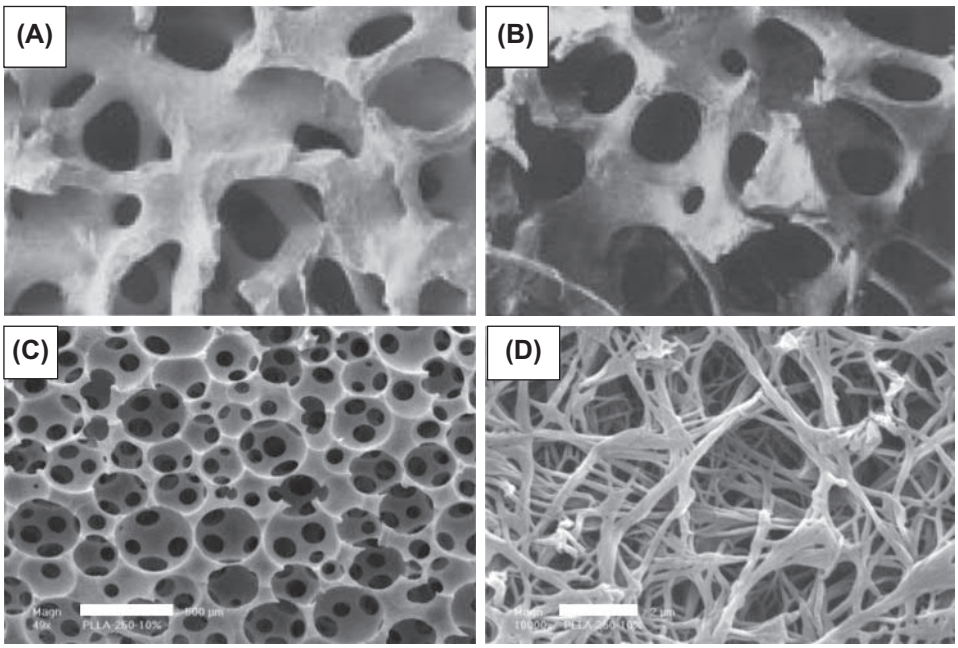


• **Figure 1.4.7.2** Examples of porous hydroxyapatite (A, left) and polyethylene (A, right) orbital implants; sagittal view of human orbit showing placement of orbital implants in the eye socket (B).

pores in biomaterial constructs. Pores are critical to support mass transport for cells and tissues and facilitate integration, both of which contribute to accelerated healing. In general, porous architectures must be sufficiently large to facilitate cell and tissue infiltration, while small enough to prevent fibrotic tissue formation and minimize interfacial cell necrosis from mechanical shear forces (Sharkawy et al., 1998; Rosengren et al., 1999). For vascular grafts, porosity helps to facilitate the formation of a stable, endothelium-lined lumen to provide an antithrombotic surface similar to native vessels (Wesolowski et al., 1961; White et al., 1983; Clowes et al., 1986; Zhu et al., 2009; Ma et al., 2010). Numerous studies demonstrate that highly porous small-diameter grafts have superior healing and long-term success compared to low-porosity grafts (Hess et al., 1984; Golden et al., 1990). Porosity allows for the ingrowth of fibrovascular tissue and infiltrating capillaries, which facilitate endothelialization and smooth muscle cell growth along the graft surface.

Macro- and microscale pores imparted to biomaterial constructs are similar to the porous organization of many physiologic tissues, such as bone (Fig. 1.4.7.3). Trabecular and cortical bone are both porous, up to 50%–90% and 3%–12%, respectively. In cortical bone, Haversian canals allow for fluid flow, which supports metabolism; pores in trabecular bone support the bone marrow that contains stem cells (Cooper et al., 2004; Lanyon and Baggott, 1976). Materials used to restore orthopedic function must be osteoconductive and capable of vascularization (Stevens, 2008; Gupte et al., 2018). Porous metals are one example of orthopedic implants, which allow bone healing and high osseointegration, similar to the dental implants mentioned earlier (Matassi et al., 2013). Highly porous metals can be fabricated from many elements, including tantalum, titanium, titanium alloy, and other alloys. Baril et al. quantified tissue response to porous metal orthopedic implants by microcomputed tomography and hard tissue histology techniques, and demonstrated that interconnected pores at the implant surface significantly improve osseointegration (Baril et al., 2011).

Critical to the success of these implants and a common theme in many implants, tissue ingrowth around and within the construct increases the likelihood of integration and long-term success and minimizes the risks of rejection. Advances in titanium porous foam manufacturing show mechanical properties similar to cancellous bone (Matassi et al., 2013). A variety of manufacturing technologies exist that allow for controlled porosity, including solid free-form machining, molding, stereolithography, laser machining, and sintering (Lewallen et al., 2015). These material modifications have a dramatic effect on clinical outcome by facilitating cell and tissue ingrowth (osseointegration) and bone formation (osteoinduction), particularly in hip and knee arthroplasty (replacement) procedures (Hanzlik et al., 2013). A challenge with porous metallic foams, such as those used in orthopedic applications, is their mechanical properties, since increasing the amount of void space within the construct decreases its stiffness and fatigue strength.



• **Figure 1.4.7.3** Porous structure and composition of coralline hydroxyapatite (A), human cancellous bone (B), and macroporous, nanofibrous PLLA scaffolds fabricated by pore leaching and TIPS demonstrate well-interconnected, spherical pores (C, scale = 500 μm) with a nanofibrous surface texture (D, scale = 2 μm). *PLLA*, Poly(L-lactic acid); *TIPS*, thermally induced phase separation. (Modified from Wei, G.B., Ma, P. X., 2006. Macroporous and nanofibrous polymer scaffolds and polymer/bone-like apatite composite scaffolds generated by sugar spheres. J. Biomed. Mater. Res. A 78A (2), 306–315.)

Biomaterials for Tissue Engineering

Considering these examples of textured and porous synthetic materials in biomedical applications, it is important for engineers to develop a toolkit of fabrication strategies to achieve desirable nano-, micro-, and macrolevel material features. In the context of tissue engineering, there is no single ideal construct; scaffolds are typically designed for specific applications. Important factors in tissue-engineering scaffold design include the selection of a biodegradable and biocompatible polymer that degrades at a rate that matches tissue neogenesis, architectural features and mechanical properties specific to the target tissue that it aims to replace, with a surface that facilitates adhesion, proliferation, and differentiation of cells, and a network for nutrient exchange and diffusion (Zhang et al., 2016b). Texture and porosity address the latter needs. Advances in materials processing strategies, which allow for controlled design at the nanometer and micrometer scales, are reviewed in the following sections.

Fabrication Methods for Biomimetic Nanoscale Texture

The purpose of a tissue-engineering scaffold is to serve as an artificial extracellular matrix (ECM), which spatially supports cells, facilitates cell adhesion, provides topological cues and mechanical support (Boyan et al., 1999; Ito, 1999). Thus it is reasonable to fabricate a tissue-engineering scaffold that mimics the fibrous proteins in the ECM found in nearly all tissue types. Collagen is the most abundant extracellular protein in the human body, with a triple helix macrostructure and submicrometer fiber diameter (50–500 nm) (Hay, 1991; Elsdale and Bard, 1972). Collagen is a natural polymer and can be used as a scaffolding material, but significantly lacks processing control particularly in regards to mechanical properties, degradation rate, batch-to-batch consistencies, and pathogenicity (Ma and Zhang, 1999). Synthetic polymers lend themselves to the highest degree of processability and tunability (Ma and Elisseeff, 2005). Poly(L-lactic acid) (PLLA) and poly(lactic-*co*-glycolic acid) (PLGA) are poly(aliphatic esters) and are the most commonly used biodegradable polymers because they degrade on a biologically relevant timescale, and are approved for biomedical use by the US Food and Drug Administration (Bergsma et al., 1995; Ma and Choi, 2001; Peter et al., 1998). A list of the most common biodegradable synthetic polymers is shown in Table 1.4.7.1. Electrospinning, self-assembly, and thermally induced phase separation are well-exploited processing technologies for achieving an ECM-like nanoarchitecture and surface texture in synthetic biomaterials, each with unique properties and applications, as summarized in Table 1.4.7.2.

Electrospinning

Electrospinning originates from the textile industry as a method of generating fibers using an electric field (Morton, 1900; Anton, 1934). Electrospinning imposes a difference in electrical charge between a needle and substrate to draw fine fibers from a polymer solution droplet. Electrodes between the polymer-charged needle and substrate create an electric potential, and the resulting electric field ejects a jet of polymer. The volatile organic solvent that dissolved the polymer evaporates to leave behind a polymeric nanofibrous or microfibrous mesh (Fig. 1.4.7.4). Current advances in electrospinning technology are working toward thinner fiber diameters, most similar to the native ECM (Liu et al., 2017).

Electrospinning has proven effective for making fibers with a variety of natural and synthetic biodegradable polymers, including collagen (Matthews et al., 2002), chitosan (Bhattarai et al., 2005), silk (Min et al., 2004), poly(glycolic acid) (Boland et al., 2001), PLLA (Yang et al., 2005), PLGA (Li et al., 2002; Kim et al., 2003), and poly(caprolactone) (Yoshimoto et al., 2003), as well as nonbiodegradable polymers (Kenawy el et al., 2003; Smith and Ma, 2004). Cells are able to survive, proliferate, and differentiate to a variety of functional phenotypes on electrospun nanofibrous or microfibrous materials (Li et al., 2003; Pham et al., 2006a,b). Electrospun nanofibrous matrices are easy to fabricate into two-dimensional (2D) sheets and meshes; however, three-dimensional (3D) constructs are difficult. It is hard to fabricate complex scaffold shapes, a critical criterion for fabricating biologically relevant tissue-engineering scaffolds. Additionally, it is difficult to incorporate an internal porous network. Construct porosity is intimately connected to nanofiber properties; in certain size ranges, it is hard to independently control fiber size and pore size/shape (Table 1.4.7.3).

Self-Assembly of Nanoscale Features

Broadly, self-assembly is defined as the autonomous organization of components into patterns or structures without intervention (Whitesides and Grzybowski, 2002). Specific to nanofiber engineering it is the rational design and chemical modification of synthetic polymers to organize into ECM-like structures. Noncovalent macromolecular bonding dictates multidimensional structures, including: hydrogen bonding, van der Waals forces, hydrophobic interactions, and electrostatic interactions (Lehn, 2002a,b). Self-assembly is advantageous for engineering very small diameter fibers (<100 nm) by exploiting ratios of copolymer section lengths with different properties. The result is self-aggregation of a 3D structure, which mimics the ECM-protein triple helix on a smaller scale (Ramachandran, 1988). Biology offers countless examples of self-assembly; this technology draws from the self-assembling nature of proteins into secondary and tertiary structures, and phospholipid macrostructures (Whitesides et al., 1991).

Synthetic peptide amphiphiles have been synthesized to mimic the ECM-protein triple helix, with a short peptide head sequence connected to a long lipid chain tail. Their

Material		Methods to Render Texture	Advantages	Disadvantages
Class	**Specific Examples**			
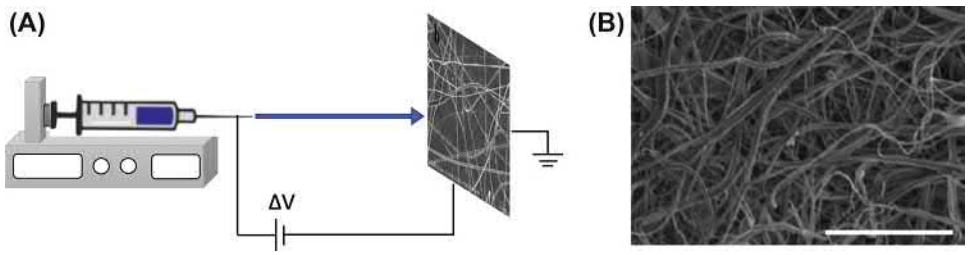
Ceramics (Sun et al., 2001; Karageorgiou and Kaplan, 2005; Simske et al., 1997)	• Hydroxyapitite • Natural coral • Calcium phosphate • Amorphous glasses	• Plasma spray • Sintering	• Similar compositions and structure to natural bone • Enhanced osseointegration and osteoconductivity using apatite-like materials • Biocompatible • Low corrosion • Bind some growth factors (i.e., BMP, LeGeros, Clin. Orthop. Rel. Res., 2002)	• Low resorption rate • Brittle mechanical properties • Difficult to control porosity • Not amenable to large-scale production • Lack biodegradability (Maquet/Jerome, Mater. Sci. Forum, 1997)
Metals (Sun et al., 2001; Karageorgiou and Kaplan, 2005; Simske et al., 1997; Ryan et al., 2006; Bobyn et al., 1999)	• Titanium and Ti alloys • Cobalt-chromium and Co-Cr alloys • Tantalum	• Plasma spray • Sintering • Grit blast • Wire mesh • Combustion synthesis • Vapor deposition	• Bioinert • Strong mechanical properties, less susceptible to fatigue • Ideal for implants	• Corrode over time • Stress shielding in vivo from high Young's modulus • Lack biodegradablility (Maquet/Jerome, Mater. Sci. Forum, 1997)

TABLE 1.4.7.2 Fabrication Methods for Nanofibrous and Textured Synthetic Polymer Matrices

Method	Description	Advantages	Disadvantages
Electrospinning	Electrostatic force is used to draw a polymer solution into fibers through a capillary	• Reproducible • Applicable to wide range of polymers • Easily fabricates 2D constructs	• Equipment investment required • Fiber diameter is larger than Type I collagen • Difficult to create 3D construct
Self-assembly	Polymer is designed to autonomously organize into cylindrical fibers based on noncovalent interactions	• Biomimetic fiber structure • Tunable fiber structure based on polymer composition	• Polymer synthesis is labor intensive • Fiber diameter is smaller than Type I collagen • Not scalable
Thermally induced phase Separation	Decreasing system temperature of a polymer solution causes a polymer to phase separate from its solvent resulting in a nanofibrous polymer matrix	• Fiber diameters are most similar to Type I collagen (native extracellular matrix) • Scalable • Minimal equipment investment • Applicable to both 2D and 3D fabrication	• Requires careful solvent choice (gelation temperature is critical parameter) • Requires certain degree of polymer crystallinity



• **Figure 1.4.7.4** Schematic of electrospinning equipment used to create large-diameter nanofibers. A polymer solution is drawn into fibers when an electric potential is applied between the syringe needle and a substrate (A); the resulting nanofibers have average diameters on the micron scale (B, scale = 20 μm). (Adapted from 2014. RSC Adv. 4, 13652–13661.)

morphologies are governed by changes in pH and solution activity, which modulate electrostatic forces. While these supramolecular fibers are shown to support cellular activity, they do not have the same bulk structure as ECM proteins (Fields et al., 1998; Yu et al., 1999). Hartgerink et al. used this strategy to fabricate peptide amphiphile nanofibrous cylindrical micelles. These nanofibers are, on average, 5–8 nm in diameter and about 1 μm in length (Hartgerink et al., 2002). Others have formed biomimetic beta-sheet structures with two distinct surfaces—polar and nonpolar—by self-assembly of ionic self-complementary oligopeptides. Upon exposure to alkaline cations, these sheets self-assemble to a nanofibrous hydrogel, which facilitates neuronal cell attachment and differentiation (Holmes et al., 2000). Similarly, multidomain synthetic peptides have been shown to self-assemble into nanofibrous hydrogels and elicit favorable cell responses toward angiogenesis and neurogenesis (Moore et al., 2018). Scientifically, self-assembled nanofibers are interesting. Complicated chemical syntheses and potentially high cost can achieve lowest end diameters of synthetic polymer nanofibers. These self-assembly techniques are largely used to make hydrogel matrices.

Thermally Induced Phase Separation

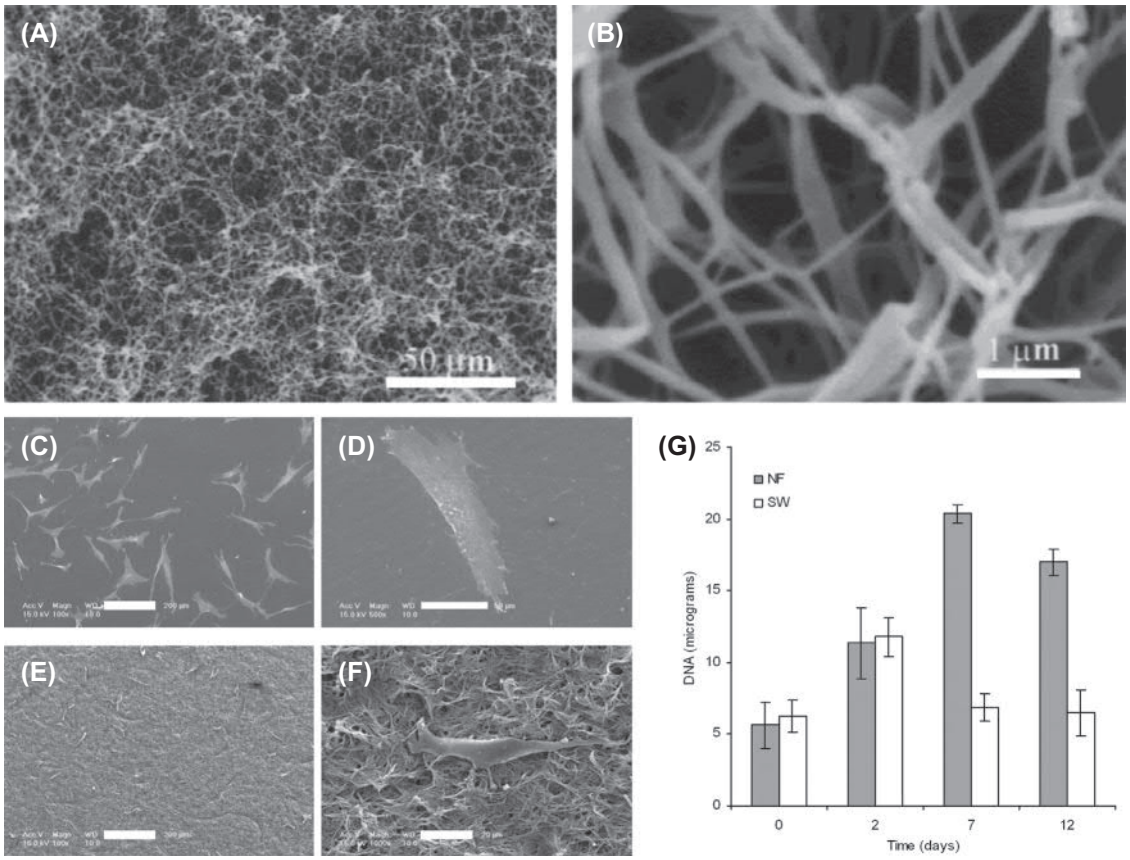
Thermally induced phase separation (TIPS) requires minimal equipment and achieves fiber diameters most similar to the native ECM. Phase separation occurs when a multicomponent system becomes thermodynamically unstable under certain conditions and separates into a multiphase system to lower its free energy (Ma et al., 2016). Originally used in the preparation of porous polymer membranes, it has since been used to fabricate porous tissue-engineering scaffolds (Zhang and Ma, 1999b) with ECM-mimicking architecture (Zhang and Ma, 2000; Peter and Ma, 1998; Wei and Ma, 2004).

In this scaffold fabrication technique, thermally induced phase separation is utilized to fabricate the nanofibrous scaffolds through the following five steps: (1) polymer dissolution in an organic solvent, typically tetrahydrofuran (THF) but other solvents are reported (Zhang and Ma, 2000), (2) phase separation and gelation induced by low temperature, (3) solvent extraction, (4) freezing, and (5) freeze drying under vacuum (Wang et al., 2007). The critical gelation step separates the solution into polymer-rich and polymer-lean phases, which control the morphology of the resulting

TABLE 1.4.7.3 Methods for Fabricating Porous Synthetic Polymer Scaffolds for Tissue-Engineering Applications

Method	Description	Advantages	Disadvantages
Porogen leaching[a] (Mikos et al., 1994)	Polymer solution is cast in preformed porogen template; porogen leaching results in 3D macropores	• Depends on porogen choice • Possible to have large amount of control over pore size, shape, and interconnectivity • Open pore architecture	• Porogen and polymer solvent compatibilities are a key parameter
	Salt leaching	• Easily leached by water	• Nonspherical • Low degree of connectivity
	Paraffin leaching	• Spherical pores of well-controlled size • High interconnectivity and tunable degree of interconnectivity	• Requires organic solvents to leach paraffin • Residual paraffin is cytotoxic
	Sugar leaching	• Spherical pores of well-controlled size • High interconnectivity and tunable degree of interconnectivity • Easily leached with water	
Phase Separation (Ma and Zhang, 1998)	Gelation of crystalline material induced by low temperature, below a critical gelation temperature. After solvent evaporation, nanofibrous matrices remain.	• Good mechanical properties • Oriented structures are possible (Ko and Ma, 2012; Zhang and Ma, 1999a,b)	• Lacks control over pore shape or interconnectivity
3D printing[a] (Sachs et al., 1992; Wu et al., 1996; Yang et al., 2001; Chen et al., 2006b)	Computer-aided design and manufacturing used to fabricate a porous scaffold by direct printing of polymer or to print a scaffold mold by reverse solid freeform fabrication	• Reproducible • Macroarchitecture and 3D shape are tunable to fit anatomy, can be patient specific	• Limited resolution for nanoscale features • Choice of material is limited
Fiber Bonding (Mikos et al., 1993)	Physical bonding of nonwoven polymer fibers to create an interconnecting mesh	• Large surface area	• Lacks mechanical strength • Difficult to control porosity, no control over shape
Emulsion freeze drying (Whang et al., 1995)	Polymer solution is homogenized with water, quenched, and freeze dried	• Open pore architecture • Aqueous phase can be used to incorporate bioactive molecules	• Difficult to control internal morphology—pore size, shape, and interconnectivity
Self-assembly (Nie et al., 2017)	Self-assembly of graphene oxide produces macrostructure based on electronic aggregation	• Allows for integration of functional moieties for improved biointegration (i.e., osteoconductive)	• Synthetically involved compared to other methods
Sintering (Borden/Laurencin J. Biomed. Mater. Res., 2002)	Thermal annealing of microspheres creates an internal 3D interconnected porous network	• Pore interconnectivity is controlled	• Difficult to control pore shape
Gas foaming[a] (Mooney 1996)	High-pressure gas dissolved to supersaturation in polymer solution to create pores	• Fast processing • No organic solvents required	• Lacks control over pore shape • Pores are not interconnected (closed pore architecture)

[a]Discussed in this chapter.

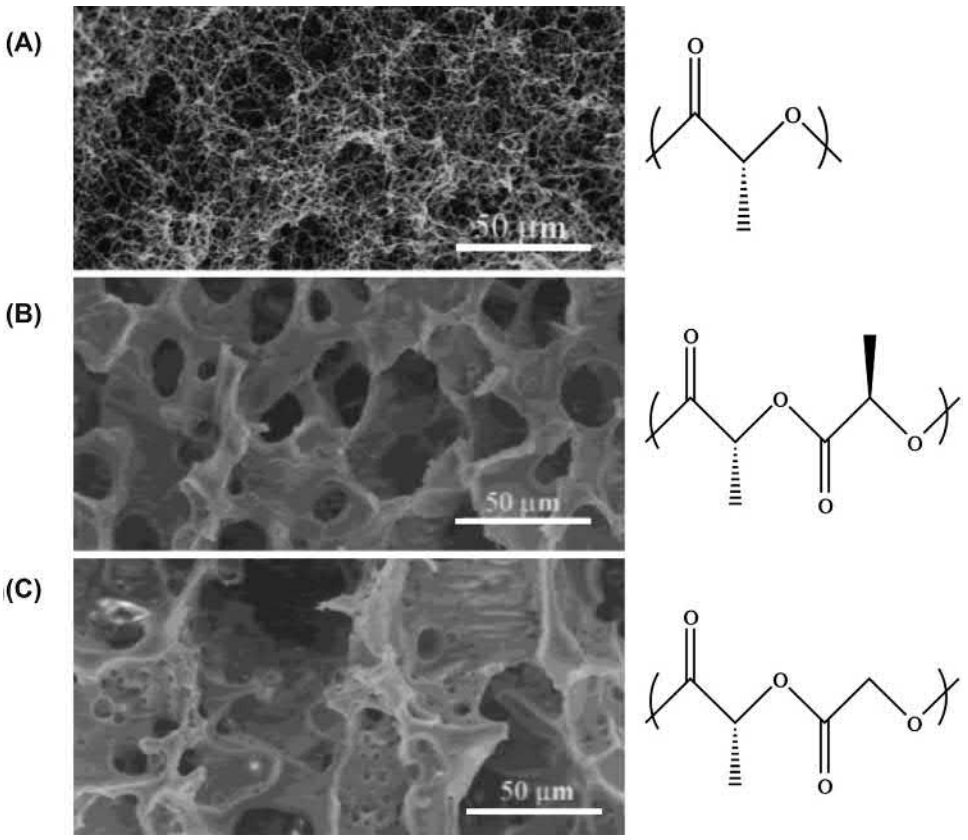


• **Figure 1.4.7.5** Scanning electron microscopy micrographs of a PLLA fibrous matrix prepared from 2.5% (wt/v) PLLA/THF solution at a gelation temperature of 8°C at 500× (A, scale = 50 μm) and 20K× (B, scale = 1 μm) magnification, demonstrating nanofibers resulting from TIPS fabrication. Cells cultured on smooth (C, scale = 200 μm; D, scale = 50 μm) and nanofibrous (E, scale = 200 μm; F, scale = 20 μm) matrices for 24 h. Osteoblast cell proliferation is increased on nanofibrous PLLA scaffolds compared to smooth scaffolds over the course of 12 days, when both scaffolds are initially seeded at the same cell density (G). *NF*, nanofibrous; *PLLA*, poly(L-lactic acid); *SW*, smooth walled; *THF*, tetrahydrofuran; *TIPS*, thermally induced phase separation. (Modified from (A,B) Ma, P.X., Zhang, R., 1999. Synthetic nano-scale fibrous extracellular matrix. J. Biomed. Mater. Res. 46, 60–72; (C–F) Hu, J., Feng, K., Liu, X., Ma, P., 2009. Chondrogenic and osteogenic differentiations of human bone marrow-derived mesenchymal stem cells on a nanofibrous scaffold with designed pore network. Biomaterials, 30 (28), 5061–5067; (G) Chen, V. J., Smith, L. A., Ma, P. X., 2006b. Bone regeneration on computer-designed nano-fibrous scaffolds. Biomaterials, 27 (21), 3973–3979.)

nanofibrous scaffold. This step is also dependent on the solvent and polymer properties (Atala and Lanza, 2001; Smith and Ma, 2004).

PLLA solution undergoes TIPS, and the solvent is exchanged to leave behind a nanofibrous matrix with fibers on the same diameter scale as natural ECM proteins, 50–500 nm (Fig. 1.4.7.5) (Ma and Zhang, 1999; Peter and Ma, 1998). Interestingly, fiber diameter does not significantly change with respect to polymer concentration, thermal annealing, solvent exchange, and freezing temperature. A lower gelation temperature (i.e., −20°C vs. liquid nitrogen) results in more well-defined fibers. At a high gelation temperature, platelet-like structures result (Ma and Zhang, 1999). These matrices have a porosity up to 98.5%, which allows cells to efficiently infiltrate the construct and facilitates nutrient exchange; they have a surface area-to-volume ratio two to three orders of magnitude higher than fibrous nonwoven fabrics made using textile technology or foams made with particulate leaching (Ma and Zhang, 1999). Because of these features, TIPS is an excellent method for achieving biologically relevant nanofibers in polymer constructs.

The TIPS phenomenon is thought to occur through spinodal liquid–liquid phase separation, and consequential crystallization of the polymer-rich phase (Smith and Ma, 2004). The ability to form a nanofibrous matrix depends on the crystallinity of the polymer, determined by its enthalpy of melting by thermogravimetric analysis. The nanofibrous textures of PLGA and poly(D,L-lactic acid) (PDLLA) matrices are evidently different from PLLA (Fig. 1.4.7.6) (Ma and Zhang, 1999). The same is noted with many PLLA-based and other functional copolymers, which must maintain a certain degree of crystallinity to be able to form stable nanofibrous structures (Liu and Ma, 2009, 2010; Liu et al., 2009).



• **Figure 1.4.7.6** Crystallinity is a critical parameter in TIPS fabrication of nanofibrous matrices. PLLA (A) forms nanofibrous matrices while PDLLA (B) and PLGA (C) do not (scale = 50 μm). *PDLLA*, Poly(D,L-lactic acid); *PLGA*, poly(lactic-*co*-glycolic acid); *PLLA*, poly(L-lactic acid); *TIPS*, thermally induced phase separation. (Reproduced from Ma, P.X, Zhang, R., 1999. Synthetic nano-scale fibrous extracellular matrix. J. Biomed. Mater. Res. 46, 60–72.)

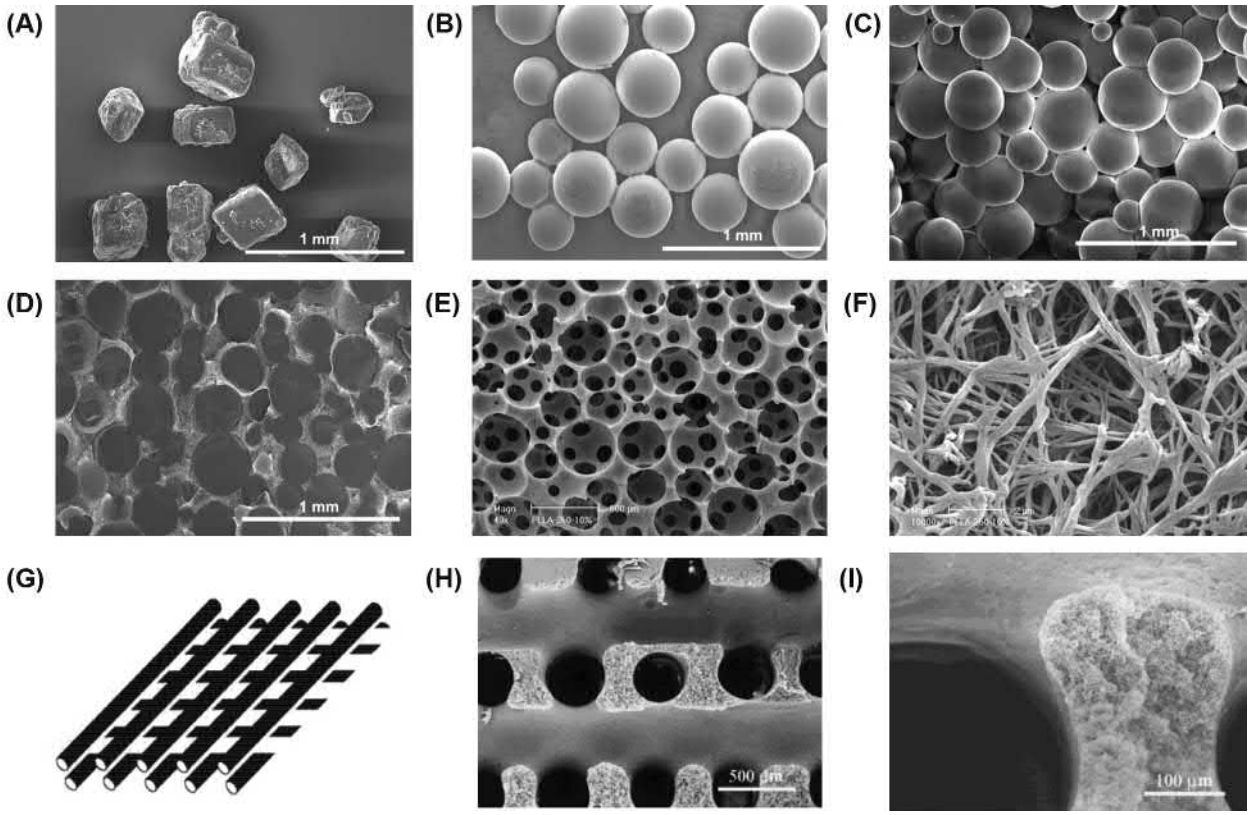
Grooves and Micropatterns

In addition to nanofibrous surface architectures, other grooved and micropatterned textured surfaces have biologic consequences on cell behavior. The ECM is critically important for organizing cell adhesion; controlling sites of cell adhesion is one method for modulating cell fate by geometric means. Capillary endothelial cells were switched from growth to apoptosis by modulating surface features of micropatterned substrates, namely so-called "adhesive islands." Other factors, including cell spreading and cell shape, are also controlled by these geometric surface features. Decreasing island size restricted cell extension and induced apoptosis. Chen and others have pioneered this so-called geometric control of cell fate, which is an enabling technology to better understand fundamental mechanisms for 2D tissue microenvironment regulation (Chen et al., 1997, 1998; Guilak et al., 2009). For example, understanding mechanisms of angiogenesis—critical to tumor growth—is important to advancing our understanding of cancer metastasis.

Micropatterned substrates are fabricated by microcontact printing, which allows for substrate patterning with regions that are selectively modified. Silicon wafers are coated with photoresist and exposed to UV light through a patterned mask. After developing the photoresist, the pattern is left on the mask, resulting in a substrate that is appropriate for making a polymer stamp (Singhvi et al., 1994). The substrate is stamped with sufficient pressure to cause contact, and proteins or other biologic molecules can be adsorbed to the surface to study cell–matrix interactions. Surface micropatterning has been demonstrated as a means of cell-based assays, as reviewed by Falconnet. This is a potentially important tool for organizing cells on sensors, as well as for drug discovery and screening applications (Falconnet et al., 2006).

Fabrication Methods for Micro- and Macroscale Architectural Features

Native tissues are organized hierarchically, with incorporated channels for mass transport of nutrients, waste, and signaling molecules, and a spatial organization of both cell–cell and cell–matrix interactions. In designing synthetic prostheses or tissue-engineering scaffolds, a biomimetic approach to recapitulating the native porous architecture is advantageous. Various studies have demonstrated the importance of interconnecting pores in a number of bone tissue-engineering and other biomedical



• **Figure 1.4.7.7** Fabrication process of sugar–porogen template leaching and TIPS, as shown by scanning electron microscopy micrographs. Sugar particles as received (250–425 μm, A) are fabricated into spherical particles via an emulsion method (250–425 μm, B). A sugar sphere template is heat treated to form a template for interconnected macropores (C) and polymer solution (PLLA/THF) is cast (D), phase separated, and solvent exchanged, resulting in a 3D macroporous (E, 50× magnification) and nanofibrous (f, 10K× magnification) scaffold. The same method can be modified to use sugar rods stacked in an orthogonal pattern (G), used to fabricate nanofibrous scaffolds (H) with tubular macropores (I). *PLLA*, Poly(L-lactic acid); *THF*, tetrahydrofuran; *TIPS*, thermally induced phase separation. (Modified from (A–F) Wei, G.B., Ma, P.X., 2006. Macroporous and nanofibrous polymer scaffolds and polymer/bone-like apatite composite scaffolds generated by sugar spheres. J. Biomed. Mater. Res. A 78A (2), 306–315; (G–I) 2000. J. Biomed Mater Res. 52 (2), 430–6.)

constructs (Wei and Ma, 2006; Zhang and Ma, 1999b; Klawitter et al., 1976; Bobyn et al., 1980; Ryan et al., 2006). While optimal pore size depends on the scaffold and tissue types, there is consensus that a minimum pore size exists to allow for vascularization, tissue ingrowth, cell infiltration, and uniform cell distribution (Chalasani et al., 2007; Gupte et al., 2018). Porous materials are fabricated from synthetic and natural polymers, ceramics, and metals—each with unique processing methods and resulting mechanical properties (Ryan et al., 2006). A porous 3D construct has a high internal surface area and void space, providing a substrate for critical cell–matrix interactions to occur (Fig. 1.4.7.3) (Ma, 2005; Alberts, 2002; Sarkisov, 2012). Porosity considerations include porosity, pore size (Gupte et al., 2018), pore shape (Kawano et al., 2014; Kasten et al., 2008), interpore connections (Chen and Ma, 2004), pore orientation (Ma and Zhang, 2001), and pore wall surface morphology (Wei and Ma, 2007). Each of these considerations and their various combinations require fabrication methods with high levels of control.

Interconnected Spherical Macropores by Porogen Methods

Porogen methods are a practical means to easily fabricate porous biomaterials with consistent macroarchitectural control, and at a low cost. Porogens are commonly used to form a template having complex pore architectures within a polymer solution by reserving free space in the matrix; once the polymer solvent evaporates and subsequently the porogen is dissolved, a porous 3D construct remains (Fig. 1.4.7.7) (Ma and Langer, 1999). Depending on the desired properties of the final construct, porogens can be solid, liquid, or gas, albeit liquid porogens are most difficult but possible in theory. For solid porogens, solvent choice and porogen/polymer solubility differences require careful consideration.

In 1991 DePonti demonstrated the first example of a porogen method using gas foaming—taking advantage of a gas-phase porogen (CO_2), which does not involve harsh solvents or high temperature to impart pores (DePonti et al., 1991). Porous PDLLA disks having up to 97% porosity

were fabricated by saturating a polymer solution with carbon dioxide for 3 days (Mooney et al., 1996). The resulting pores have a closed pore structure and solid exterior skin, both of which are not conducive to mass transport phenomena. The pores are generally nonuniform and irregularly shaped in these foams. Recent developments aim at determining appropriate parameters to achieve a more desirable pore network using supercritical fluid technology (Bhamidipati et al., 2013).

Salt was the first solid porogen and is the most frequently used method for pore fabrication (Mikos et al., 1994). First, salt is ground into small particles; particles of desired size are collected by sieving and packed into a mold. Polymer/solvent solution is cast over a packed water-soluble salt template. Salt leaching technique is discussed thoroughly in the literature (Ma and Langer, 1999). After the solvent evaporates, the solid polymer is laden with salt particles; soaking the polymer foam in water leaches away salt crystals, leaving behind pores throughout the scaffold. Salt particulate leaching can be combined with high-pressure carbon dioxide gas foaming to increase the size of pores achieved by gas foaming only, which has demonstrated utility in smooth muscle engineering (Harris et al., 1998). Despite the ease of fabrication, it is difficult to control pore shape (limited to cubic crystal structure of salt), interconnectivity (limited by nonspherical pore shape), and interpore opening size.

To improve on interconnectivity, critical to facilitate mass transport, a spherical porogen with the ability to be controllably fused is necessary. Paraffin spheres are the first example of a uniformly spherical porogen used in tissue-engineering scaffold fabrication (Ma and Choi, 2001). Spheres are fabricated by a dispersion method and annealed slightly with heat treatment in a mold. After polymer casting and solvent evaporation, a paraffin-laden polymer matrix results. Paraffin is removed in a nonpolar solvent that selectively dissolves paraffin but not the polymer, leaving behind a porous scaffold with interconnected pores.

Paraffin spheres are easily fabricated; however, it is an incompatible porogen (soluble) to many organic solvents. Additionally, its leaching can leave behind trace amounts of residual hydrophobic porogen that may have unfavorable consequences to cell activity. Sugar is an excellent alternative because it is easily processible and can be dissolved by water (Zhang and Ma, 2000). D-Fructose is emulsified in mineral oil with a nonionic surfactant, washed and sieved to desired size ranges (Fig. 1.4.7.7). Sugar is heat treated and polymer solution is cast. After leaching, scaffolds are highly porous with well-interconnected macropores and superior control over interconnectivity. Varied amounts of heat in the annealing step controls pore interconnectivity; longer heat treatment results in larger openings between pores (Ma and Choi, 2001). The compressive modulus of resulting scaffolds decreases with increasing porosity (Ma and Choi, 2001). Progress has been made in more-interconnected microchanneled and porous scaffolds by salt leaching (Tran et al., 2011) and processing salt into round particles to fabricate interconnected pores (Mukhopadhyay et al., 2010).

Nonspherical Architectural Patterning

Many tissues in the human body are naturally organized in oriented, tubular, or fibrous bundle architectures. The anisotropic properties of tissues, including nerve, muscle, dentin, tendon, and ligament, can be mimicked with carefully designed scaffolds (Ma, 2004; Ma and Zhang, 2001). Pores are incorporated by growing rod-shaped crystals in polymer solution by inducing phase separation along a uniaxial temperature gradient. Following TIPS, a network of aligned nanotubules results. When seeded with MC3T3 preosteoblasts, cells organize along tubular channels to form an oriented tissue, mimicking the organization of dentin and long bone (Ma and Zhang, 2001).

Larger oriented pores can be achieved using a tubular porogen, similar to spherical macropores discussed in detail in the section Interconnected Spherical Macropores by Porogen Methods. Melted D-fructose can be drawn into thin fibers and solidified at room temperature. Their diameter, on average 100–500 μm, can be controlled by the drawing rate from melted bulk. Fibers are organized in a mold to create a porogen frame within a PLLA solution; after TIPS, sugar fibers are leached by water leaving behind a network of uniaxially oriented tubular macropores with a nanofibrous surface texture (Zhang and Ma, 2000). It is possible to fabricate scaffolds with layered orthogonal or helicoidally oriented macropores through a layer-by-layer assembly of fibers of similar diameter in varied orientations. Pores are interconnected at contacting points of the sugar fibers. Nonporogen methods for achieving these types of macroporous architectures are also achieved by 3D printing (Chen et al., 2006b) and by injection molding around objects such as needles (Sun et al., 2012).

Combining Multiple Fabrication Methods

A review of the literature supports the importance of nanofibrous surfaces that mimic the cellular ECM, and porous constructs that support diffusion and infiltration. Nanofibers provide a continuous biomimetic fiber network that, at the cellular level, selectively increases protein adsorption compared to smooth wall constructs (Woo et al., 2003), and promotes cellular adhesion and proliferation in a variety of cell types (Smith et al., 2010; Wang et al., 2011; Liu et al., 2009). Integrin expression also mediates cell–matrix interactions and may activate pathways like focal adhesion kinase, which plays a role in cell differentiation (Smith et al., 2009); nanofibers have been shown to facilitate stem cell differentiation toward multiple differentiation fates depending on culture conditions and exogenous factors (Hu et al., 2009; Gupte and Ma, 2012; Subramanian et al., 2009; Hu et al., 2010a,b; Ahmadi et al., 2011; Liu et al., 2015; Feng et al., 2012). Scaffolds should also have an internal interconnected porous network that facilitates cellular integration, uniform cell distribution, vascularization, and nutrient/waste exchange (Ma, 2008). Uniformly spherical particles are advantageous for controlling pore interconnectivity by

heat treatment. Macropores are particularly important in cell-free constructs where endogenous cells migrate and differentiate to fill a defect (Woo et al., 2009). These 3D tissue-engineering scaffolds with interconnected macropores have demonstrated regenerative potentials in a variety of tissues and physiological systems in as little as 4 weeks. It is critical for materials scientists and biomedical engineers to consider fabrication methods that can be combined to have tailorable biomaterial processing at nano-, micro-, and macroscales.

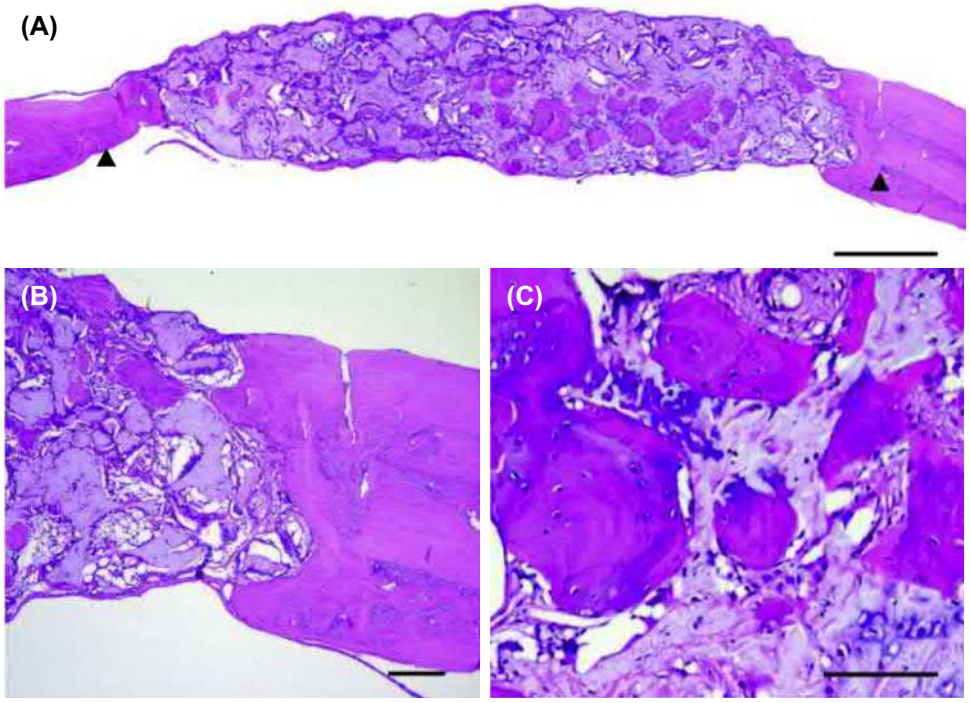
Macroporous, Nanofibrous Tissue-Engineering Scaffolds

Methods such as porogen leaching and TIPS are examples of two separate fabrication methods that are combined to yield a favorable combination of surface texture and an interconnected macroporous network. This has been demonstrated with a variety of porogens, including salt (Zhang and Ma, 2000), sugar fibers (Zhang and Ma, 2000), paraffin spheres (Chen and Ma, 2004), and sugar spheres (Wei and Ma, 2006). Porogens are chosen to be cold temperature insensitive such that polymer solutions can be cast over them and quickly chilled to gelation temperature, inducing TIPS to result in a nanofibrous matrix after solvent removal. Resulting matrices have high porosity (98%) and a high surface area (90–110 m^2/g) with biomimetic nanoarchitecture features suitable for cell attachment, proliferation, and differentiation (Wei and Ma, 2006). Sugar is an ideal porogen because it is completely leached by water.

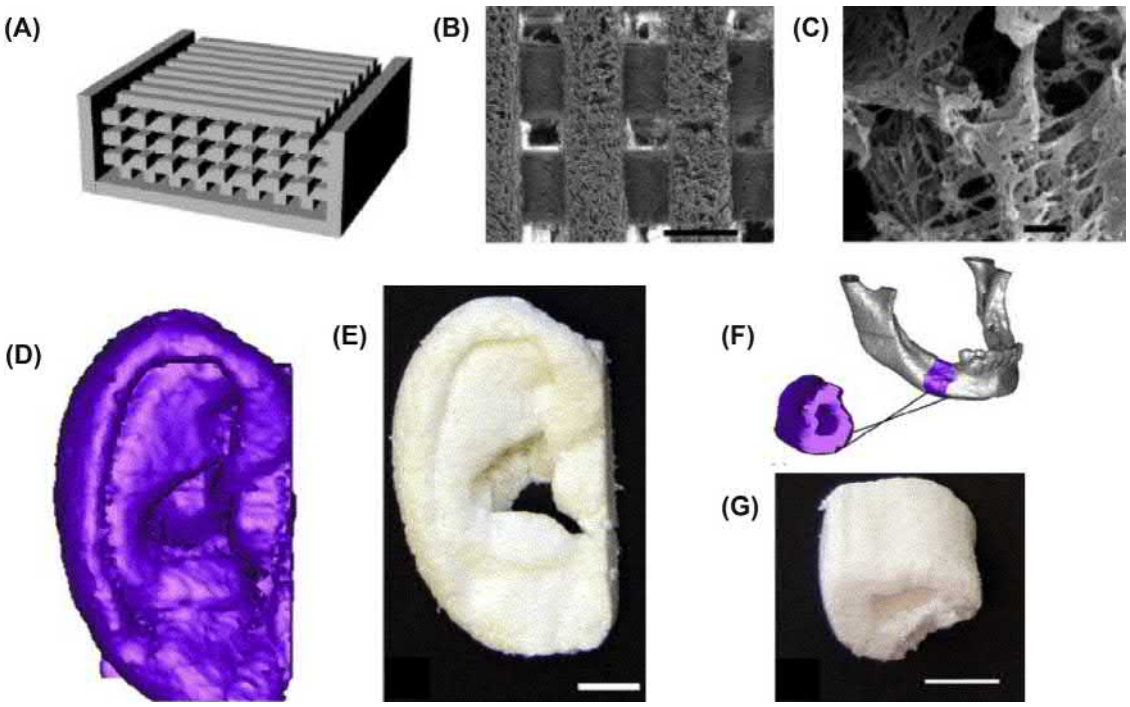
One example of the success of these constructs is seen in mineralized tissue neogenesis: odontogenesis of dental pulp stem cells in vitro and in vivo (Wang et al., 2011; Chatzistavrou et al., 2012; Soares et al., 2018), and osteogenic differentiation of multiple cell types, including embryonic stem cells (Smith et al., 2009, 2010, Hu et al., 2010) and bone marrow stromal cells in vitro (Woo et al., 2009; Hu et al., 2008). In vivo critical sized calvarial defect models have demonstrated the importance of well-interconnected macropores for vascularization as well as in supporting endogenous and exogenous osteoblasts and osteoprogenitor cells (Fig. 1.4.7.8) (Woo et al., 2009; Hu et al., 2008; Gupte et al., 2018).

Multiphasic Scaffolds

Within a single construct it is possible to incorporate multiple architectural motifs and multiple variants of the same motif. For example, in engineering a construct for the repair of an osteochondral defect it is necessary to consider the physiologic needs of cartilage and bone tissues, and their interface. It is unlikely that one scaffold design meets the needs of two distinct tissue types. However, it is equally unlikely that two unique cell-scaffold constructs, cultured separately, then combined, will result in continuous integration and distribution of cells to form a functional tissue interface (Gao et al., 2001; Alhadlaq and Mao, 2005). Patterning of architectural features can be used in directed 3D tissue differentiation within a single material construct (Hu et al., 2009). One can imagine taking advantage of



• **Figure 1.4.7.8** Histological images of H&E-stained nanofibrous scaffold implanted in a mouse calvarial defect for 8 weeks (A, *arrow* marks site of original defect, scale = 1 mm). Peripheral (B, scale = 100 μm) and central (C, scale = 100 μm) images show bone tissue neogenesis throughout the scaffold construct. (Reproduced from Woo, K., Chen, V., Jung, H., Kim, T., Shin, H., Baek, J., Kim, G., 2009. Comparative evaluation of nanofibrous scaffolding for bone regeneration in critical-size calvarial defects. Tissue Eng. A 15 (8), 2155–2162.)



• **Figure 1.4.7.9** Computer-aided design/computer-aided manufacturing-designed three-dimensional (3D) printed tissue engineering scaffolds are advantageous because of their ability to be fabricated in complex 3D macroscale shapes with well-defined features. 3D PLLA scaffolds can be fabricated from reverse solid freeform fabrication; a negative mold (A) is used for polymer casting, where the solid struts eventually become open pores in the nanofibrous scaffold (B, scale = 500 μm; C, scale = 2 μm). Computed tomography scans can be used to capture topographic features of a human ear (D, E, scale = 10 mm) and mandible (F, G, scale = 10 mm) in tissue-engineering scaffold. *PLLA*, Poly(L-lactic acid). (Reproduced from 2006. Biomaterials 27 (21), 3973–3979.)

the multipotency of bone marrow-derived mesenchymal stromal cells (BMSCs) to differentiate into osteoblasts or chondrocytes depending on the environment, and design a bioinstructive biphasic tissue-engineering scaffold to accommodate both tissue types in distinct zones (Caplan, 1991).

3D Printed Scaffolds

The macroscale shape of 3D tissue-engineering constructs is often a challenge for repairing clinically relevant large defects; new technologies in 3D printing can allow for controlled and customizable 3D scaffold shape. The earliest examples of 3D printed tissue-engineering constructs date to the mid-1990s (Giordano et al., 1996; Park et al., 1998). Computer-aided design (CAD) is employed to design scaffolds for solid freeform, reverse solid freeform, and rapid prototyping manufacturing (Giordano et al., 1996; Yang et al., 2002; Lin et al., 2004; Smith and Ma, 2012). One facile method for scaffold fabrication is to print a negative mold from a material that can later be dissolved (i.e., wax) by solid freeform methods. The mold can be filled with porogen, polymer cast, and frozen to induce TIPS. After dissolving the mold and porogen, a customized 3D scaffold shape with macroporous and nanofibrous features remains (Ma, 2004). To make scaffolds customized to a patient or injury site, a computed tomography scan of the void to be filled is taken and using CAD software the scaffold or mold can be printed to an exact fit, for example, mandibular bone regeneration following trauma (Fig. 1.4.7.9) (Chen et al., 2006b). Powder inkjet printing has also been demonstrated to be feasible, but requires improvements in efficiency before it is commercially adopted (Butscher et al., 2011). 3D printing is advantageous because it is highly reproducible; however, it is currently limited by selection of materials, which are both biocompatible/biodegradable and printable, and by pixel resolution of the printers. This area has potential for significant growth in personalized medicine applications.

Injectable Tissue-Engineering Scaffolds

To accurately fit an irregular 3D defect site with minimal intervention, a biodegradable injectable scaffold is ideal, maintaining nanofibrous and macroporous architectural motifs. In the last 15 years there has been explosive interest in using micro-/nanospheres in tissue engineering (Wang et al., 2012). The first example of a microcell carrier was by Van Wezel in 1967—using dextran microcarriers to support cell attachment, growth, and proliferation in cell culture (Van Wezel, 1967). Multiple types of anchorage-dependent mammalian cells have been shown to thrive in microcarrier culture (Posillico, 1986; Tang et al., 1994; Freed et al., 1993).

Microspheres provide a unique opportunity for tunability with control over both their interior and exterior surfaces,

nanofibrous texture, macroporous architecture, and size. Depending on polymer composition and fabrication protocol, a variety of structures can be formed, including nanofibrous solid microspheres (Liu and Ma, 2010), nanofibrous hollow microspheres (Liu et al., 2011), and nanofibrous spongy microspheres (Kuang et al., 2015; Zhang et al., 2015b). Nanofibrous surface architecture is driven by the same TIPS process described earlier, and microlevel architectures are determined by emulsion conditions. Nanofibrous hollow microspheres (NF-MSs) are fabricated from star-shaped PLLA dendrimers dissolved in THF; glycerol is slowly added to the emulsion before quenching in liquid nitrogen to induce TIPS. NF-MSs are used as an injectable platform for cartilage regeneration to successfully repair a critical size osteochondral defect in rabbits, performing better than commercially available poly(ethylene glycol) hydrogels (Liu et al., 2011). Nanofibrous spongy microspheres (NF-SMSs) are made similarly, beginning from star-shaped PLLA, critical for a hollow microsphere architecture by acting as a surfactant. A reverse emulsification process is implemented where the THF/polymer solution is added into glycerol, then quenched by liquid nitrogen to induce nanofiber formation (Kuang et al., 2015; Zhang et al., 2015b) (Fig. 1.4.7.10). The combination of nanofibers and interconnected micropores is the result of a self-assembly process, controlled by the number of arms in the core dendrimer and arm length (Zhang et al., 2015b). The microporous structure maximizes cell–matrix interactions, in turn maximizing regenerative outcomes; NF-SMSs are shown to support odontogenic differentiation of human dental pulp stem cells and are a suitable injectable cell carrier for dentin regeneration (Kuang et al., 2016). Injectable cell carriers have demonstrated a great capacity for regeneration and interest in the field. Future clinically motivated research in this area will focus on how these carriers can be further tailored and modified to direct cell differentiation and be produced in mass.

Surface Modification of Biomaterial Constructs

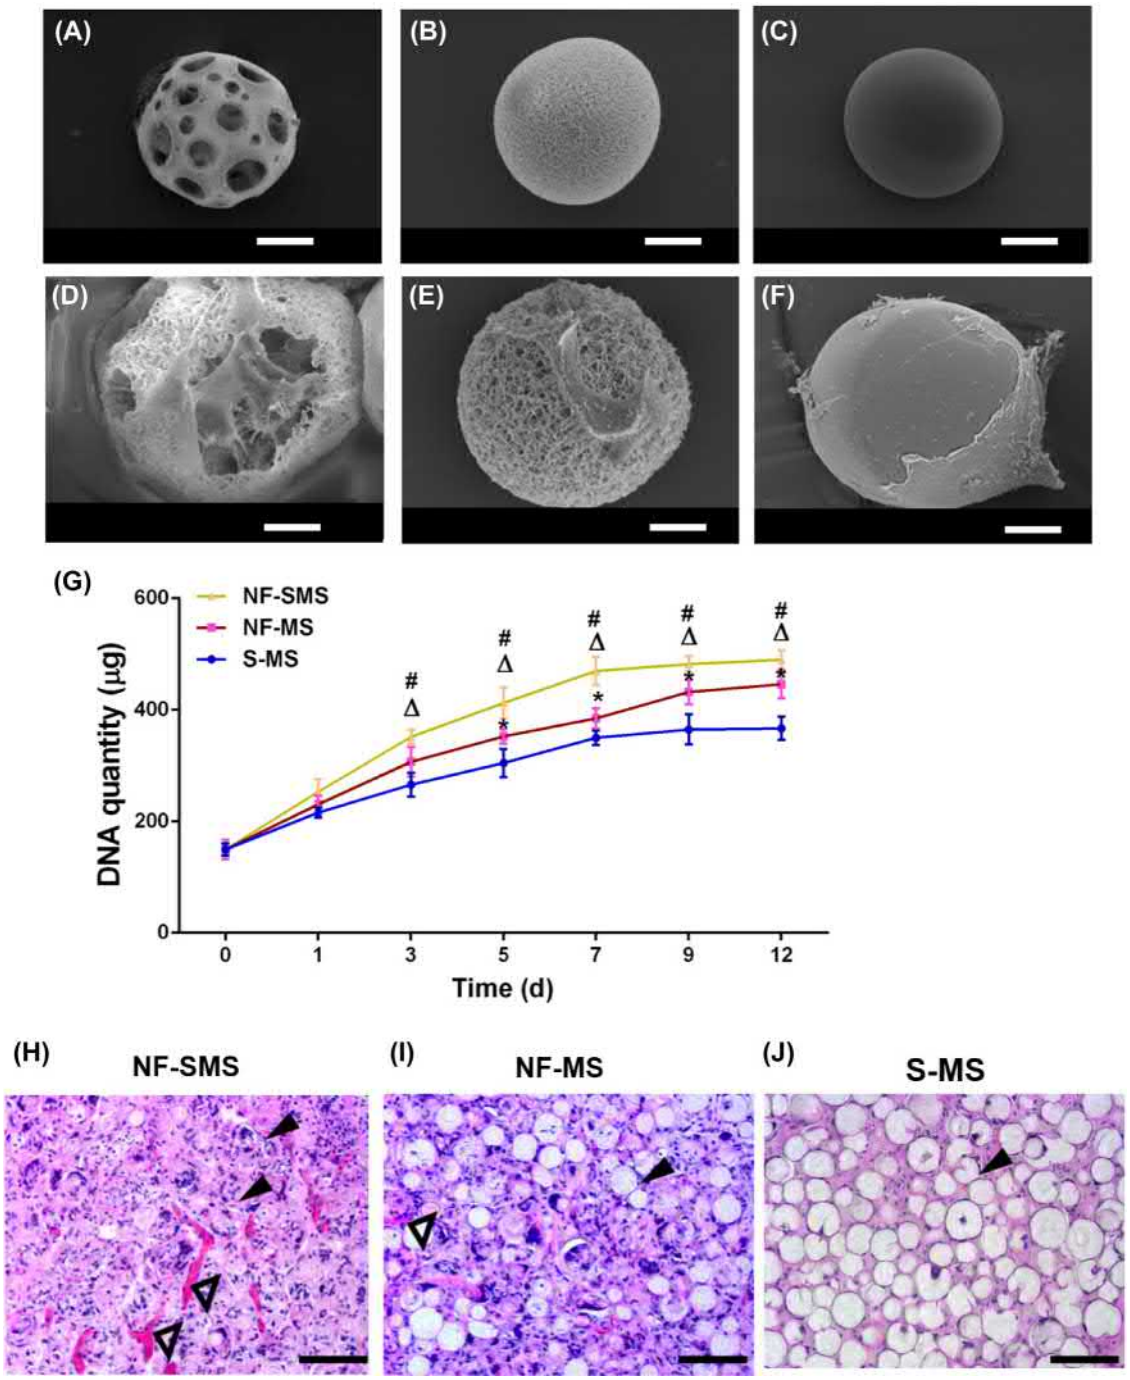
Nanofibrous and porous materials have been explored for their very high surface area to impart additional biologic functionality. Cell–matrix interactions and cell fate can be further modulated by providing additional cues that influence growth, adhesion, proliferation, and differentiation (Ma, 2004). Early examples of scaffold modification are direct modifications of scaffold surfaces to enhance the cell–material interaction. Noncovalent deposition of biomacromolecules, including albumin, heparin, and RGD peptides, to improve or resist surface adhesion (Ratner, 1993; Amiji and Park, 1993). Plasma treatment has similarly been used to promote protein immobilization (Nitschke, 2008). Specific to bone tissue engineering, hydroxyapatite surface coatings have been used to promote bone formation and mineral deposition by providing a site for mineral nucleation (Chen et al., 2006a; Zhang and Ma, 1999a, 2004; Ma et al., 2001). Mineral can also be deposited by mineral growth under an electric field, which helps to maintain small-scale architectures of scaffolds (He et al., 2010). Electrodeposition methods have also been developed to deposit charged biomacromolecules to the surface of scaffolds in a layer-by-layer method (Liu et al., 2005; Zhu et al., 2003). Other growth factors and small proteins are commonly coated to the surface of biomaterials to improve biologic outcomes; recent advances in phage selection and genetic engineering technologies are useful in determining application-specific surface proteins to mediate biologic outcomes (Ramaraju et al., 2017).

Chemically reactive functional groups can be incorporated into otherwise unreactive poly(aliphatic ester) chains through copolymerization, allowing for more flexible material design, which is amenable to modification (Shin et al., 2003; Quirk et al., 2001). Barrera et al. demonstrated the utility of poly(L-lactide)-*co*-poly(lysine) to attach RGD peptides to terminal lysine residues and enhance cell adhesion (Barrera et al., 1993). In the tin(II) 2-ethylhexanoate ($Sn(Oct)_2$)-catalyzed ring opening polymerization of L-lactide, initiators can be chosen to impart end-group functionality, for example, hydroxy(alkyl)methacrylate (Zhang et al., 2015a; Liu and Ma, 2010). Similarly, graft copolymers such as poly(hydroxyalkyl(meth)acrylate)-*g*-poly(L-lactic acid) contain repeating functional hydroxyl groups that can be functionalized with bioactive molecules to control cell–matrix interactions (Liu and Ma, 2010).

Finally, the high surface area of porous structures can be used to incorporate biomolecule delivery systems. PLGA nano- and microspheres are excellent candidates for encapsulation (Langer, 1998; Wei et al., 2004), which can be physically attached to the tissue-engineering construct by solvent wetting throughout a 3D construct (Wei et al., 2007; Hu et al., 2009; Zhang et al., 2015a). More complex delivery systems, for example, micro-RNA (Zhang et al., 2016a) and plasmid-DNA (Feng et al., 2017) delivery vectors, are incorporated through two-stage delivery systems. Growing interest in biologically derived therapeutics will require new innovation to incorporate these deliverables into adequate delivery and tissue-engineering systems. Multifunctional tissue-engineering scaffolds will be a large area of exploration in the coming years.

Summary and Future Perspectives

Textured and porous biomaterials show enhanced performance in terms of both short- and long-term successes of many biomedical devices by promoting cell adhesion, tissue infiltration, host integration, and improved biocompatibility. A high degree of fabrication controls over design architectures at both micro- and nanoscales is paramount to the diverse applications of biomaterials in clinically adopted medical products. For example, texture is important at the nanoscale to recapitulate the surface morphology of the native ECM-mimicking proteins (collagen, elastin), which supports cells and tissue organization, and porosity is important at the microscale where highly interconnected pores support



• **Figure 1.4.7.10** Scanning electron microscopy images of nanofibrous spongy microspheres (A, D), nanofibrous microspheres (B, E), and smooth microsphere (C, F) with diameters ranging from 30 to 60 μm, for use as injectable cell carriers (scale = 20 μm). hDPSCs attach to all three types of microspheres (D–F) after 24 h. Nanofibrous spongy microspheres are advantageous because of their increased porosity, which allows for cell attachment on both the inside and outside of the cell (D, G). After just 12 h this is evident by DNA quantification (G, #: $P < .05$, NF-SMS vs. S-MS, Δ: $P < .05$, NF-MS vs. S-MS). Subcutaneous injection of hDPSC–microsphere complexes generated tissue after 4 weeks in vivo; *solid triangles* indicate microspheres and *hollow triangles* indicate blood vessel formation. The most neotissue was formed with the highly porous NF-SMS (H–J, scale = 50 μm). *hDPSCs*, Human dental pulp stem cells; *NF-MS*, nanofibrous microspheres; *NF-SMS*, nanofibrous spongy microspheres; *S-MS,* solid microspheres. (Modified from Kuang, R., Zhang, Z., Jin, X., Hu, J., Shi, S., Ni, L., Ma, P.X., 2016. Nanofibrous spongy microspheres for the delivery of hypoxia-primed human dental pulp stem cells to regenerate vascularized dental pulp. Acta Biomater. 33, 225–234.)

nutrient transfer, and promote cell migration and proliferation, leading to host integration. Both nanofibrous texture and porosity increase construct surface area, creating space for cells to attach and proliferate, and a space to embed other signals at the surface of polymeric constructs. Such biomaterial architectural features can be achieved by using different fabrication methods discussed in this chapter. Moreover, multiple fabrication methods can be combined to fabricate constructs with multiple levels of architectural features.

In the coming years significant expansion in the fields of biomaterials science is expected, particularly in the areas of regenerative medicine and tissue engineering. Some future foreseeable challenges for porous and textured biomaterials are:

- **Scalable processing:** Many of the methods mentioned in this chapter have been developed in academic settings and are laborious in nature, making their scalability potentially challenging for future industry partners. Additionally, some steps in these processes, including solvent evaporation, are not rapid and may require days to weeks. In developing new biomaterial technologies, scalability must be considered early in development to facilitate future clinical and industry adoption.
- **Advances in 3D printing:** Macro-scale architectural control of construct shape is conveniently accomplished through 3D printing, and recently resolution has improved dramatically (Chia and Wu, 2014). Means of combining existing and new nano- and microscale feature fabrication strategies with 3D printing remains a challenge.
- **Range of biomaterial choices:** A long-standing issue with all biomaterial constructs is the limited selection of materials approved by the US Food and Drug Administration for use in humans. Materials scientists and engineers must find practical ways to maximize the functionality and bioeffectiveness of approved materials.
- **Compromised mechanical properties:** Porous materials inherently have a much higher surface area, directly responsible for cell–material interfacial interactions, at the expense of low density (Rouquerol et al., 1994; Sarkisov, 2012). Altered mechanical properties of materials as a result of processing make it difficult to match those of the surrounding tissues. Mismatch leads to insufficient integration capacity, and ultimately compromises longevity and utility of biomaterial constructs. This mismatch can lead to stress shielding, reduced interfacial stability, and ultimately rejection by the host.
- **Host reaction and long-term biosafety:** Biomaterial constructs must be strategically designed to synergize with local tissues, rather than cause local inflammation, which leads to rejection. Rather than fibrous tissue encapsulation, engineers must design biomaterial constructs that interface with native tissue. Over the last 30 years, the field of biomaterials has seen explosive growth, in particular in novel processing technologies discussed in this chapter, which increase biocompatibility and facilitate quicker, better outcomes for patients. Long-term validation of the effects of these biomaterial implants and products is still being assessed, and will inform future directions of the field. Biocompatibility studies, complete with organ pathology studies, are necessary to demonstrate the absence of systemic toxicity. Poly(L-lactide), one of the most common synthetic biomaterials, has been demonstrated safe beyond 110 weeks of in vivo implantation (Pistner et al., 1993). The effects of processing techniques must be minimal to maintain the safety and biocompatibility of such materials.

Despite these challenges, the biomaterial market worldwide continues to expand at a rapid pace, valued at US$134.3 billion in 2017, and will be a fruitful space for innovation in processing, fabrication, and manufacturing technologies (Rohan, 2017).

Increasing collaboration between clinicians, engineers, and biologists will continue to move the field toward clinical solutions. Recent trends in tissue engineering indicate a movement toward cell-free therapies to avoid issues with cell transplantation (Ikehara, 2013; Wei et al., 2007; Zhang et al., 2016a); tissue engineering constructs and biomedical devices require increasingly more inherent bioinstructive features to fill complex roles within physiologic systems. Therefore continued development of fabrication methods that allow for separate feature control at multiple architectural levels will increase the tunability of scaffolds. In developing new fabrication strategies, engineers and scientists in the space of biomedical innovation must keep in mind certain factors, including cost, fabrication simplicity, batch-to-batch consistency, relevant mechanical properties, biodegradability, and immune inertness. Additional work to elucidate cellular mechanisms influencing cell–artificial matrix interactions and long-term tissue-engineered construct success is necessary, with appropriate controls. In the coming years, biomaterials technology will continue to expand and be refined to suit an even wider variety of clinical needs.

Chapter Exercises

1. What are the major challenges for successful structural and functional integration of biomedical implants with native tissues?

There is a clear need for seamless and functional integration of synthetic implants with host tissue. Properties of biomedical implants must be balanced with their specific application. Important considerations include vascularization and innervation, and minimizing fibrous tissue encapsulation. Architectural and biochemical properties of the cell microenvironment, particularly at the cell–material interface, are critically important and tailorable. For example, nanofibers promote cell adhesion, proliferation, and differentiation on the material surface; porous implants facilitate tissue ingrowth and host integration.

2. Many strategies to engineer a functional tissue equivalent propose the use of an appropriate biomaterial that mimics the native ECM. What are the critical considerations of a biomaterial to be considered appropriate?

Key considerations include recapitulating native mechanical properties, physiological response, degradation rate and degradation products, cell infiltration and integration, cost, ease of manufacturing, and minimizing immune response. These factors can be modulated by selecting materials with appropriate mechanical properties, chemical composition and degradation rates, surface modification, and choosing appropriate fabrication methods for nano-, micro-, and macrolevel architectures.

3. Collagen, in the native ECM, imparts tensile strength to tissues. What aspects of collagen are structurally favorable? How can this favorable 3D structure–function relationship be recapitulated by synthetic biomaterials? What are the limitations of naturally isolated collagen as a biomaterial?

Type I collagen, which composes a majority of the native ECM, is a protein with a triple-helical fiber structure. Fiber diameters are roughly 50–500 μm. Therefore synthetic polymers must be fabricated with similar fiber diameters. This is best accomplished by TIPS. Collagen lacks processing control in regards to mechanical properties, degradation rate, batch-to-batch inconsistencies, and pathogenicity.

4. You have synthesized a new biodegradable polymer for potential use in tissue-engineering scaffold applications. What design criteria would be implicated in:

a. Increasing cell adhesion to the scaffold construct? Nanofibrous surface texture.
b. Directing cell alignment in the scaffold construct? Aligned macropores using a tubular porogen.
c. Promote osteogenic differentiation and calcium secretion? Use the increased surface area of a nanofibrous macroporous scaffold to adhere osteogenic factors such as bone morphogenetic proteins or hydroxyapatite.

5. Angiogenesis is critical to influence tissue neogenesis and integration of synthetic biomaterial constructs. What strategies would you employ to enhance vascularization in a synthetic prosthetic implant? Outline an appropriate experiment, with controls, to test this strategy.

To enhance vascularization, blood vessels must be able to form at the surface of and into the implanted construct. Therefore a macroporous texture is advantageous to allow cell and blood vessel infiltration. To test this hypothesis, smooth and macroporous implants could be implanted into an animal; after adequate time, histology for blood vessel formation can be quantified.

6. A patient presents with a critical size osteochondral defect (bone and cartilage) in their knee as the result of repeated athletic injury. Describe a method for fabricating a tissue-engineering scaffold that is suitable for regeneration of both tissue types in this defect.

Bone and cartilage must be combined in the same tissue-engineering construct in two distinct regions. Considerations may include pore size, pore interconnectivity, and surface decoration.

7. You are a senior staff scientist at a pharmaceutical company, working in the biomedical devices and implants division. The director of research and development has tasked you with leading a phase 1 project of an implantable biosensor for optical blood pressure sensing. What specific features would you propose to increase biocompatibility of the synthetic construct?

To increase long-term device success, you want it to integrate with the surrounding tissue without being encapsulated by fibrous tissue. Therefore ECM-like nanofibers and/or a porous surface texture are important to allow tissue ingrowth.

8. Implantation of biomaterials leads to a host of reactions that can be characterized by a series of cellular responses. You are tasked with designing a composite temporal mandibular joint implant. In general, how would you circumvent complications associated with host rejection and expedite wound healing?

ECM-like nanofibers and/or a porous surface texture are important to allow tissue ingrowth. Pores, in particular, are advantageous and must be large enough to facilitate cell and tissue infiltration, but small enough to prevent fibrous tissue formation. Nanofibers are important to disrupt capsule formation by disrupting collagen fiber orientation.

1.4.8

Biomedical Applications of Additive Manufacturing

Introduction

Additive manufacturing, broadly known as 3D printing, is a class of manufacturing processes in which a 3D construct is built through sequential layer fabrication. This rapid prototyping methodology is transforming how medical devices are designed, developed, and manufactured by enabling low-volume and on-demand production without dedicated equipment or tooling. In brief, computer-aided design software is used to generate a 3D model that is then exported into a file format that describes the volume or surface mesh in 3D space. Another program, generally known as a "slicer," is then used to translate the 3D data into individual layers to be printed using a multi-axis positioning system through a variety of processes, including extrusion deposition, solidification, polymerization, sintering, or binding. A subset of additive manufacturing includes living cells during the printing process and has been termed bioprinting (Jose et al., 2016). Specifically, bioprinting enables robotic deposition of cells and materials into custom shapes and patterns to replicate anatomical complexity associated with tissues and organs (Chimene et al., 2016). Bioprinting has been adopted for tissue engineering with the goal of developing highly customized cell-laden scaffolds to enable healthy human tissue to be regrown from a patient's own stem cells (Murphy and Atala, 2014; Kang et al., 2016; Norotte et al., 2009). This chapter provides an overview of common 3D printing modalities and design considerations for bioprinting. Current applications of 3D printing technologies in different facets of the medical field are highlighted to demonstrate the current and future impact of additive manufacturing in healthcare.

3D Printing Modalities

There are numerous additive manufacturing modalities with new commercial variants under continuous development. In an effort to structure this rapidly expanding portfolio of technologies, process categories were utilized to group these techniques based on the material type and method used to combine each layer. Table 1.4.8.1 provides common families of 3D printing processes as published originally in the 2012 ASTM F2792—12a Standard Terminology for Additive Manufacturing Technologies. For each of these modalities, a general description of the process and material requirements is provided with representative application cases within the medical field.

Vat Photolithography

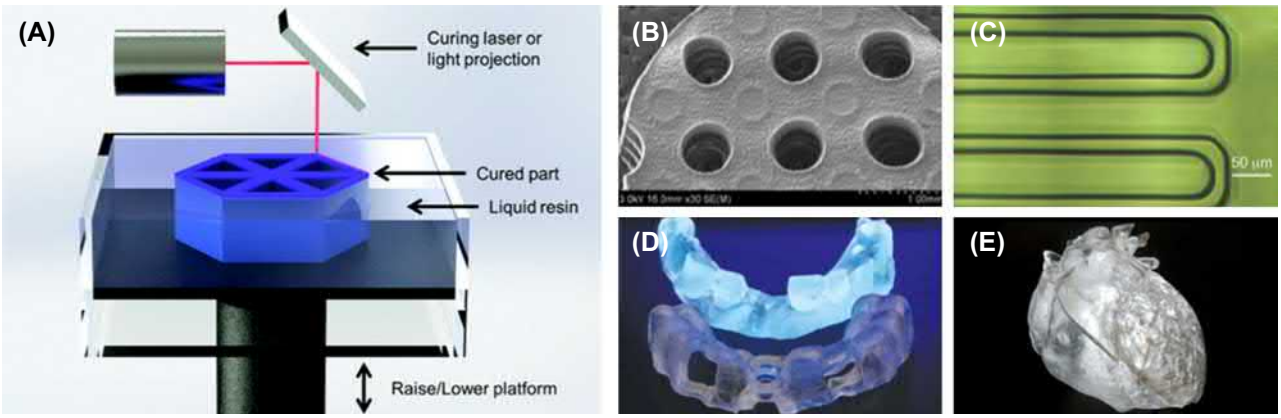
Stereolithography (SLA) is a vat photopolymerization technique that uses a laser to cure a photopolymer reservoir layer by layer. A platform is initially positioned so that there is one layer height of the photopolymer between the platform and the light source. The laser is projected onto the surface of the photopolymer reservoir, curing a path determined by the print design (Melchels et al., 2010). Once a layer is cured, the platform is moved so that successive layers of photopolymer can be cured to form the object (Wong and Hernandez, 2012). The most common photopolymer resins used are low-molecular weight, multifunctional monomers that usually cure to form brittle constructs (Melchels et al., 2010). New polymers have been fabricated that are biocompatible (e.g., urethane dimethacrylate, diisopropyl acrylamide) and biodegradable (e.g., polypropylene fumarate, linear poly(D,L-lactide)-methacrylate) for use in biomedical applications. The print resolution is limited by the layer height, which can be as low as 20 μm (Kamran and Saxena, 2016). This is a very high accuracy and versatile technique that does not require any support material to print hollow or porous structures (Sachlos and Czernuszka, 2003). The main drawback is the limited number of commercially

TABLE 1.4.8.1 Schematics of Different 3D Printing Methodologies

Vat polymerization		The build platform is lowered into a vat of liquid photopolymer resin. A UV light cures the resin in layers on top of the platform. *Alternative Names:* SLA – Stereolithography Apparatus, DLP – Digital Light Processing *Resolution:* *10* μm
Material jetting		Droplets of material are deposited onto the surface using a thermal or piezoelectric method. Each layer is cooled or cured by UV light. *Alternative Names:* Inkjet printing, MJM – Multi-jet modeling *Resolution:* *25–100* μm
Material extrusion		A material spool is fed and melted through a heated nozzle and deposited onto the surface, layer by layer. *Alternative Names:* *FDM – Fused deposition modeling* *Resolution:* *50–200* μm
Powder bed fusion		The material in powder form is spread over the surface and fused to other layers using a laser or electron beam. *Alternative Names:* *SMS – Selective metal sintering, SHS – Selective heat sintering, DMLS – Direct metal laser sintering* *Resolution:* *80–250* μm
Binder jetting		Building material in powder form is rolled/spread into a flat sheet. A liquid binding agent is selectively applied between layers as an adhesive. *Alternative Names:* *PB – Powder bed printing* *Resolution:* *80–250* μm
Sheet lamination		Material in sheet form is placed on a cutting bed and bonded over the surface using an adhesive. Each layer is cut to shape by laser, knife, or drill after bonding. *Alternative Names:* *UC – Ultrasonic consolidation, LOM – Laminated object manufacturing* *Resolution:* *Depends of thickness of laminates*
Direct energy deposition		Material, typically in the form of a powder or wire, is deposited onto the surface and melted using a laser or electron beam upon deposition. *Alternative Names:* *LMD – Laser metal deposition, LENS – Laser engineered net shaping* *Resolution:* *250* μm

available photopolymers. This technique has been used to print patient-specific models and implant devices, such as noncytotoxic polyacrylate and hydroxyapatite composite bone parts (Melchels et al., 2010). The development of biodegradable resins has allowed printing of resorbable tissue-engineered scaffolds with highly tailored pore architectures to promote cell attachment and tissue regeneration.

Like SLA, **digital light processing (DLP)** is a low-cost, high-throughput vat photopolymerization technique. It is a localized photopolymerization process, triggered by a



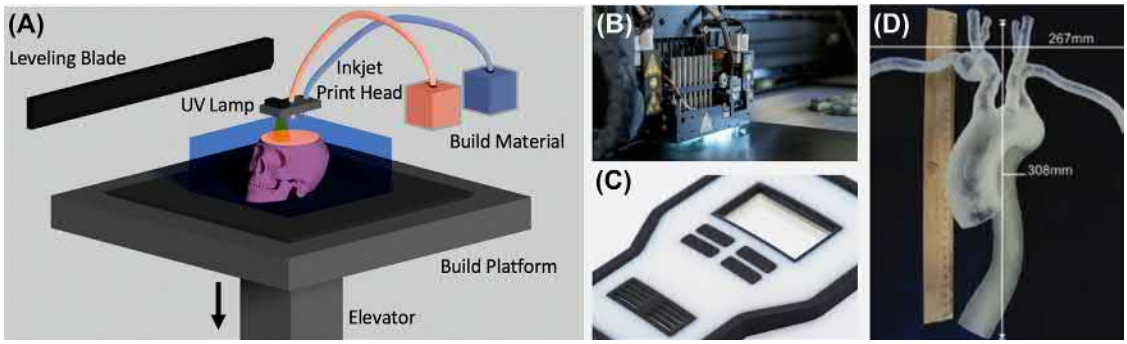
• **Figure 1.4.8.1** (A) A schematic of vat photopolymerization (Sears et al., 2016), (B) electron microscopy of a stereolithographic bone scaffold (Kim et al., 2010), (C) DLP-SLA-printed microfluidic channels (Gong et al., 2017), (D) SLA-printed model and surgical guide for dental reconstruction surgery (Patel et al., 2017), and (E) a transparent SLA-printed heart model for congenital heart disease intervention (Meier et al., 2017).

digital mirror device (DMD), a matrix of mirrors that beam light in a pixel pattern onto a bath of uncured macromer (Hornbeck, 1997). There are a limited number of liquid resin photopolymers available for DLP, and they often result in brittle prints. The photopolymer resins most often used are low-molecular weight, multifunctional monomers. This technique is capable of generating a variety of complex micro- to mesoscale structures with microscale architecture and micrometer precision, which are beneficial when printing biomaterial constructs (Kamran and Saxena, 2016). This technique also reduces printing time by curing an entire layer of resin at once. However, the resolution of the print is limited by the pixel size of the DMD, which can be as small as 16 µm (Patel et al., 2017). This printing technique is further limited by the number of commercially available photopolymer resins. DLP has been used to print lattice metamaterials, pneumatically actuated soft robots, and structures connected with trusses or cavities. It can construct 3D-printed gel scaffolds with long-term control over cell proliferation, morphology, and geometric guidance. It can also print hearing aids, physical dental models for dental restoration, and 3D convoluted vessel-like microfluidic channels (Patel et al., 2017) (Fig. 1.4.8.1).

Material Jetting

Inkjet printing and multijet modeling are two examples of material jetting printing processes. In a simple **inkjet printing** process, droplets of material, typically in liquid form, are deposited based on a predetermined path and allowed to solidify or cool before deposition of the next layer. Droplet extrusion is dependent on a pressurized system or thermal system (Cui et al., 2012). Different materials can be printed with inkjet printing, including polymers (conductive, structural, and biological), metals, nanoparticles, ceramics, and biological materials (proteins, small molecules, and nucleic acids) (Derby, 2010). Printing resolution is controlled by changing parameters like extrusion temperature, pulse frequency, and ink viscosity. Nozzle sizes for the printers range from 10 to 30 µm, with matching resolution for the droplet size. The advantages of using this method include the ability to precisely control the position of jetting, volume of material deposited, versatility in the material printed, and relatively high-speed printing (Nakamura et al., 2005; Bose et al., 2013). Inkjet printing is used in different fields, including optics, fabrication of transistors, and more recently in biomedical applications such as tissue engineering (Alamán et al., 2016; Sirringhaus et al., 2000). Research groups have demonstrated the printing of hydrogels, stiff scaffolds, and complex matrices such as native tissue vasculature (Chia and Wu, 2015). Additional developments to the printer technology now allow for the printing of live cells, typically suspended in a material solution (Chia and Wu, 2015; Boland et al., 2006).

In **multijet modeling (MJM)**, the printer has multiple nozzles (with as many as 96 nozzles) that can be simultaneously used to deposit material. The nozzles are engaged to deposit the liquid material and support material with each layer allowed to cool, or ultraviolet (UV) cured prior to deposition of the next layer (Bikas et al., 2016). This type of printing needs support material that is typically printed in pillars along the side of the actual print and then removed using a water jet or peeled off (Vaezi et al., 2013). Photopolymers are most commonly used for building materials and gel or wax materials used for the supporting structure. These printers can process complex objects with high accuracy and resolution without the use of complex lasers or beams. The print objects have a smooth surface finish and a resolution ranging from 25 to 50 µm in thickness (Bikas et al., 2016). It is a user-friendly instrument that can be used in any environment at high speed. However, the support pillars must be broken off and the bottom surface finish can be very poor, resulting in pitting and decreased strength of the material. For maintenance of exact layer thickness and compensation for small variations of droplet size, some of the more recent machines use a mechanical planarization, which can remove the excess material on each pass (Bikas et al., 2016; Vaezi et al., 2013). Several labs have demonstrated the use of this technique to print biomaterials as well. Biological materials, such as protein solutions, were printed onto cellular



• **Figure 1.4.8.2** (A) A schematic of material jetting, (B) image of a material jetting 3D printer demonstrating its UV curing lamp (3D Printing Hubs, 2018), (C) material jetting prototype with both rigid (white) and flexible (black) material (3D Printing Hubs, 2018), and (D) a material jetted model of an aorta used for surgical planning (Mitsouras et al., 2015). locations on solid substrates, which allows control of bioactive surfaces of cellular scaffolds (drop-on-demand method) (Zhu et al., 2015). MJM can also be used to develop cellular colony arrays for rapid drug screening or cytotoxicity testing (Amin et al., 2016) (Fig. 1.4.8.2).

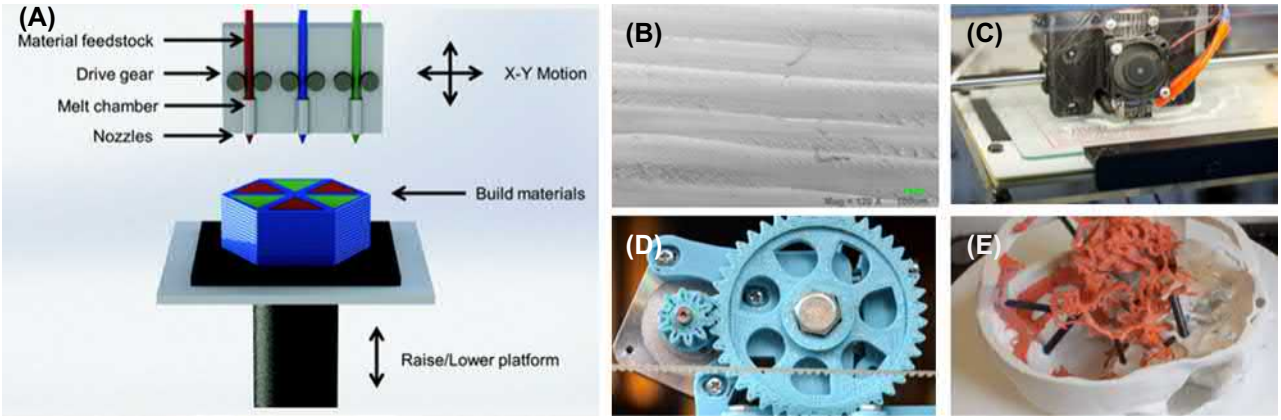
Material Extrusion

Fused Deposition Modeling (FDM) is an extrusion-based printing technique that requires the use of a nozzle to deposit material onto a platform. Extrusion of the material is dependent on pneumatic pressure or can be driven by a motor-actuated plunger system (Mohamed et al., 2015; Turner et al., 2014). Selective deposition layer by layer allows for buildup of the object from bottom to top, creating a three-dimensional (3D) object in space (Novakova-Marcincinova and Kuric, 2012). The most widely used materials for FDM printing are thermoplastic filaments, including acrylonitrile butadiene styrene, poly(lactic acid), high-impact polystyrene, thermoplastic polyurethane, and aliphatic polyamides (Nikzad et al., 2011). FDM systems can be calibrated to print materials at different temperatures and extrusion rates, and use of additional nozzles can facilitate printing of multimaterial constructs. Print resolution can depend on several different factors, including nozzle size, precision of the extruder movements in X/Y space, layer height, print speed, and shape retention of the extruded material (Ozbolat and Yu, 2013). Typical resolution is in the range of 10–300 microns (Bin et al., 2016). FDM offers several advantages, including low cost, limited use of material, accessibility, and relatively rapid turnaround, but there are several limitations to be considered (Lee et al., 2014). It is difficult to print constructs that require the printing of overhanging parts because the technique lacks an innate support system (Crump et al., 1996). This can hinder printing of certain shapes, but it has been demonstrated that secondary structures using sacrificial materials, such as sucrose or starch, can be printed to aid in the printing of overhangs. In certain cases, potential delamination of layers can introduce anisotropy and result in mechanically unstable constructs (Ahn et al., 2002). More recent developments in technology and application of materials science now allows for a broader range of materials to be printed with this technique, broadening properties of the printed constructs. Multiple research groups have demonstrated the use of FDM to print viscous liquids such as hydrogel solutions, emulsion inks, and other paste-like compositions (Zein et al., 2002; Kalita et al., 2003). This has opened up new potential applications for the printed constructs because they maintain new properties like elasticity, the ability to respond to environmental changes like pH or heat, or can act as carriers for cells, proteins, and other biological molecules (Fig. 1.4.8.3).

Powder Bed Fusion

Electron Beam Melting (EBM) is a type of powder fusion additive manufacturing technique. The instrument setup involves a vacuum chamber that contains a moving bed with powder material and an electrical optical column from which the electron beam is generated. Briefly, a heated tungsten filament in the upper column generates an electron beam that is focused and deflected off magnetic coils in the lower column (Gong et al., 2012). For each layer, the stage rakes a new, thin layer of powder and the electron beam traces a path depending upon the designed computer-aided design model. As the electron beam traces the path, the powder material is heated (average temperature between 600 and 800°C), melted, and then rapidly solidified in an inert environment such as purified argon (Murr et al., 2012b). For each layer, this process is repeated to build an object in 3D space. The most widely used powder materials for EBM include aluminum, steel, copper, titanium, and nickel, as well as different alloys of these metals (Körner, 2016). Printed construct resolution depends on parameters like beam current and diameter, thickness of each layer (0.05–0.2 mm), and the powder size (ranging from 10 to 100 μm). EBM is an efficient printing technique, with an overall approach that has reduced cost and rapid speed. Additionally, printed



• **Figure 1.4.8.3** (A) A schematic of material extrusion (Sears et al., 2016), (B) electron microscopy of the layers of a material extrusion 3D-printed object (Cuiffo et al., 2017), (C) image of common-use material extrusion prints (Halford, 2018), (D) material extrusion 3D-printed gear mechanism prototype (Schubert et al., 2014), and (E) a material extrusion 3D-printed model used in surgical planning for neurosurgery (Ventola, 2014). ((E) 3D Print Exchange. National Institutes of Health. Available at: http://3dprint.nih.gov. Accessed July 9, 2014.)

constructs maintain strong material properties because printing conditions prevent residual stresses or any distortion/warpage of the prints (Seagle et al., 1962; Rafi et al., 2013). Complex prints with novel characteristics like material gradients make EBM popular for a variety of different applications. In the field of biomaterials specifically, it has been used to impart open cellular structures into solid implants to promote stiffness compatibility (Murr et al., 2010). It has been demonstrated that incorporation of these porous structures enhanced cell growth and improved implant stability by eliminating the need for using adhesive cementing, a common but invasive practice for implant strategies (Murr et al., 2012a). With the current technology, use of EBM for other biomaterial applications is relatively limited because it can print primarily metals. Additional developments to the technology have to be made to broaden its use for fabrication of other types of biomaterials.

Selective laser sintering (SLS) and **selective heat sintering (SHS)** are additive manufacturing techniques based on powder fusion binding. SLS creates 3D parts through the application of laser energy on a powder bed, based on computer-aided design descriptions. Each layer of the print is created as the laser scans a specific path over the powder, causing the particles to sinter together in thin layers. For the SHS technique, each layer of the print is created in a similar way, but the laser will melt the particles and bond them together (Mercelis and Kruth, 2006; Chia and Wu, 2015). Subsequent layers are then created as a new layer of powder is spread on top of the previously printed layer and the laser traces the path again, thus building the object in space layer by layer. Commonly used powder materials for this technique include thermoplastics, ceramics, plasters, and composites, as well as various types of metal powders (Shirazi et al., 2015; Agarwala et al., 1995). The resolution of SLS/SHS prints depends on the size of the laser or heat source, and the size of granules. To maintain higher resolution in the prints, it has been observed that the preferred particle size is 10–150 μm (Exner et al., 2008). Furthermore, material properties, such as structure or mechanical stability, can also depend on process factors such as laser energy density, bed temperature, layer thickness, and hatch distance (Bhatnagar et al., 1999). Advantages of using this technique over other additive manufacturing techniques include fabrication of strong functional prints, design freedom, and minimal need for support structures for complex shapes. Although these are important benefits, products printed using this technique tend to have a rough, grainy surface (Mazzoli, 2013). Additionally, large shrink rates increase the probability of the parts to shrink or warp, and SLS/SHS printed products can only be printed using the materials mentioned previously. In the field of biomaterials, various research groups have demonstrated the use of SLS to fabricate mechanically strong scaffolds that have designed geometry, compositional gradients, and surface modifications with bioactive molecules (proteins) (Tan et al., 2005; Williams et al., 2005). Their results have demonstrated that incorporating these features into the scaffolds helped improve biocompatibility, increased cell proliferation, and promoted bone regeneration, proving SLS as a competent technique for fabrication of bone replacement devices (Fig. 1.4.8.4).

Binder Jetting

Powder binding is the most typical of the binder jetting processes. In contrast to other powder bed printing processes, the **powder binding** process involves two different materials: a powder material and a liquid binding material. The manufacturing process involves spreading a thin layer of the powder material and the selective deposition of a liquid binding material using a computer-aided design model. The jetted binding droplets on the powder surface cause the powder to agglomerate (Gokuldoss et al., 2017). The next

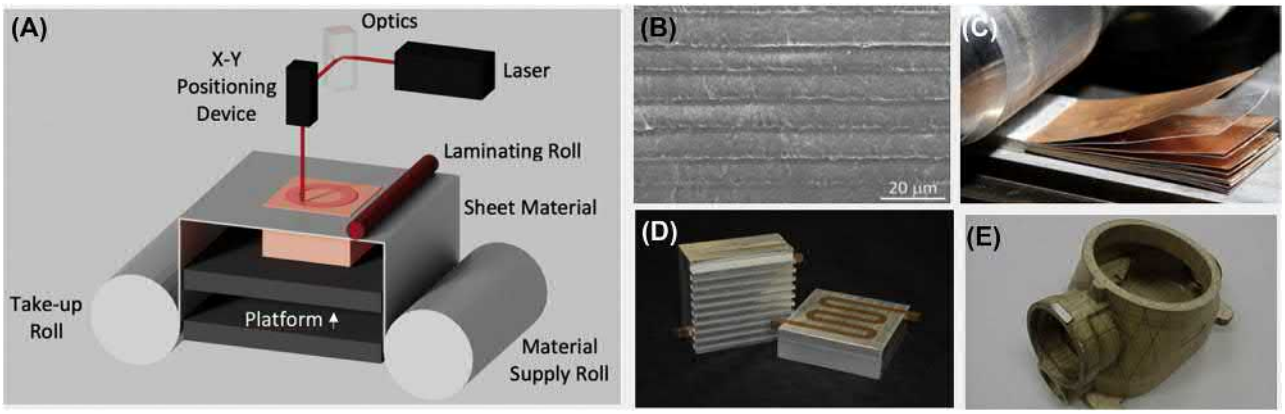
• **Figure 1.4.8.5** (A) A schematic of binder jetting (Jackson et al., 2017), (B) SEM of water-atomized powders used in powder binding printing (Mostafaei et al., 2017), and (C) metal binder jetting printed splinted framework for dental reconstruction (Cascón and Revilla-León, 2018).

layer of powder is added, spread, and the process of binder jetting is repeated. The final construct is built after all iterations of this process are completed (number of iterations varies per individual construct) (Gao et al., 2015). Common materials that can be used for this printing technique include metals/alloys (aluminum, copper, iron, nickel, and cobalt), ceramics (glass, sand, and graphite), and any other material that is available in powder form (Gonzalez et al., 2016). Product resolution depends strongly on the velocity, initial size, and path of the droplets, as well as nozzle diameter and liquid binder properties (Gibson et al., 2015a). The powder binding process is a relatively popular method as parts can be produced without support structures and it is a relatively rapid and cost-effective technique. Although the process does not involve heating during the build process, thermal treatments such as curing, sintering, and annealing after the initial printing with the binder are often required for consolidation (Gokuldoss et al., 2017). These postprint processes are required to generate sufficient mechanical properties for use and can add significant time and cost to the prints. Additionally, the resulting coarse microstructure of the printed constructs can reduce material mechanical properties due to the presence of microscale porosity in between the sintered particles. Research groups have fabricated ceramic implants with various geometrical designs such as porous structures and cylindrical holes for bone regeneration in vivo demonstrating the potential benefit of using this technique for designing medical implants (Gokuldoss et al., 2017) (Fig. 1.4.8.5).

Sheet Lamination

Laminated Object Manufacturing (LOM) is an additive manufacturing technique based on laser cutting of cross-sections from solid materials. These materials are typically provided in a sheet form (Park et al., 2000). For every layer,



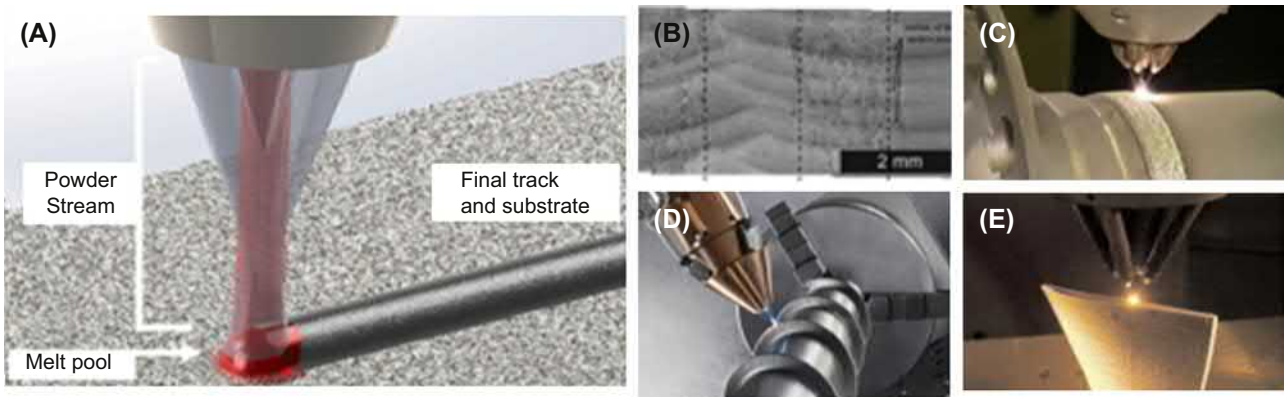
• **Figure 1.4.8.6** (A) A schematic of sheet lamination (Suresh et al., 2017), (B) SEM showing structure of laminated sheets (Yamamoto et al., 2014), (C) an image of a material-binding layer in sheet lamination (Additive Manufacturing Group, 2014), (D) a multimaterial print using ultrasonic consolidation (3D Diligent, 2019), and (E) a laminated object manufacturing (LOM) model of a valve flange (Manufacturing Technology Centre, 2018).

after the laser cuts along the contour of the specific part's geometry, a new sheet of material is spread over a movable substrate in preparation for cutting the next layer (Mekonnen et al., 2016). Laser cutting patterns are determined by computer-aided design models and relayed to the cutter. In postcutting, the layers are bound together with a hot roller that compresses the sheets and activates adhesives on the sheets (Zocca et al., 2015). Sheet material that can be used for this technique includes layers of paper, plastic, metal, foil, or ceramics (Wong and Hernandez, 2012; Bikas et al., 2016). Print resolution depends on parameters such as laser power/speed, temperature, and cross-hatch size. The main advantage of using this method is the high fabrication speed, largely because the laser only has to cut through one sheet at a time, not the entire cross-section of material. Additional benefits include low cost, no postprocessing or supporting material needed for printing structures, high durability parts, and use of nontoxic or reactive materials (Mueller and Kochan, 1999; Klosterman et al., 1998). Although there are numerous benefits, it has been commonly observed that the surface of LOM-generated objects typically has a poor finish due to limited control over how thick the sheets used can be and smaller pieces commonly have lower detail reproduction due to limited accuracy in the Z-dimension of the laser. Additionally, large amounts of waste can be generated depending on the design and shape of the part being printed (Gibson et al., 2015b). The LOM technique is used commonly for rapid prototyping of plastic parts, molding, and foundry, but use in the biomedical field has been limited to reproducing models of organs (Mueller and Kochan, 1999) (Fig. 1.4.8.6).

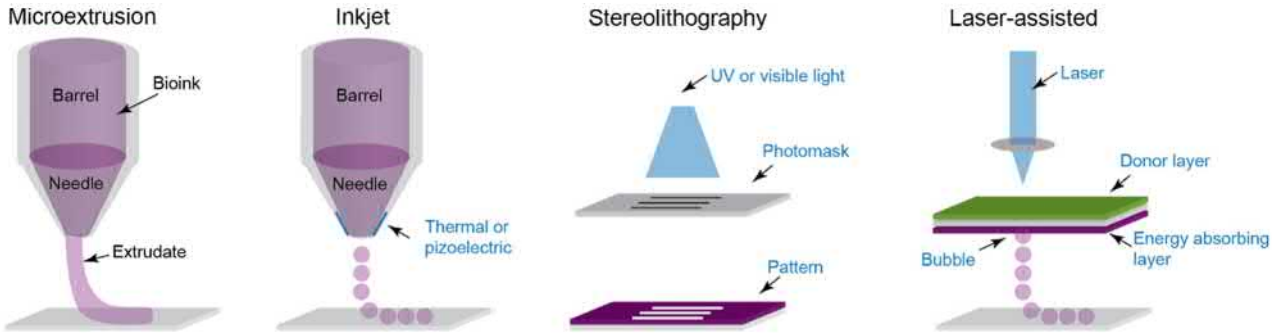
Ultrasonic Consolidation (UC) is a printing technique that combines additive manufacturing and computer numerical control to generate specific constructs from computer-aided design models. Briefly, this technique involves sequential, layer-by-layer binding of metal foils together using ultrasonic welding (White, 2003). Ultrasonic vibrations are applied to the tape (metal foils) through a sonotrode that vibrates at a specific frequency and amplitude. The sonotrode is rolled along the length of the tape, thus bonding the tape to the ones below producing a weld between the two (Kelly et al., 2014). This technique is most commonly used to fabricate metal composite structures or metal–matrix composites, with the main foils fabricated using materials such as aluminum, copper, iron, and nickel. Several different parameters dictate resolution in UC, including: higher oscillation amplitudes for the sonotrode, high magnitude of normal force, higher substrate temperature, and lower welding speeds (Chua and Leong, 2014). Furthermore, it is important to note that these parameters often need to be modified depending on the material and vary from machine to machine. Advantages to using this technique include fabrication of parts with high dimensional accuracy, good surface finish, and fabrication of complex structures such as internal passageways, honeycomb structures, or objects made from many different types of metals. Furthermore, the fabrication process does not involve any sort of melting, limiting shrinkage, residual stresses, or distortion in finished parts. Finished part quality highly depends on the frictional conditions at the sonotrode/foil interface and can propagate defects within the part, ultimately affecting mechanical properties, surface finish, and overall quality (Kelly et al., 2014). Thus far, UC has mostly been used for the fabrication of metal parts, limiting its use in the field of biomaterials to fabrication of implants. Limited research has been done to demonstrate the utility of this technique for medical applications.

Directed Deposition

Laser Metal Deposition (LMD) is a direct energy deposition technique that is often used to 3D print metallic parts or add features to an existing metallic structure (Herzog et al., 2016). It uses a high power laser beam to melt the metal surface while simultaneously depositing a metal powder or wire (Kaierle et al., 2012). The metallic powder is extruded through one or more deposition nozzles to form a part layer by layer. Varying laser power, extrusion width, speed of



• **Figure 1.4.8.7** (A) A schematic of direct energy deposition (Pinkerton, 2015), (B) optical micrographs of the overlap of lines of a titanium alloy using DED (Saboori et al., 2017), (C) image of a laser metal deposition (DED) machine (Jackson et al., 2018), (D) using LMD to create threads on a metal shaft, and (E) a processor blade being created using Laser Engineered Net Shaping (LENS) technology (Gill).



• **Figure 1.4.8.8** Schematic overview of bioprinting processes.

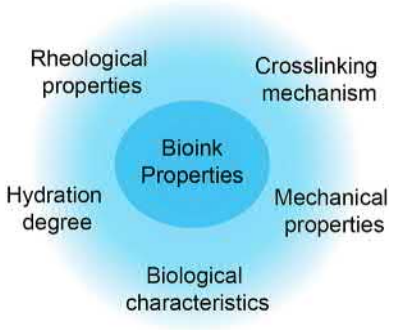
motion, and powder feed rates allow control of speed and resolution of the print (Santos et al., 2006). LMD can be used to print objects from millimeters to meters in size with a resolution as low as 1 mm (Pinkerton, 2015). Different metal materials can be used, such as nickel, cobalt, iron, copper-based metals, and carbide materials. It can also print titanium alloys, which are widely used in medical devices (Gu et al., 2012). The high level of control over the heat and positioning of the laser beam allow for very reliable results with low heat distortion and improved microstructure. However, relatively high cost and low reproducibility make it a less used method for printing parts (Kaierle et al., 2012). LMD has been used to create implants that have improved, controlled properties to promote osseointegration and cell ingrowth. It can print implants with a highly controlled and interconnected porous microarchitecture, a key property for cell ingrowth. The implants can also be printed with load-bearing capabilities and antibacterial coatings to limit infection. LMD process parameters allow for printing multiple different metals at a time, so one metal can be used to print an inner porous structure to promote bone in-growth, while another metal can be used to coat certain areas to give mechanical strength or antimicrobial properties to the implant. Fabrication of implants with even pore structure and size is a critical and distinct advantage of using LMD over other metal printing methods (Trevisan et al., 2018; Ahsan et al., 2011) (Fig. 1.4.8.7).

Bioprinting

Bioprinting involves robotic deposition of cell-laden bioinks into custom shapes to facilitate regeneration of tissue. A range of bioprinting approaches are currently used, including microextrusion, inkjet, stereolithography, and laser-assisted bioprinting. Bioinks, which are a crucial component in bioprinting, need to be designed within the "biofabrication window" by optimizing a range of material characteristics, including rheological properties, hydration characteristics, mechanical properties, cross-linking mechanism, and biological characteristics. A range of polymers are combined with bioactive agents to improve the functionality of cell-laden printed scaffolds. In this section, we will discuss some of the key components in bioprinting, including the types of bioprinting approaches and bioink design, including selection of biomaterials for bioinks.

Bioprinting Approaches

A range of additive manufacturing approaches have been developed for 3D bioprinting, including microextrusion, inkjet, stereolithography, and laser-assisted bioprinting (Fig. 1.4.8.8) (Derby 2010; Duan et al. 2014). In all these approaches cell-laden bioinks are printed to mimic native tissue structure and facilitate tissue regeneration. In



• **Figure 1.4.8.9** Bioink design parameters that need to be optimized to obtain high fidelity cell-laden constructs.

microextrusion bioprinting, cell-laden bioink is extruded through micron-sized nozzles (Exner et al., 2008). Multiple nozzles can be employed for extrusion-based bioprinting to obtain multimaterial complex structures, while in inkjet bioprinting, bioink droplets are deposited via thermal, piezoelectric, or electromagnetic means. In stereolithography, a focused UV light beam is used to cross-link liquid photopolymer via a layer-by-layer approach to fabricate scaffolds (Gong et al., 2012). In a similar approach, laser-assisted bioprinting involves use of laser energy to volatilize a sacrificial layer, propelling a payload to a receiving substrate (Ferris et al., 2015). Approaches that combine multiple modality are also investigated to obtain hybrid structures. For example, by combining extrusion bioprinting and stereolithography, cell-laden hydrogels and hard thermoplastic can be combined (Gonzalez et al., 2016). More recently, microfluidic bioprinting was developed by combining microfluidic printheads with extrusion printing for high-velocity printing of multiple materials (Gu et al., 2012). This new modality makes it possible to program sequential or simultaneous extrusion of different bioinks with complex spatiotemporal control such as printing of gradients into structures (Gunatillake and Adhikari, 2003; Haramati et al., 2002; Herozg et al., 2016).

Bioink Design Parameters

A vital aspect and bottleneck to the design and implementation of a bioprinting system is consideration of a bioink. Bioinks are mainly comprised of a polymer matrix loaded with cells and bioactive signals (Boland et al., 2006). By controlling the physical and chemical properties of the extracellular matrix (ECM), cell behavior can be regulated to accelerate tissue integration and functional recovery. Thus it is important to carefully select bioprinting process, bioink characteristics, type of cells, and bioactive signals for bioprinting to support and enhance tissue regeneration in a spatiotemporal manner (Chung et al., 2013). A range of parameters dictates the 3D bioprinting process, including rheological properties, cross-linking mechanism, hydration characteristics, mechanical properties, and biological functionality (Fig. 1.4.8.9). In this section, we will discuss how these different aspects can affect the performance of printed scaffolds for regenerative medicine:

- **Rheological Properties:** Hydrogels are poorly suited to 3D printing, and adapting them to 3D bioprinting has proven to be a consistent challenge to the field (Chimene et al., 2016; Huebsch et al., 2010). Rheological properties of bioink, including viscoelasticity and shear-thinning characteristics, are important for obtaining high print fidelity and structural stability of 3D bioprinted structures (Das et al., 2013; Wüst et al., 2014). In addition, uniform distribution of cells within the bioink formation is also controlled by bioink viscosity. For example, low viscosity of bioink will result in sedimentation of cells during the printing process, which results in uneven distribution of cells in the printed scaffolds.
- **Cross-Linking Mechanism:** Prior to cross-linking, hydrogels are typically liquid polymer solutions that collapse into puddles, making it impossible to support subsequent layers. The type of cross-linking techniques and gelation kinetics used to obtain a 3D network depend on polymer type and printing modality. A range of cross-linking mechanisms involving use of light, ionic strength, electrostatic interactions, pH, and temperature can be employed to obtain structurally stable polymeric networks. The primary criteria for selection of cross-linking method will be to maintain high viability of encapsulated cells.
- **Hydration Degree:** The water content of bioinks dictates its viscosity, printability, and mechanical properties. In addition, porosity of hydrogel networks also controls transport of oxygen and nutrient through the cell-laden hydrogel, which is a prerequisite for successful tissue regeneration.
- **Mechanical Properties:** The mechanical properties of bioink are heavily reliant on chemical composition, polymer concentration, and cross-linking density. However, increasing polymer concentration or cross-linking density significantly interferes with the viability and function of encapsulated cells by reducing permeability and porosity. Therefore an understanding of the factors that influence mechanical behavior is required to effectively design bioink formulation.
- **Biological Characteristics:** Physical properties of bioinks influence cellular behavior and are important parameters in determining applicability of polymers for generating specific tissues. For example, polymers with cell adhesive sites are required to enhance survival and proliferation of adhesive types of cells such as osteoblasts. However, chondrocytes would prefer to be encapsulated in hydrogels with minimum cell adhesion sites.

Biofabrication Window

Bioprinting living cells requires a very specific set of conditions such as aqueous environment, sufficient oxygen, and nutrient diffusion, as well as appropriate pH and osmolality along with key vitamins and minerals for cellular functions, which are best met with a special class of

biomaterial hydrogel bioinks (Michalski and Ross, 2014; Sachlos and Czernuszka, 2003). Bioinks are rationally designed materials intended to improve the functionality of cell-laden printed scaffolds within the "biofabrication window" (Chimene et al., 2016; Malda et al., 2013). The biofabrication window is a concept that describes required compromises between the printability of a bioink formulation and cell viability (Fig. 1.4.8.10). Generally, hydrogels are used as bioink in most 3D bioprinting due to high water content (70%–99%), which makes hydrogels highly porous and permeable, allowing rapid diffusion of oxygen and nutrient throughout the scaffold (Zorlutuna et al., 2012; Sachlos and Czernuszka, 2003; Ferris et al., 2013). Hydrogel networks are highly porous and provide support to cell adhesion, proliferation, and migration, which are key components to facilitate tissue regeneration. Hydrogels can also be created from synthetic as well as natural polymers. Synthetic polymers, such as poly(ethylene glycol) (PEG), provide customized physical and chemical properties, while natural polymers like collagen and hyaluronic acid provide a native-like microenvironment to help direct cellular functions. Combination of natural and synthetic polymers can provide composite hydrogels with tailored characteristics. After printing, these cell-laden hydrogels can be cross-linked using cell-friendly scaffolds. Thus hydrogels are the universal choice for 3D bioprinting as they closely mimic the native microenvironment of cells (Chimene et al., 2016; Ferris et al., 2013; Huebsch et al., 2010).

Biomaterials for Bioprinting

A range of polymers can be used to design hydrogel-based bioinks to control and direct cell functions, leading to enhanced cell motility, proliferation, and subsequent differentiation. Both natural and synthetic polymers have been investigated as hydrogel bioinks (Mano et al., 2007). Natural polymer bioinks provide a number of advantages due to their chemical and structural similarities to native ECM. Some of the natural polymers that are currently being explored for bioprinting include collagen, gelatin, alginate, fibrin, hyaluronan, and dextran. Synthetic polymers, however, can be more easily tailored for a given application by optimizing mechanical properties, degradation rates, or bioactivity (Gunatillake and Adhikari, 2003). Some of the synthetic polymers that are currently used in bioprinting include PEG, poly(lactide-*co*-glycolide), poly(ε-caprolactone), and poly(L-lactic acid). Blends of both natural and synthetic polymers can result in a combination of benefits in an attempt to enhance and tailor cellular responses within the 3D fabricated scaffolds. For example, synthetic polymers can be copolymerized with enzymatic degradation sites found in natural polymers to enhance cell migration and aggregation within the scaffold (West and Hubbell, 1999). These polymer combinations used in conjunction with the spatial resolution of many bioprinting technologies enable a more efficacious tissue and organ regeneration process.

Medical Applications of 3D Printing

This section focuses on applications of 3D printing technologies in different facets of the medical field, including surgical planning, medical training, design and fabrication of implants, and development of personalized drug delivery systems. For each category, representative application cases from both advanced studies and newly developed medical protocols will be explained, along with a discussion on different materials being used and the features or advantages of each 3D printing technology.

Surgical Planning and Medical Training

Medical imaging, such as computerized topography, magnetic resonance imaging, and ultrasound, are commonly employed for disease diagnosis and surgical planning and generate a stack of two-dimensional images to visualize the tissue or organ of interest (Vannier and Marsh, 1996; Haramati et al., 2002). With these imaging modalities, assisted by contrast agents and postimage processing, technicians can differentiate the boundary of benign and malignant tissue and identify abnormal dilation or contraction to support preliminary diagnosis and sequential surgical planning. Although the images can be converted into 3D visual models, they cannot provide direct 3D demonstration and a precise reflection of the spatial relations of the tissues. Using 3D printing technology in combination with these imaging results, researchers and surgeons can generate patient-specific anatomical structures with intricate and accurate presentation of the tissues and organs. 3D printed models can also mimic the physical properties of the targeted tissue, including compressive or tensile modulus, elasticity, and stiffness (Tymrak et al., 2014; Bose et al., 2013; Schumacher et al., 2015). Utilizing these models reduces the operation time, avoids disproportionate planning, and achieves a more cost-effective use of research and medical resources (Ventola et al., 2014). Fig. 1.4.8.11 shows several cases where 3D

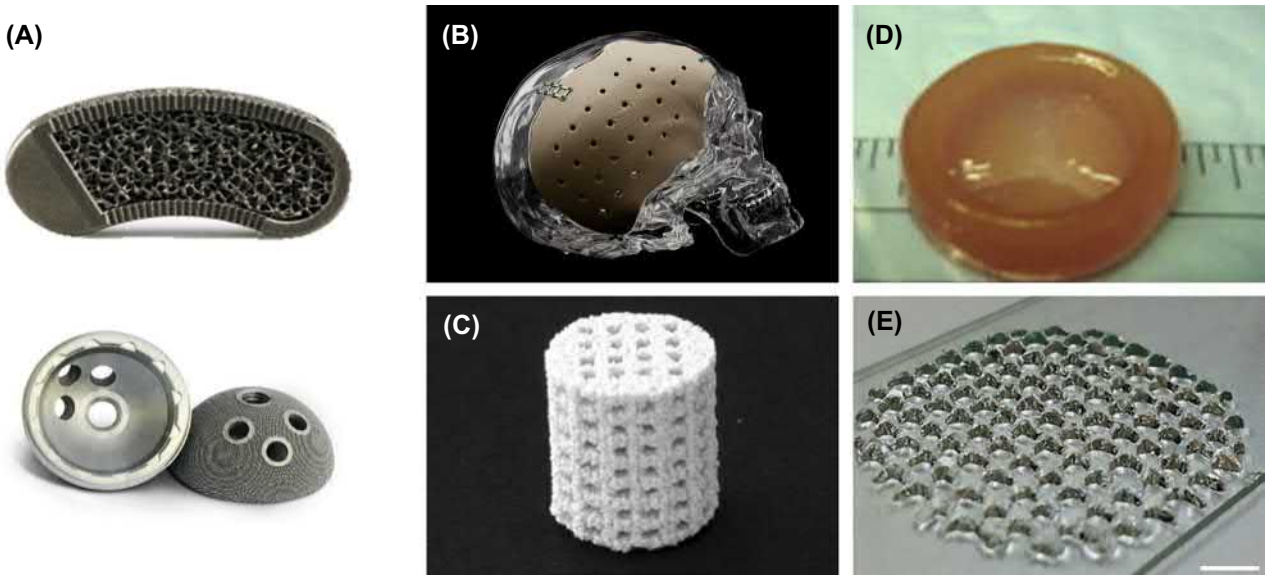
• **Figure 1.4.8.11** Applications of 3D printing in surgical planning and training: (A) blood vessel reconstruction for neurosurgery guidance (Walter Reed National Military Medical Center), (B) 3D printed aorta model for thoracic complex aneurysm patient (Rengier et al., 2010), (C) a replica of liver for transplant surgical planning (Klein GT et al., 2013), (D) Personalized bolus that serves as radiological shield in skin cancer radiotherapy (Canters et al., 2016).

printing techniques can generate 3D replicas of patient-specific anatomies, including brain vessels, disordered aorta, and liver. Researchers from Walter Reed National Military Medical Center have been employing multimaterial 3D printing to construct skull, neural vasculature, and nerve models with various photocross-linking polymers (Fig. 1.4.8.11A). Specifically, the models with blood vessels and nerves depict the complicated spatial relationships that can be studied to avoid potential damage in surgical procedures. Surgeons can also determine reliable and effective incision and operational paths based on these models. Similarly, 3D printing techniques are being applied to cardiovascular surgical plans. In Fig. 1.4.8.11B, an aorta model was fabricated with rapid prototyping for a patient with a thoracic aortic aneurysm, displaying a well-defined vessel dilation region (Rengier et al., 2010). The model allowed the surgeons to evaluate the pathological progress and develop personalized treatment plans. It also improved communication with the patient in regard to the pathology and discussion of surgical options. In parallel to surgical applications, 3D printing is also employed in medical training for procedures such as colonoscopy. Prevalent training is performed on cadaver dissection; however, cadavers are subject to low availability, high cost, and no relevant pathology (Ventola, 2014). On the contrary, using 3D printed models can reduce the cost and replace cadaver usages.

3D printing is also playing a significant role in improving organ transplantation procedures. One of the major challenges in organ transplantation surgery is that the donor organ cannot always meet the recipient size requirements (e.g., pediatric recipient of adult organ); however, in situ organ trimming can delay and complicate the transplantation. To avoid such complications, Dr. Maki Sugimoto from Japan's Kobe University Hospital (Klein GT et al., 2013) replicated the donor's organ prior to surgery with 3D rapid prototyping. The liver replica (Fig. 1.4.8.11C) showed the structures of different compartments and distribution of blood vessels. In addition, additive manufacturing techniques can contribute to personalizing treatments such as radiotherapy. To reduce unnecessary radiation to the normal tissue, 3D printing is applied to create patient-specific radiological shields for susceptible regions. As shown in Fig. 1.4.8.11D, a plastic bolus was made to block the radiation around the patient's nose, which has skin susceptible to radiation (Canters et al., 2016).

Fabrication of Complex Implants

Implants and prostheses are often employed to replace diseased or damaged tissue, including bone grafts (Sears et al., 2017), regenerative cartilage scaffolds (Markstedt et al., 2015), vascular grafts (Kolesky et al., 2014), or filling content, and to make adjustments in plastic and reconstructive surgeries (Kamali et al., 2016). Generally, implants can be fabricated or assembled with single materials, including metal, ceramics, and polymers, or combinations of multimaterials. With these materials, there are two categories of implant fabrication methods: negative manufacturing, based on shaving and drilling away material to generate construct, and additive/positive manufacturing with layer-by-layer addition of material to generate construct. Despite its advantage of high integrity, negative manufacturing of implants is undermined by its mismatch of detailed structures to the target tissue or organ and the possible defects that can lead to implant failure. As a novel method of additive manufacturing, 3D printing techniques are applied in implant fabrication with these advantages: (1) lower expense for implant fabrication, (2) patient-specific rapid prototyping, (3) detailed reconstruction of targeted structure, and (4) integration of multimaterial composition. Moreover,



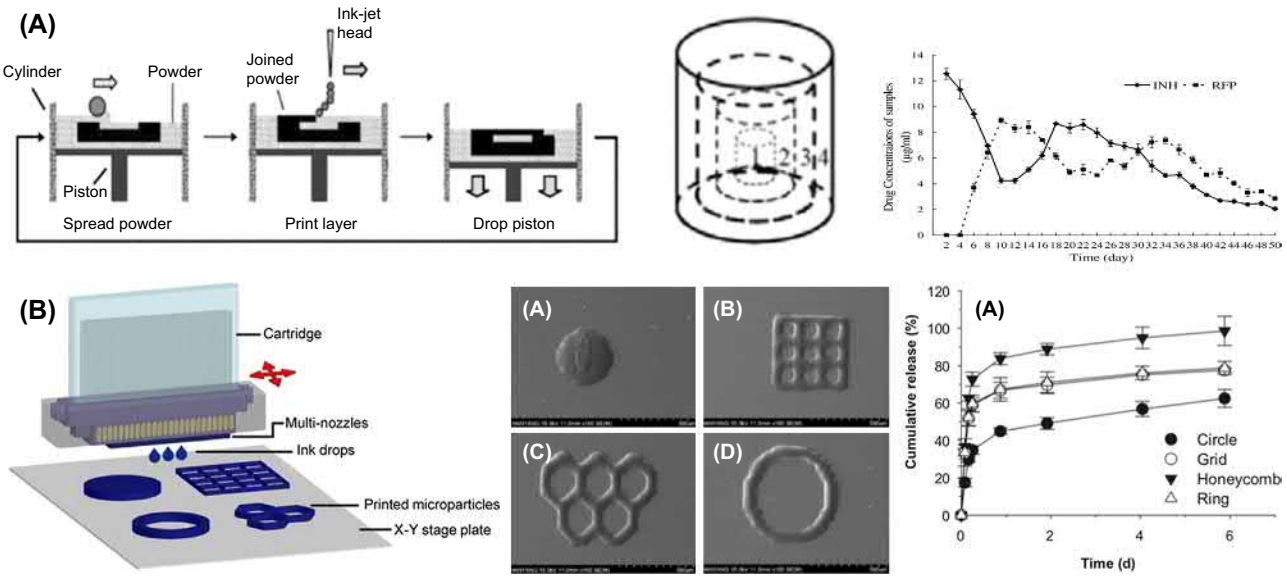
• **Figure 1.4.8.12** Implants or scaffolds based on 3D printing techniques: (A) commercial metallic implants of Ti–4Al–6V alloy, spinal cage (top) and artificial acetabular cup (bottom) (3D Systems), (B) the OsteoFab Patient Specific Cranial Device in replacement of skull bony voids (Oxford Performance Materials), (C) synthetic bone replacement of hydroxyapatite scaffold (Leukers et al., 2005), (D) heart valve conduit with encapsulated human aortic valve interstitial cells (HAVIC) (Duan et al., 2014), (E) 3D printed polyelectrolyte gelatin-chitosan hydrogel for skin tissue engineering (Ng et al., 2016).

additive manufacturing techniques can be used to fabricate tissue regenerative scaffolds designed to serve as a supplementary ECM during the tissue regeneration process. Previous research probed into how these scaffolds allow for cell delivery, endogenous cell recruitment, attachment, proliferation, and differentiation to restore the functionalities of targeted tissues or organs (Do et al., 2015). The material choices for tissue regenerative scaffold range from synthetic polymers, such as poly(ε-caprolactone), to naturally derived materials like alginate, chitosan, cellulose, collagen, fibrinogen, and hyaluronic acid (Do, 2015). Researchers have demonstrated the use of solid free-form fabrication to create high-resolution scaffolds with or without cells. In Fig. 1.4.8.12, examples of implants or scaffolds made from different materials for various applications display the versatility of 3D printing in this field.

In Fig. 1.4.8.12A, commercially available, customized Ti–4Al–6V alloy implants are represented by a spinal cage for spinal fusion surgery and acetabular cup used in total hip replacement (3D Systems). These metal implants are designed and manufactured by 3D Systems, Inc., a company specialized in providing advanced on-demand solutions with direct digital manufacturing on the basis of metal 3D printing in a variety of fields, including dental, spinal, and orthopedic healthcare. Besides metal implants, 3D printed cranial devices made from polymer are also accessible with customization. Oxford Performance Materials, Inc. has pioneered the promotion of polymer implant development and has used an originally invented high-performance polymer, polyether-ketone-ketone. The polymer has been utilized in areas of aerospace and biomedical and industrial manufacturing. One of the exemplar products is OsteoFab, a patient-specific cranial device that serves as a complementary structure for cranial defect caused by skull maldevelopment or major trauma (Materials) (Fig. 1.4.8.12B). Many research groups that develop all types of implants have provided promising results and potentials for eventual medical applications. Hermann Seitz and his collaborators (Leukers et al., 2005) developed a 3D printed hydroxyapatite scaffold for bone regeneration. The hydroxyapatite scaffold maintained a complex internal structure and was printed with high-resolution and important detailing (Fig. 1.4.8.12C). In this case, cell studies and histological analysis results showed invasive cell proliferation into the scaffold with a dynamic cultivation method and pointed to further inquiry of the osteogenic differentiation with high interconnection. Other groups have fabricated heart valve conduits with cell encapsulation (Duan et al., 2014) (Fig. 1.4.8.12D) and developed polyelectrolyte gelatin–chitosan hydrogel as skin constructs (Ng et al., 2016) (Fig. 1.4.8.12E). In conclusion, 3D printing techniques allow for the fabrication of implants for various tissues and tissue-engineering scaffolds with high-resolution and complicated structures, providing a low-cost, rapid solution for a diversity of surgical and therapeutic scenarios.

Personalized Drug Delivery Systems

Another medical field being redefined by 3D printing techniques is pharmaceutical research and drug delivery systems. Physicians and patients are increasingly interested in novel drug delivery systems, of which 3D printed tablets or drug delivery devices top the list (2016). The traditional manufacturing steps of tablets for drug delivery are



• **Figure 1.4.8.13** Applications of 3D printing techniques in drug delivery system design, including technique schematic (left), system model (middle), and release profile (right). (A) Temporal control on multi-drug release based on the drug spatial distribution (Wu et al., 2009) and (B) geometry-dependent kinetic control with a piezoelectric inkjet printing system (Lee et al., 2012).

mixing, milling, drying, wet granulation, and compression or molding (Prasad et al., 2016). However, these methods are limited by low drug stability caused by degradation in production and are not suitable for personalized dosage due to large-scale manufacturing. 3D printing offers the following advantages in drug delivery: (1) product consistency by standardization and mechanization, (2) customization of the drug delivery system specific to the patient's condition (e.g., multiple chronic diseases), and (3) facilitated combinations of various drugs and substrates (Prasad et al., 2016). By adjusting the drug dosing, dosage forms, and drug release profiles with the assistance of automated 3D printing systems, personalized pharmaceutical treatment can result in better patient compliance with improved therapy outcomes. To this end, researchers have invested resources and manpower in the development of reliable and tunable 3D printing-manufactured drug delivery systems. Wu et al. designed a multireservoir system to release two first-line antituberculosis drugs, isoniazid and rifampicin (Fig. 1.4.8.13A) in 2009 (Wu et al., 2009). Fabrication of the drug implant was based on a layer-by-layer sintering process to generate the multichamber structure. As shown in the middle schematic of the structure, chambers 1 and 3 contained rifampicin, while chambers 2 and 4 contained isoniazid. Therefore there was an alternating release profile of the two drugs over a timeframe of 50 days. This example provides insight into how 3D printing can be utilized to create systems that have the temporal control of drug delivery by the spatial distribution of therapeutic agents. Additionally, the shape of the delivery unit can influence the drug release kinetics. In 2012, Lee et al. investigated how the structure of drug-encapsulated microparticles can induce differences in drug release rate (Lee et al., 2012). They fabricated microparticles of different shapes, such as a circle, grid, honeycomb, and ring, using a piezoelectric inkjet printing system. The release profiles of microparticles with different geometries showed different levels of burst release percentages and overall release rates. Thus both studies demonstrate control over the drug release profiles, maintaining difference in the mechanism and target, demonstrating the versatility of 3D printing. More importantly, given that the delivery of multiple agents has been achieved and individual agent release rates can be modified, more complicated and compositional deliveries of multiple agents will be foreseen with more advanced high-resolution 3D printing techniques and proper substrates.

Summary

Since its first introduction to researchers and industries by Charles Hull (Schubert et al., 2014), 3D printing has revolutionized traditional medical device development processes and treatment strategies (Ventola et al., 2014). The adaptation of current 3D printing techniques for biomedical applications has enabled a broad range of medical advances from patient-specific surgical guides to personalized drug delivery systems to complex cell-laden scaffolds that more closely mimic native organs and tissues. Despite the strong potential and diversity of 3D printing in the medical field, there remain many challenges that relate to both the printing process and the materials available for printing. There is a continued need for improved resolution, increased speed, and more versatile materials. In addition, there is a corollary needed for new standards and quality control systems for additive manufacturing in each of these applications.

Chapter Review Questions

1. Why does SLA print objects with a smoother surface finish than FDM does?
   Higher resolution is possible due to the laser being smaller than the nozzle diameter, and less force being applied to the object during the printing process.
2. Why is DLP a faster printing process than SLA?
   DLP prints an entire layer of resin at once using a pixel pattern, while SLA prints along a path with a laser.
3. Why is it beneficial that SLA and DLP do not use support materials?
   Supporting structures require postprocessing, which makes the printing process longer and may result in damage or breaking of the surface connected to the support.
4. Why is wax often used as the support structure in MJM printing?
   Wax has a lower melting temperature than most of the photopolymers used in MJM printing, so it can be melted away while the cured polymer stays intact. Melting the wax allows for hands-off postprocessing to minimize damage to the object.
5. What is the benefit of using multiple nozzles?
   This allows for simultaneous printing of multiple materials in a single print to impart variable characteristics and properties.
6. Compare and contrast the following techniques: EBM, SLS, and LMD.
   Similarities: Materials that are used to print these techniques include different types of metals, and all techniques can be used to generate implants.
   Differences: EBM prints based on an electron beam melting down powder materials, SLS uses a laser beam to melt down powder materials, and LMD uses a laser to melt a metal surface.
7. What are the benefits of using FDM to fabricate biomaterial constructs compared to SLA? What are the limitations?
   FDM is an extrusion-based printing technique that can translate to limited use of material and there is rapid turnaround. Furthermore, it was previously used to print thermoplastics but now can be used to print pastes, gels, and other viscous materials. SLA has higher resolution compared to FDM, which might be better for printing biomaterials such as implants or scaffolds, but often requires the use of large volumes of material.
8. What is the advantage of using LMD for metal implants compared to other metal printing techniques such as EMD or SLS? How does this advantage make it a potentially useful technique for biomaterials?
   LDM process parameters allow for printing multiple materials (metals) at a time, as compared to single material printing with EMD or SLS. Previous attempts have demonstrated fabrication of implants with coatings of different types that promote antibacterial resistance and mechanical strength in one single fabrication step.
9. What is bioprinting? Please list four bioprinting methods currently used for printing cell-laden bioinks.
   Bioprinting is a 3D printing strategy that involves robotic deposition of cell-laden bioinks into custom shapes for facilitating regeneration of tissue. Four bioprinting methods that are currently being used for printing bioinks include microextrusion, inkjet, stereolithography, and laser-assisted bioprinting.
10. Describe major bioink properties that affect the performance of printed scaffolds.
    Specific bioink properties that affect the performance of printed scaffolds include ink rheological properties, cross-linking mechanism, degree of hydration, ink mechanical properties, and biological characteristics.
    - Rheological properties: The material for printing needs to be viscoelastic and shear thinning to allow for high print fidelity and structural stability. In addition, the viscosity of the ink must be controlled enough to allow for uniform distribution of cells within the ink.
    - Cross-linking mechanism: Enables solidification of the ink upon deposition and can be achieved via light, ionic strength, electrostatic interactions, pH, and temperature. The primary criteria to select a cross-linking method should consider how viability of encapsulated cells is affected.
    - Degree of hydration: Amount of water that is present in the ink. This can affect viscosity, print fidelity, and scaffold mechanical properties. In addition, modulation of this property can enable control over porosity, which facilitates transport of oxygen and nutrients through the scaffolds.
    - Mechanical properties: These properties are dependent on chemical composition, polymer concentration, and cross-linking density. Optimization of these parameters must be investigated thoroughly because they can significantly affect viability/functionality of encapsulated cells.
    - Biological characteristics: Presence of biological components can affect how cells encapsulated inside the bioink behave. Depending on what type of cells are encapsulated and printed, the biological properties of the ink (for example, presence or lack of adhesion sites) should be considered and designed.
11. What is the biofabrication window?
    The biofabrication window is an important concept that describes the required compromises between the printability of a bioink formulation and cell viability. This allows for rational design of materials to improve the functionality of the cell-laden printed scaffolds.
12. What are the advantages and opportunities afforded by 3D printing techniques utilized in surgical planning and medical training models?

A 3D printed tissue model has the following advantages:

1. Compared with imaging examination techniques, a 3D printed model demonstrates a more straightforward and intuitive spatial relationship of targeted tissues and organs;
2. High-resolution 3D printing can exhibit more details;
3. A 3D printed model helps to reduce the operation time and to achieve more cost-effective management of medical resources.
4. In medical training, 3D printing provides an alternative option with a lower cost and higher availability.

13. In 3D printing of medical implants, what parameters should be taken into consideration? Support your statement with specific examples.

Based on target tissue, one or multiple materials can be used for the fabrication of implants. The mechanical properties and bioactivity of the material should be in compliance with the application as well as its biostability or biodegradability. For example, alloys can be fabricated into bone grafts due to a similar mechanical property and a polymer with high elasticity and flexibility used to mimic the heart valve tissue.

A proper 3D printing method must be chosen to integrate multiple materials and even incorporate bioprinting with cells. The fabrication resolution requirement also differs with different implant applications. The example of the 3D printed heart valve conduit with encapsulated human cells requires a combination of hydrogel printing and bioprinting.

2.1.1 Introduction to Biology and Medicine—Key Concepts in the Use of Biomaterials in Surgery and Medical Devices

MICHAEL J. YASZEMSKI[1], BUDDY D. RATNER[2]

[1]Orthopaedic Surgery and Biomedical Engineering, Mayo Clinic College of Medicine, Rochester, MN, United States

[2]Bioengineering and Chemical Engineering, Director of University of Washington Engineered Biomaterials (UWEB), Seattle, WA, United States

Biomaterials Science: An Introduction to Materials in Medicine directly addresses the multidisciplinary nature of the biomaterials field by providing concise tutorials in the key concepts essential for practitioners of biomaterials science. The word "biomaterials" implies an intersection of biology and materials. This Section 2.1 addresses the fundamental "bio" science relevant to biomaterials (Section 1.2 serves a similar function for the fundamental materials science relevant to biomaterials). The background biology is important, because this scientific foundation will help us to understand, predict, and engineer the in vivo responses observed by the biomaterials scientist/engineer, the physician, and the patient.

When a synthetic material is placed in a biological milieu (implantation in a living organism, for example), a series of reactions is initiated almost instantaneously. Water molecules (and H^+ and OH^-), being the lowest molecular weight species, should reach the biomaterial surface first (in milliseconds). Their considerable impact on subsequent reactions is elaborated upon in Chapters 1.2.5 and 1.4.3A. Although water is not considered a biomolecule, it sets the stage for the biological reactions to follow.

Proteins, dissolved in serum at a concentration of approximately 7 g/dL, arrive next at the surface by either diffusion or convection. There are 700 or more proteins in blood. Some are relatively nonbioreactive, such as albumin, and others have numerous biological activities, such as fibrinogen or fibronectin. When proteins diffuse to a biomaterial interface, they will arrive in order of molecular weight (small proteins like thrombin, 35 kDa, arrive before heavier proteins like IgG, at 160 kDa). Once at the surface, proteins can adsorb, desorb, exchange with other proteins, denature, and either increase or decrease their biological activity. This complex landscape, comprised of many proteins in many states of organization and elaborated upon in Chapter 2.1.2, "Adsorbed Proteins on Biomaterials," by Robert A. Latour, becomes the environment to which cells will respond (and cells do indeed respond to proteins). The fundamentals of in vitro cell interaction with surfaces (or more accurately, interactions with the protein layer on biomaterial interfaces in water) are described in Chapter 2.1.3, "Cells and Surfaces in Vitro," by Ali Khademhosseini and Nureddin Ashammakhi. This chapter is particularly relevant for surface diagnostic devices (enzyme-linked immunosorbent assays, DNA microarrays, and protein microarrays), cell culture, and biosensors, but it also addresses many reactions observed in vivo.

Chapter 2.1.4, "Functional Tissue Architecture, Homeostasis, and Responses to Injury" by Frederick Schoen and Richard Neal Mitchell, discusses the biology of cells, with an emphasis on what the cells do under various conditions and what happens when they are injured (a surgical site always contains injured cells). In addition, rubbing and mechanical forces associated with medical implants can induce cell injury. Single cell types rarely exist alone. They aggregate or interact to form tissues, as discussed in Chapter 2.1.5, "The Extracellular

Matrix and Cell–Biomaterial Interactions," by Andres J. Garcia, Woojin M. Han, and Young Charles Jang. Some principles that govern tissue formation from individual cell types are relatively simple and have been elaborated upon by researchers such as Malcolm S. Steinberg, who demonstrated that cell membrane surface tension associated with cell surface cadherin molecules can drive cell aggregation into organized multicellular structures. Other aspects of tissue formation are governed by the complex mechanisms observed in studying the developmental biology of organisms. Biomaterials and medical devices interface with tissues; thus understanding tissues, their organization, and their properties is important. Furthermore, the cells in tissues make a "grout" that holds them together; this material is called the extracellular matrix (ECM). The ECM serves a mechanical function in stabilizing the tissues but is, in its own right, highly biologically active. For example, it has been shown that triple-helical collagen I, the primary component of ECM, can bind in a specific manner to more than 50 other biomolecules, including some with high biological activity such as fibronectin. Thus the ECM presents to the cells bioactive biomolecules in optimal conformation and orientation, whereby it directs their actions. This concept is particularly important to tissue engineering (Section 2.6). Also, the degradation products of ECM can be highly bioactive. For example, the work of Judah Folkman, Robert Langer, and colleagues demonstrated that degradation fragments of some collagens are inhibitory to angiogenesis. Since ECM is synthesized by tissue cells and is broken down by cells such as the macrophage, the bioactive fragments from the breakdown can impact tissue formation and biological reaction.

Chapter 2.1.6, "Effects of Mechanical Forces on Cells and Tissues," by Aaron Baker, Austin Veith, and Lei Mei, addresses mechanical forces, their effects on cells and tissues, and their importance for biomaterials. Living organisms move, and blood flows. Thus all implants in living organisms are subjected to mechanical forces. Although Chapter 2.1.6 focuses on the liquid–biomaterial interface (i.e., blood interactions), the concepts of force communication from the environment external to the cell, to the cell membrane, particularly from an engineering standpoint, are elaborated upon. The work of Donald Ingber (e.g., Ingber, D.E. From mechanobiology to developmentally inspired engineering. Phil. Trans. R. Soc. B 373, 20170323) and others helps us to understand how this mechanical trigger at the cell membrane can signal to the cell nucleus, leading to downregulation or upregulation of specific genes, which then leads to expression of new cytokines and/or other signaling molecules. Mechanical forces can impact cells macroscopically, but also impact them at a microscopic level. Carter, S.B., January 21, 1967. Effects of cytochalasins on mammalian cells. Nature 213 (5073), 261–264. UI: 6067685 in which he showed that cells follow micron-dimension scratches in a plastic film, a phenomenon he named contact guidance. We use that term to this day to describe this mechanically induced response of cells to micron-scale features. Chapters 1.4.5 and 1.4.7 give us patterning, texture, and porosity tools to manipulate cell–mechanical interactions at both the micro- and nano-levels.

2.1.2

Adsorbed Proteins on Biomaterials

THOMAS A. HORBETT[1], ROBERT A. LATOUR[2]

[1]Bioengineering and Chemical Engineering, University of Washington, Seattle, WA, United States

[2]Bioengineering Department, Clemson University, Clemson, SC, United States

Introduction

The replacement of injured or diseased tissues with devices made from materials that are not of biologic origin has been a longstanding approach in biomaterials science and clinical practice. The prevalence of this approach is due largely to the fact that these materials are not attacked by the immune system, unlike donor tissues or organs. This fundamental difference arises from the presence of immunologically recognizable biologic motifs on donor tissue, and their absence on synthetic materials.

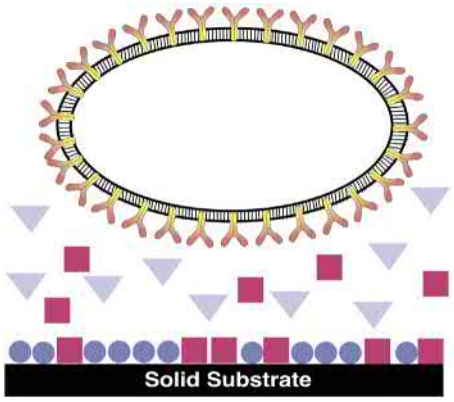
Nonetheless, there are other types of biological responses to implanted synthetic biomaterials that often impair their usefulness, including the clotting of blood and the foreign-body reaction. Clearly, the body does recognize and respond to these types of biomaterials. The basis for these reactions is the adsorption of adhesion proteins to the surface of the biomaterials that are recognized by the integrin receptors present on most cells. The adsorption of adhesion proteins to the biomaterial converts it into a biologically recognizable material, as illustrated in Fig. 2.1.2.1. The protein adsorption event is rapid (seconds) and generally happens on all materials implanted into biological systems with few exceptions. Note: familiarity with protein structure is essential to appreciate the content of this chapter. All introductory biochemistry textbooks can provide this critical background material.

The interaction of adhesion receptors with adhesion proteins thus constitutes a major cellular recognition system for biomaterials. Therefore, the role of adsorbed adhesion proteins in mediating cellular interactions with biomaterials will be the primary focus of this chapter. Examples illustrating the ability of adsorbed adhesion proteins to influence cellular interactions with foreign materials are presented first. Then, some of the major physicochemical characteristics of protein adsorption are illustrated and discussed, including rapid kinetics, monolayer adsorption, and competitive adsorption. Molecular spreading events related to the conformational stability of the protein are presented at some length, as background for a section on how the biological activity of adsorbed adhesion proteins is affected by the substrate. This is then followed by a section summarizing the principles underlying the role of adsorbed proteins in mediating the platelet response to biomaterials, as an illustrative case study representative of many other types of cellular responses. The next-to-last section of this chapter summarizes the development of surface chemistries that are highly resistant to protein adsorption (i.e., nonfouling surfaces), in an attempt to eliminate biological recognition of the biomaterial altogether, which is followed by concluding remarks. Each of these topical areas is discussed in greater detail in several previous journal publications and review articles (Horbett, 1993, 1994, 1996, 1999, 2003; Horbett and Brash, 1995; Latour, 2008; Latour et al., 2012; Norde et al., 2012; Thyparambil et al., 2015; Thompson et al., 2017a).

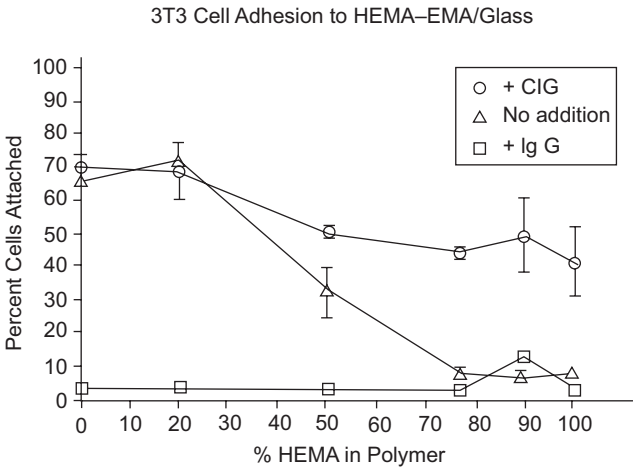
Most studies of protein interactions with biomaterials and their effects on cells have been done in vitro after relatively short contact periods, leading to the focus here on effects in the shorter term that involve undegraded adhesion proteins that mediate cell interactions. However, the adsorbed protein layer on biomaterials implanted in humans or animals for longer times includes smaller size fragments [observed on breast implants (Backovic et al., 2007), glucose sensors (Gifford et al., 2006), and kidney dialyzers (Cornelius and Brash, 1993)] that are presumably due to proteolytic attack. The functional role of any of these changes to the adsorbed proteins on the interaction of biomaterials with the body remains to be elucidated.

Examples of the Effects of Adhesion Proteins on Cellular Interactions With Materials

Protein adsorption to materials can be performed with a single protein, typically in a buffer solution, or from complex, multiprotein solutions, such as blood plasma, which can



• **Figure 2.1.2.1** Cell interactions with foreign surfaces are mediated by integrin receptors with adsorbed adhesion proteins that sometimes change their biological activity when they adsorb. The cell is shown as a circular space with a bilayer membrane in which the adhesion receptor protein molecules (the slingshot-shaped objects) are partly embedded. The proteins in the extracellular fluid are represented by *circles*, *squares*, and *triangles*. The receptor proteins recognize and cause the cell to adhere to only the surface-bound form of one protein, the one represented by a *solid blue circle*. The bulk phase of this same adhesion protein is represented by a *blue triangle*, indicating that the solution and solid-phase forms of this same protein have a different biological activity. The figure is schematic and not to scale.



• **Figure 2.1.2.2** 3T3 cell adhesion to HEMA–EMA copolymers varying from hydrophilic (HEMA-rich) to hydrophobic (EMA-rich): effect of no adsorbed protein, preadsorption with fibronectin (designated CIG in the figure), or preadsorption with immunoglobulin G (IgG). (The data are from the Horbett laboratory.)

contain hundreds of proteins. Experiments done with single proteins in buffer can be used to study fundamental aspects of protein adsorption, such as adsorption rates or conformational changes, and to study biological responses, such as cell adhesion to each protein. Adsorption from complex media approximates the adsorption conditions encountered by implanted biomaterials, and thus provides a more realistic insight into the functional role of adsorbed proteins. Examples of the effects on cellular responses of protein adsorption done under both conditions are presented below.

The Effects of Preadsorption With Purified Adhesion Proteins

Preadsorption of certain proteins onto a solid substrate, such as tissue culture polystyrene, greatly increases its adhesiveness to many kinds of cells, and such proteins are called adhesion proteins. The increased adhesiveness is due to the fact that many cells have receptors in their cell membrane that bind specifically to these specialized proteins. The adhesion receptors involved in cell adhesion to biomaterials and extracellular matrices such as collagen are called integrins. For example, fibronectin preadsorption greatly increases the adhesion of fibroblasts, while albumin preadsorption prevents it (Horbett, 1994). Experiments of this type have been done with a wide variety of cells and adhesion proteins, with basically similar results. Adhesion proteins also promote the flattening out or spreading of the cell onto the surface. A specific example is provided by measuring the percentage of attached cells that spread on polystyrene surfaces pretreated with increasing concentrations of fibronectin. Spreading is only about 5% on albumin-coated surfaces, but increases to nearly 100% as the fibronectin concentrations in the preadsorption solution are increased from 0.03 to 3 μg/mL (Horbett, 1994).

In studies of protein-mediated cell adhesion, it is necessary to eliminate or reduce the role of nonspecific cell adhesion directly to the uncoated surfaces, as this is often high, so that the special ability of adhesion proteins compared to other proteins would not be masked. This nonspecific cell-adhesion process can be understood to actually be mediated by a nonspecific protein-adhesion process—but in this case, the proteins involved are the membrane-bound proteins that are presented from a cell's surface. Thus, when testing for the ability of a preadsorbed protein to specifically cause cell adhesion, any residual uncoated sites left after preadsorption with the putative adhesion protein should be filled by a second adsorption step with a known nonadhesive protein, such as albumin, which is commonly used to block exposed surface sites. Because proteins themselves are highly resistant to the nonspecific adhesion of other proteins, the complete coverage of a material surface with a layer of preadsorbed protein will thus inhibit nonspecific cell adhesion. The results for this surface with the preadsorbed adhesive protein and albumin are then compared to a control surface that is completely coated with adsorbed albumin. Under these conditions, any elevation in cell adhesion compared to the albumin control can be ascribed to the test protein, rather than nonspecific cell adhesion due to the cell's direct contact with the surface.

An example of the effect of fibronectin adsorption is shown in Fig. 2.1.2.2, which also contrasts it with the effects of the nonadhesive protein immunoglobulin G (IgG). As shown in the figure, the adhesion of the fibroblast-like 3T3 cells to a series of polymers and copolymers of 2-hydroxyethyl methacrylate (HEMA) and ethyl methacrylate (EMA) not previously adsorbed with protein (and without proteins in the cell suspension) varies, being much less on the hydrophilic polyHEMA-rich surfaces than on the hydrophobic

polyEMA-rich surfaces. These data are an example of direct or nonspecific cell adhesion in which the cells adhere directly to the surfaces, rather than to adsorbed proteins. The preadsorption of the surfaces with immunoglobulin G (IgG) greatly reduces the adhesion of the cells to all the surfaces, because this protein effectively blocks the nonspecific adhesion of the cells to the surfaces. In the presence of IgG, the high nonspecific cell adhesion to EMA-rich surfaces cannot occur, as the cells do not have direct contact with the surfaces. In contrast, surfaces preadsorbed with fibronectin (designated CIG in the figure) are much more adhesive than the same surface adsorbed with IgG. After fibronectin coating, even surfaces rich in HEMA that are not adhesive to the cells themselves become adhesive, as the cells now interact not with HEMA, but with the adsorbed adhesive protein.

Preadsorption of adhesion proteins also affects cell interactions with surfaces studied under in vivo conditions. For example, blood platelet deposition onto polymeric arteriovenous shunts in dogs is greatly increased when fibrinogen or fibronectin are preadsorbed to the surfaces in comparison to albumin-coated surfaces (see Chapters 2.2.6 and 2.3.5).

Depletion Studies

Although the preadsorption of purified adhesion proteins to a surface is one way to see their effect on cell adhesion, as presented in the previous section, it does not mimic very well what occurs with implanted biomaterials. This is because biomaterials are exposed to blood and/or interstitial fluid during the surgical procedure to implant them, with these body fluids containing complex mixtures of different proteins, so the adhesion protein must compete with many others for adsorption to the biomaterial surfaces. Under those conditions, a given adhesion protein present in the biological fluid that the biomaterial is initially exposed to may really play little or no role. It is possible that very little of the adhesion protein may adsorb to the surface, as it is "out-competed" by other proteins for the limited surface sites. Thus, a more biologically relevant way to understand the role of an adhesion protein in reactions to implants is to study the effect of their selective depletion from the complex mixture. The observations presented in this section, and the articles they are based on, are presented in greater detail in a review article by Horbett (Horbett, 1999).

Selective depletion means that only one of the proteins is removed from the mixture at a time, either by immunoadsorption chromatography, by use of plasma from mutant individuals lacking the adhesion protein of interest, or by selective enzymatic degradation. Thus, the more important role of adsorbed vitronectin, as opposed to fibronectin, in mediating attachment and spreading of cells on many surfaces has emerged from immunoadsorption studies. Several studies illustrate the important role that adsorbed fibrinogen plays in the adhesion of platelets, neutrophils, and macrophages.

The effects of removal of fibronectin or vitronectin or both proteins from serum on the adhesion of endothelial cells depend on the surface chemistry. On tissue-culture polystyrene (TCPS) fibronectin removal has little effect, while vitronectin removal greatly reduces adhesion. These results clearly show the primary role of adsorbed vitronectin in supporting endothelial cell adhesion to TCPS. In contrast, adhesion to a surface modified by ammonia in a glow discharge (see Chapter 1.4.2) requires fibronectin, since removal of that protein greatly reduces adhesion to this surface, while vitronectin removal has little effect. However, the results for TCPS are more typical; i.e., on most surfaces studied by this method it appears that vitronectin, not fibronectin, is the primary agent responsible for cell adhesion.

The *solid line* represents the platelet adhesion to Immulon I preadsorbed with a series of dilutions of normal plasma, whereas the *dotted line* represents the platelet adhesion to Immulon I preadsorbed with a series of dilutions of afibrinogenemic plasma. The *arrow* at the lower right corner indicates platelet adhesion to Immulon I preadsorbed with 2% BSA only. *BSA*, bovine serum albumin. (Reproduced from Figure 4 in Tsai, W.-B., Horbett, T.A., 1999. Human plasma fibrinogen adsorption and platelet adhesion to polystyrene. J. Biomed. Mater. Res. 44, 130–139. Copyright permission received.)

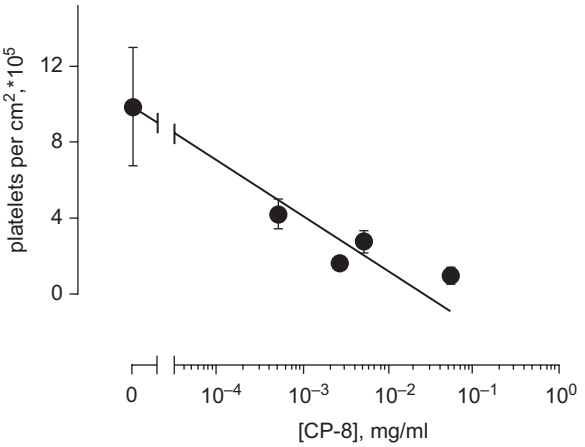
Platelet adhesion to surfaces preadsorbed with blood plasma that is deficient in fibrinogen is much less than to the same surface preadsorbed with normal plasma, as illustrated in Fig. 2.1.2.3. Most of the adhesion-supporting activity can be restored to fibrinogen-deficient plasma by the addition of exogenous fibrinogen at concentrations well below that in normal plasma. Platelets are very sensitive to fibrinogen as they adhere to some surfaces at fibrinogen adsorption levels of only 5 ng/cm^2, in comparison with adsorption values in the range of 100–200 ng/cm^2 in the presence of normal fibrinogen concentrations. In contrast, removal of fibronectin, vitronectin, or von Willebrand's factor from plasma has little effect on platelet adhesion (data not shown), even though these other plasma proteins act as adhesion proteins when adsorbed from single-protein solutions to surfaces. It appears that too little of these other proteins adsorb from plasma to make much difference; i.e., competition from fibrinogen and other proteins keeps their surface concentration too low, and so their removal has no effect.

The apparently negligible role of von Willebrand's factor in platelet adhesion discussed above only applies when platelet adhesion from static suspensions or low wall shear strain rates is measured. At higher wall shear strain rates (e.g., >500 s^{-1}), platelet adhesion to biomaterials is highly dependent on the presence of adsorbed von Willebrand's factor. This dependence is most clearly illustrated by the effects of increasing the shear rate on platelet adhesion. On surfaces preadsorbed with normal plasma (i.e., containing von Willebrand's factor, fibrinogen, and the other proteins), platelet adhesion is much higher at higher shear rates than low shear rates, because of the enhanced transport of the platelets to the surface; i.e., the greater number of platelet–surface encounters at high shear rate allows for an increase in the number of adhesive outcomes. On surfaces preadsorbed with plasma deficient in von Willebrand's factor only, raising the shear rate not only does not result in an increase in adhesion, but the adhesion at high shear is actually lower than at low shear, exactly the opposite of what happens in the presence of von Willebrand's factor. Thus, von Willebrand's factor adsorption plays a major role in platelet adhesion at higher shear rates. The special role of von Willebrand's factor in high-shear adhesion is thought to be due to the ability of the platelet receptor GPIb-IX to form and break bonds very rapidly with immobilized von Willebrand's factor, causing the platelets to first adhere and then roll along the surface until they are activated and can form a permanent bond that stops the rolling. The role of von Willebrand's factor in shear-mediated adhesion was documented in several recent studies (summarized in Zhang et al., 2008). Interestingly, the adsorbed von Willebrand's factor molecule is itself subject to distortion by both mechanical and fluid shear (Siedlecki et al., 1996). That may play a role in the surface activation of von Willebrand's factor by exposing platelet-binding sites on the molecule.

When mice are depleted of fibrinogen by treatment with an enzyme that degrades it, the adhesion of neutrophils and macrophages to a polymer implanted in their peritoneal cavity is greatly reduced. The fibrinogen-depleted animals exhibited near normal neutrophil and macrophage adhesion to the implants if the implants were preadsorbed with fibrinogen. These studies clearly illustrate the power of the depletion method. Previously, it had been thought that either complement or IgG would be the main adhesion proteins for neutrophils and monocytes, due to the presence of receptors on these cells that bind these proteins. Instead, it appears that an integrin receptor for fibrinogen (CD11b/CD18, also known as Mac-1) plays a major role, at least during the initial or acute phase of the foreign-body response in the mouse peritoneal cavity.

Inhibition of Receptor Activity With Antibodies

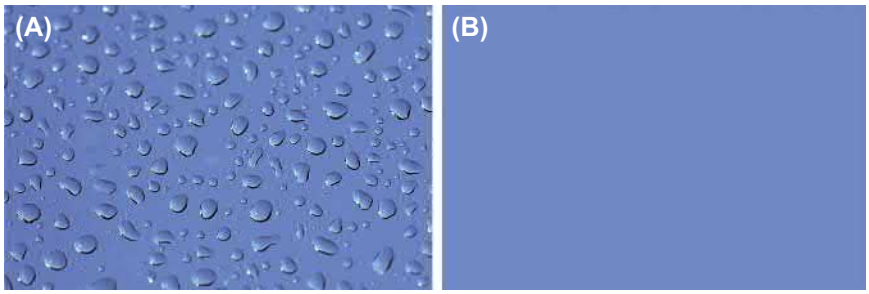
Another way to show the role of adhesion proteins in cell interactions with biomaterials is to add specific inhibitors of their function. Adhesion proteins cause cell adhesion by binding to integrin receptors that specifically recognize the adhesion protein. One way to inhibit this reaction is to add an antibody that binds to the adhesion receptor or adhesion protein. Examples of these approaches are presented next.



• **Figure 2.1.2.4** Effect of anti-IIb/IIIa antibody on platelet adhesion to Biomer preadsorbed with plasma. Adhesion of platelets incubated in monoclonal antibody CP-8 [monovalent Fab' fragment directed against the glycoprotein (GP) IIb/IIIa complex] to Biomer. Substrates were contacted with 1.0% plasma for 2 h, then washed with antibody-treated platelets for 2 h. (From Chinn J.A., Horbett T.A., Ratner B.D., 1991. Baboon Fibrinogen Adsorption and Platelet Adhesion to Polymeric Materials. Thromb. Haemost. 65, 608–17.)

Platelet receptor-mediated interactions appear to be the primary mechanism of platelet interaction in vivo with certain vascular grafts, because platelet deposition is largely inhibited by antibodies to the glycoprotein IIb/IIIa receptor, the major integrin on the surface of platelets. In vitro platelet adhesion to surfaces preadsorbed with blood plasma is also inhibited by antiglycoprotein IIb/IIIa in a dose-dependent manner, as illustrated in Fig. 2.1.2.4 (Chinn et al., 1991). In this study, samples of the polyurethane Biomer were preadsorbed with plasma and then exposed to platelets in an albumin-containing buffered saline suspension that had increasing amounts of the antibody. As shown in the figure, adhesion declined to very low values when high concentrations of the antiintegrin antibody were present.

There is currently much interest in the ability of biomaterials to regulate stem-cell differentiation, including the role of proteins adsorbed to the biomaterials. Thus, antibodies to vitronectin and fibronectin were used to study the role of these two proteins in osteogenic differentiation of mesenchymal stem cells on polycaprolactone. The vitronectin antibody selectively blocked adhesion and differentiation, but the fibronectin antibody did not, showing the importance of vitronectin-mediated adhesion in the behavior of this type of stem cell (Chastain et al., 2006). Combinatorial screening methods to find biomaterials that promote neural stem-cell differentiation found a role for adsorbed fibronectin and other adhesion factors in combination with immobilized growth factors (Nakajima et al., 2007). A much broader combinatorial screen (3456 assays) for biomaterials conducive to human mesenchymal stem-cell adhesion has also been done (Anderson et al., 2005). Modification of biomaterials with various adhesion-promoting peptides



• **Figure 2.1.2.5** The conversion of nonwettable polystyrene surface (A) into one completely wettable by water (B) is due to the adsorption of proteins (simulated images based on actual observations).

to promote stem-cell adhesion and differentiation has also come under active study, because it is thought to be a good way to "provide a microenvironment where adhesive moieties are expressed in a spatial and temporal manner to control cellular behaviors" (Hwang et al., 2008).

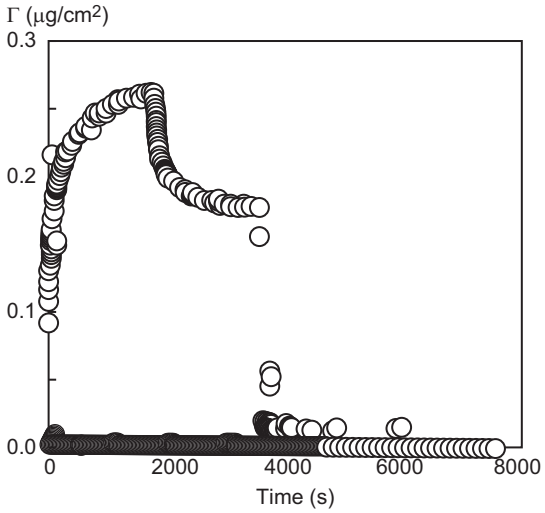
The Adsorption Behavior of Proteins at Solid–Liquid Interfaces

Adsorption Transforms the Interface

Fig. 2.1.2.5 illustrates an experiment that was performed by Horbett to demonstrate the adsorption of proteins to surfaces. As illustrated in part (A), water droplets sprayed on the surface of an unused polystyrene cell-culture dish are easily visible because they bead up, i.e., the contact angle between the droplet and the polystyrene surface is very high due to the water repellent, hydrophobic nature of polystyrene (see Chapter 1.2.4). If a cell were placed on a polystyrene dish instead of the water droplet, it would also encounter a very nonwettable surface. Part (B) of the figure illustrates the results of spraying water droplets on the surface of a polystyrene dish that had first been exposed to a protein solution for a short time, and then rinsed extensively with water. As illustrated, no water droplets can be seen on this surface, reflecting the fact that in this case the added drop of water completely spread out over the surface of the preadsorbed dish. This happens because the water in part (b) was not able to interact with the polystyrene surface, because the surface had become coated with a layer of the hydrophilic protein adsorbate. Similarly, cells that come into contact with surfaces adsorbed with proteins do not directly "see" the substrate, but instead they interact with the intervening protein adsorbate.

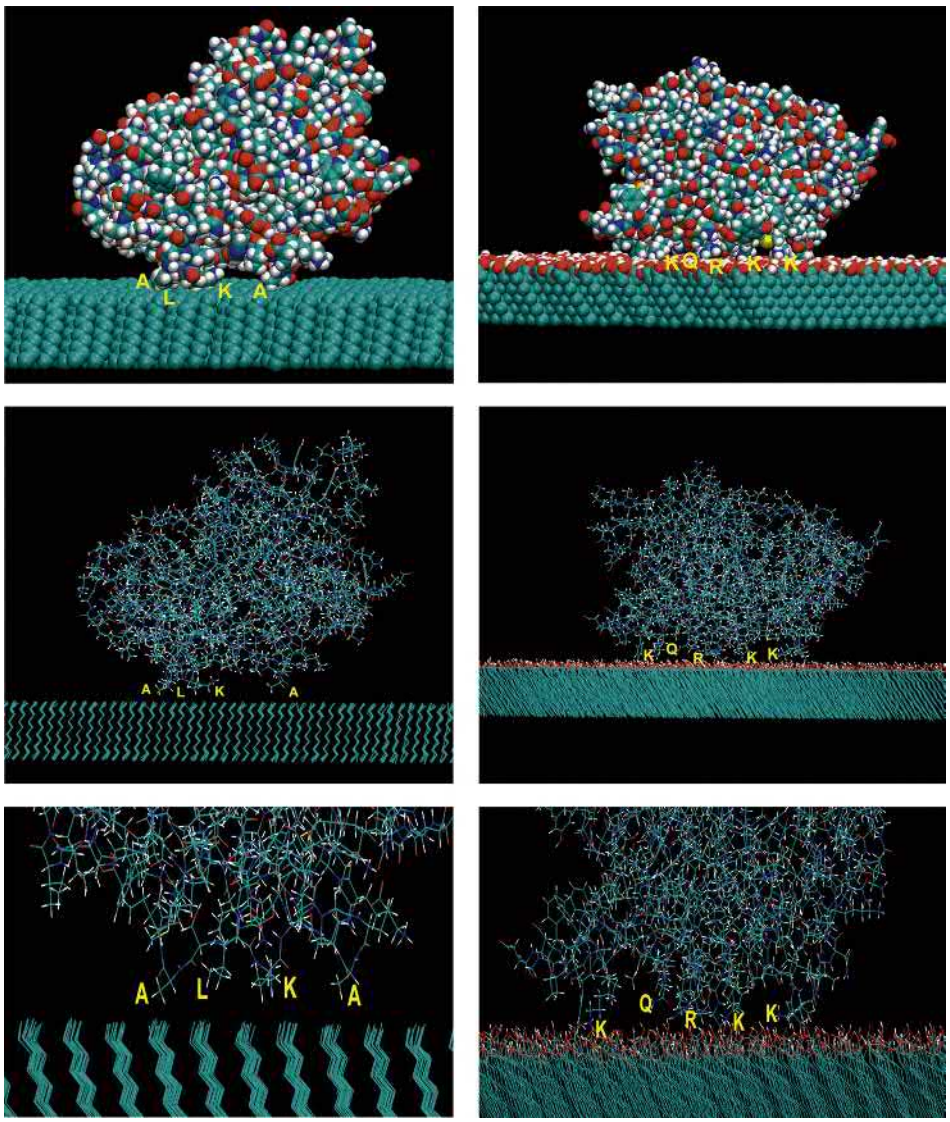
Rapid Adsorption Kinetics and Irreversibility

The kinetics of adsorption of proteins to solid surfaces typically consists of a very rapid initial phase, followed by a slower phase upon approach to the steady-state value. Initially, proteins adsorb as quickly as they arrive at the largely empty surface. In this phase, adsorption is linear when plotted against the square-root of time, characteristic of a diffusion-controlled process. In the later, slower phase, it is more difficult for the arriving proteins to find and fit into an empty spot on the surface.



• **Figure 2.1.2.6** The adsorption kinetics of lysozyme to a silica surface as studied with ellipsometry. The adsorbed amount versus time for adsorption of lysozyme to silica followed by buffer rinsing after 1800 s, addition of surfactant (sodium dodecyl sulfate) after 3600 s, and a final rinse with buffer after 5400 s (*open circles*). Adsorption from a mixture of the protein and surfactant for 1800 s followed by rinsing is also included (*closed circles*). The experiments were carried out at 25°C in 0.01 M phosphate buffer, 0.15 M NaCl, pH 7. (Reprinted with permission from Arnebrandt, T., Wahlgen, M., 1995. Protein–surfactant interactions at solid surfaces. In: T.A. Horbett., J. Brash. (Eds.), Proteins at Interfaces II: Fundamentals and Applications, ACS Symposium Series (pp. 239–254). Washington, DC: American Chemical Society. Copyright © 1995 American Chemical Society.)

Fig. 2.1.2.6 shows the time course of adsorption of lysozyme on silica measured with a high-speed, automated ellipsometer capable of very rapid measurements (Arnebrandt and Wahlgen, 1995). At the earliest measurement time, less than a second into the study, the adsorption has reached almost half of the steady-state value. At 2000 s, the protein solution was replaced with a buffer, resulting in some removal of loosely bound protein, but the adsorption stabilizes and would have remained at this value for much longer than shown, due to the tight, irreversible binding. At 4000 s, a solution of the detergent sodium dodecyl sulfate (SDS) was infused, leading to complete removal of the protein. Thus, this experiment illustrates the rapid adsorption

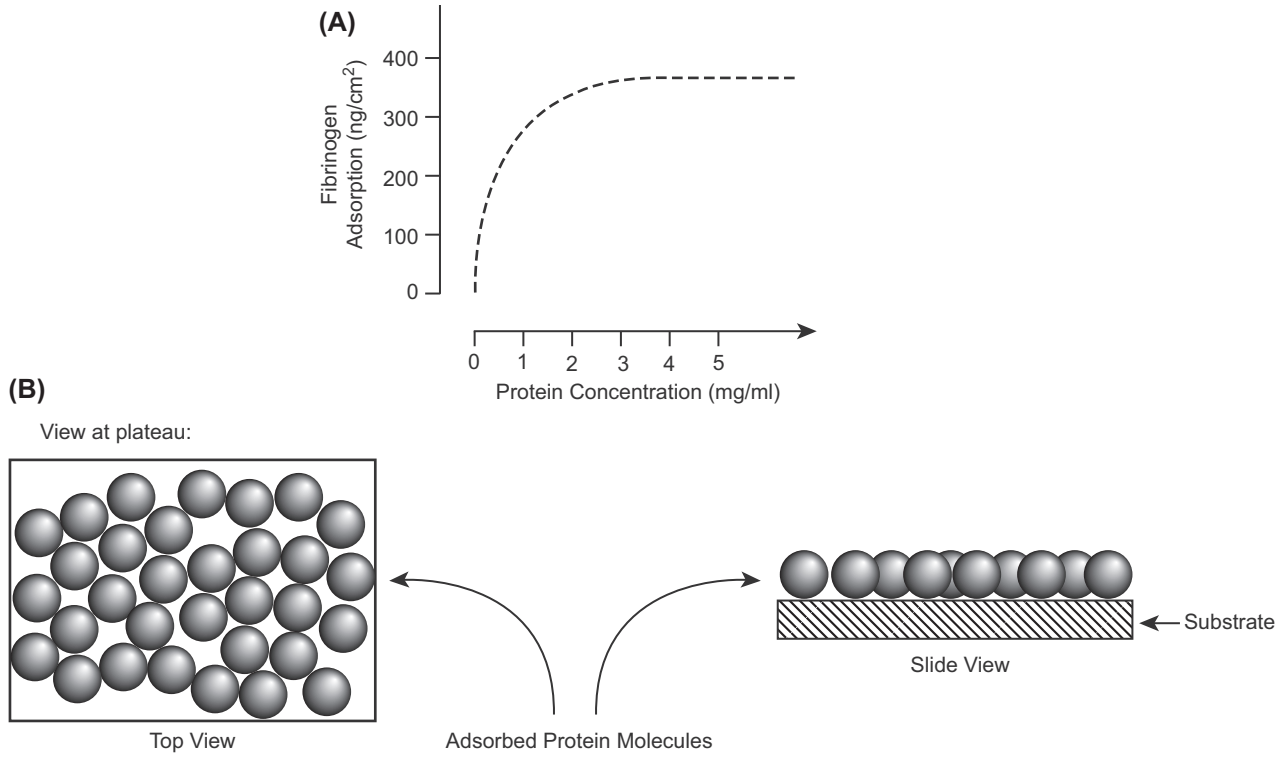


• **Figure 2.1.2.7** Molecular interactions of the 30-kDa C-terminus γ-chain fragment of fibrinogen with self-assembled monolayers with terminal CH_3 (left) and COOH (right) groups. Spacefill and wireframe models were newly created by R. Latour from the trajectory data for simulations described by Agashe et al. (2005). The models for the CH_3 surface show the interactions of the side chains of two alanine residues (A), one leucine (L), and the CH_2 groups of a lysine residue (K). The models for the COOH surface show the interactions of the side chains of three lysines (K), a glutamine (Q), and an arginine (R). Color code: green = C; red = O; blue = N; white = H; yellow = S. For clarity, interactions not easily seen in the full molecule views are not labeled.

of proteins. It also illustrates that most of the adsorbed protein is irreversibly bound, as indicated by the fact that washing the surface with buffer does not remove the protein. The adsorbed protein is only removed when a strong surfactant (SDS in this example) is used. All these features are characteristic of protein adsorption to solid surfaces.

Fig. 2.1.2.7 provides an example from molecular modeling studies illustrating the complex array of interactions possible for a protein interacting with a surface (Agashe et al., 2005). The illustrations are for the gamma chain of fibrinogen interacting with either a CH_3- or a COOH-terminated self-assembled monolayer (SAM) (see Chapter 1.4.2), and show that many atoms in the protein's amino acid side chains come near the surface, and could thus contribute to bonding. These modeling studies start with high-resolution protein structures, and apply molecular dynamics calculations that allow the protein molecule and its atoms to move in space, in order to find favorable interactions with surfaces. It is found that the protein rolling over the surface eventually oriented itself with several residues near the surface, as shown.

For the CH_3-terminated SAM, the position of the protein illustrated is a stable orientation that has hydrophobic groups, namely the side chains of alanine and leucine, and the CH_2 of a lysine side chain, lying close to the surface forming hydrophobic interactions with the methyl surface. In this orientation, the hydrophilic functional groups of the protein residues remained hydrated and well separated from the surface.



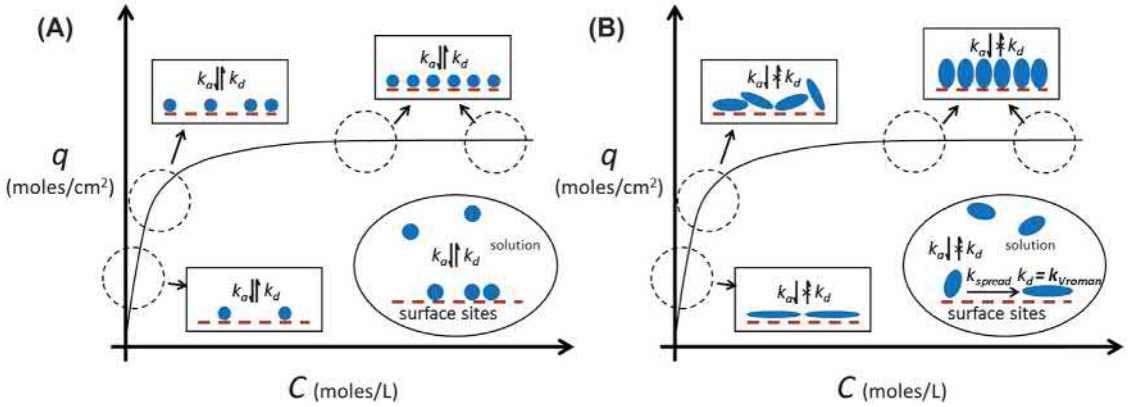
• **Figure 2.1.2.8** Adsorption isotherms (A) and the monolayer concept (B).

For the COOH surface, the position of the molecule that is a preferred orientation is quite different than for the CH_3 surface, as comparison of the overall shapes of the molecule against the two surfaces indicates. A clearer indication of these differences is the types of amino acid side chains found near the COOH interface. As shown, the near neighbors are three lysines (positively charged side chain), a glutamine (polar side chain), and an arginine (positively charged side chain), providing favorable interactions with the negatively charged deprotonated COOH groups presented from the surface.

The Monolayer Model

The existence of a close-packed monolayer of adsorbed protein is suggested by studies with single protein solutions, in which a saturation effect can often be observed in the adsorption isotherm (Fig. 2.1.2.8). Adsorption to surfaces exposed to different solution concentrations of protein until steady-state adsorption is achieved (2 h or more) increases steeply with increasing solution concentration at low concentrations, and then typically reaches a plateau or saturation value at some higher solution concentration. Despite the fact that protein adsorption to biomaterials is generally an irreversible process, this observed concentration dependence of adsorption for pure protein solutions thus often exhibits the shape of the Langmuir isotherm, which is only applicable for reversible adsorption processes such as gas adsorption.

One explanation for this behavior is that the space occupied per protein molecule in a close-packed layer (i.e., its "footprint") varies depending on the adsorption conditions. The difference between this type of adsorption behavior and true Langmuir adsorption is illustrated in Fig. 2.1.2.9. Fig. 2.1.2.9A represents true Langmuir adsorption behavior, which occurs under conditions where the adsorption process is reversible, each adsorption site is equivalent in size and in its interaction with the adsorbing solute, and the adsorbed solutes do not interact with one another. Fig. 2.1.2.9B, on the other hand, illustrates typical protein adsorption behavior. In this case, the appearance of a Langmuir-like adsorption process is caused by the fact that when adsorbed from low solution concentrations, the irreversibly bound proteins have time to molecularly spread onto the surface and form a larger footprint; i.e., a packed layer of more spread protein molecules is formed, thus resulting in a complete monolayer with a relatively low surface concentration. In contrast, when adsorption is done from higher solution concentrations, the adjacent sites are rapidly filled with other proteins, and so the spreading of each protein molecule into these sites on the surface is inhibited. In this case, a packed layer of irreversibly adsorbed protein is also formed, but the molecules are less spread, so that there can be more of them per unit area than when adsorption occurs at lower concentration (Wertz and Santore, 2001; Latour, 2015). Support for the existence of variations in molecular spreading and protein footprints is provided by the fact that proteins adsorbed at lower concentrations tend to be more tightly bound, as judged by lower desorption upon exposure to buffer or other proteins or detergents. Support is also provided by circular dichroism spectropolarimetry (CD) studies that show increasingly greater degrees of protein unfolding on

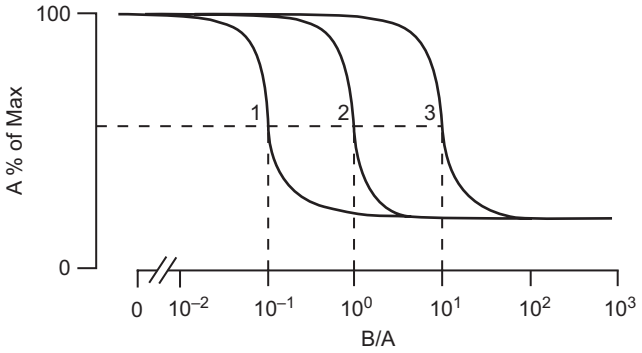


• **Figure 2.1.2.9** Adsorption isotherms; k_a, k_d, k_{spread}, k_{Vroman} are the kinetic rates of adsorption, desorption, spreading, and displacement by Vroman effects, respectively. The y-axes (q) represent the moles of solute adsorbed per cm² of surface area. The x-axes (C) represent the concentration of the solute in solution. (A) Illustration of a reversible solute adsorption process that exhibits true Langmuir adsorption isotherm behavior. (B) Illustration of irreversible protein adsorption behavior, which exhibits a Langmuir-shaped isotherm, but does not actually represent a Langmuir adsorption process. Copyright © 2014 John Wiley and Sons.)

surfaces as the protein is adsorbed from increasingly lower solution concentrations (Sivaraman et al., 2009; Sivaraman and Latour, 2010a,b).

Because protein adsorption isotherms can take the shape of the Langmuir isotherm, there is a temptation to apply the Langmuir model to a protein adsorption isotherm and use it to calculate an equilibrium constant for the adsorption process. However, given the fact that protein adsorption tends to be an irreversible process apart from Vroman effects, and deviates from each one of the underlying requirements for Langmuir adsorption, the calculation of an equilibrium constant for protein adsorption in this manner is completely erroneous and simply should never be applied (Latour, 2015).

Usually, the plateau adsorption value observed in measured adsorption isotherms falls within the range expected for a close-packed monolayer of protein (about 0.1–0.5 μg/cm², depending on the diameter and orientation assumed for the protein). The adsorption values from complex protein mixtures are also typically in the monolayer range. For example, the sum total of the amount of adsorption of the three major proteins in plasma (albumin, IgG, and fibrinogen) on the HEMA-EMA series of surfaces is also in the range 0.1–0.5 μg/cm². In addition, the fact that competition exists between proteins for adsorption to a surface (see section "Competitive Adsorption of Proteins to Surfaces from Protein Mixtures," below) also indicates the existence of limited sites. Thus, when a monolayer is the limit, there must be some selection for which proteins are present in the adsorbed film. It should be noted that well-defined plateaus are not always observed, but instead adsorption continues to rise as solution concentration is increased, although much more slowly than at the low solution concentrations; i.e., Freundlich isotherms do occur.



• **Figure 2.1.2.10** Competitive adsorption of two proteins from a mixture. (From Horbett, T.A., 1993. Principles underlying the role of adsorbed plasma proteins in blood interactions with foreign materials. Cardiovasc. Pathol. 2, 137S–148S.)

Competitive Adsorption of Proteins to Surfaces From Protein Mixtures

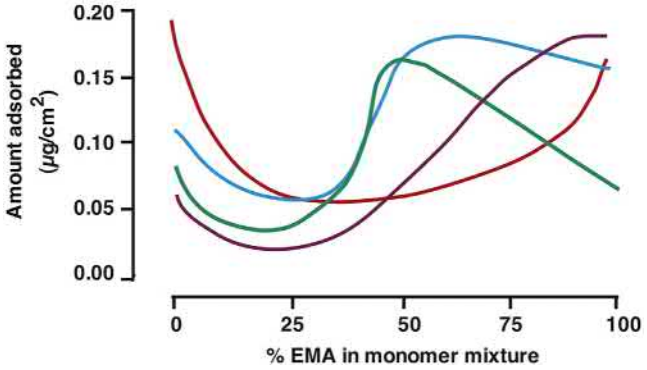
Adsorption from mixtures of proteins is selective, leading to enrichment of the surface phase in certain proteins. In this context, enrichment means that the fraction of the total mass of the adsorbed protein layer corresponding to a given protein is higher than the fraction of this protein in the bulk solution-phase mixture from which it adsorbed. Since the solid can accommodate only a small fraction of the total protein present in solution, and proteins vary greatly in their affinity for surfaces, some adsorbed proteins are present in greater amounts than others. Studies of surfaces exposed to blood plasma have shown that many different proteins are present in the adsorbed film with stoichiometries that differ greatly from plasma.

The competitive phenomena underlying differential enrichment from multiprotein mixtures are most clearly illustrated in binary mixtures of proteins. Fig. 2.1.2.10 has three separate curves in it, which overlap at the high and

low ends (Horbett, 1993). These curves represent the typical outcome of binary mixture studies, but for three different conditions. For example, when a radiolabeled protein such as fibrinogen ("A" in the figure) is mixed with various amounts of an unlabeled protein such as albumin ("B" in the figure), the adsorption of fibrinogen ("A") always declines when sufficiently high amounts of albumin ("B") are present. However, the amount of competing protein needed to inhibit the adsorption of the labeled protein is different in each curve. This is meant to illustrate that, for a given pair of competing proteins, the competition curves will be different if the surfaces they are competing for are different. In addition, if the surfaces are kept the same, but the competitions of different pairs of proteins are studied, the curves will differ because the ability of proteins to compete for surface sites is quite different for different proteins. A convenient way to characterize these binary competition curves is the ratio of competing protein it takes to cause 50% inhibition of the adsorption of the labeled protein. If this ratio is 1.0, it reflects the fact that the proteins are equal in affinity for the surface; if the ratio is much less (or much greater) than 1.0, it signifies that much less (or much more) of the competing protein is needed to reduce the adsorption, and so the competitor has a much higher (or much lower) affinity for the surface.

For example, inhibition of fibrinogen adsorption to polyethylene requires roughly 10-fold excess by weight of lower-affinity competing proteins such as albumin, but is effectively inhibited by the higher-affinity protein hemoglobin, even when hemoglobin is present at only 10% of the mass of fibrinogen. However, the amounts needed for this inhibition will depend on the surface chemistry, because the affinity of proteins changes with surface chemistry. Affinity variation is thus a major principle determining the outcome of the competitive adsorption processes.

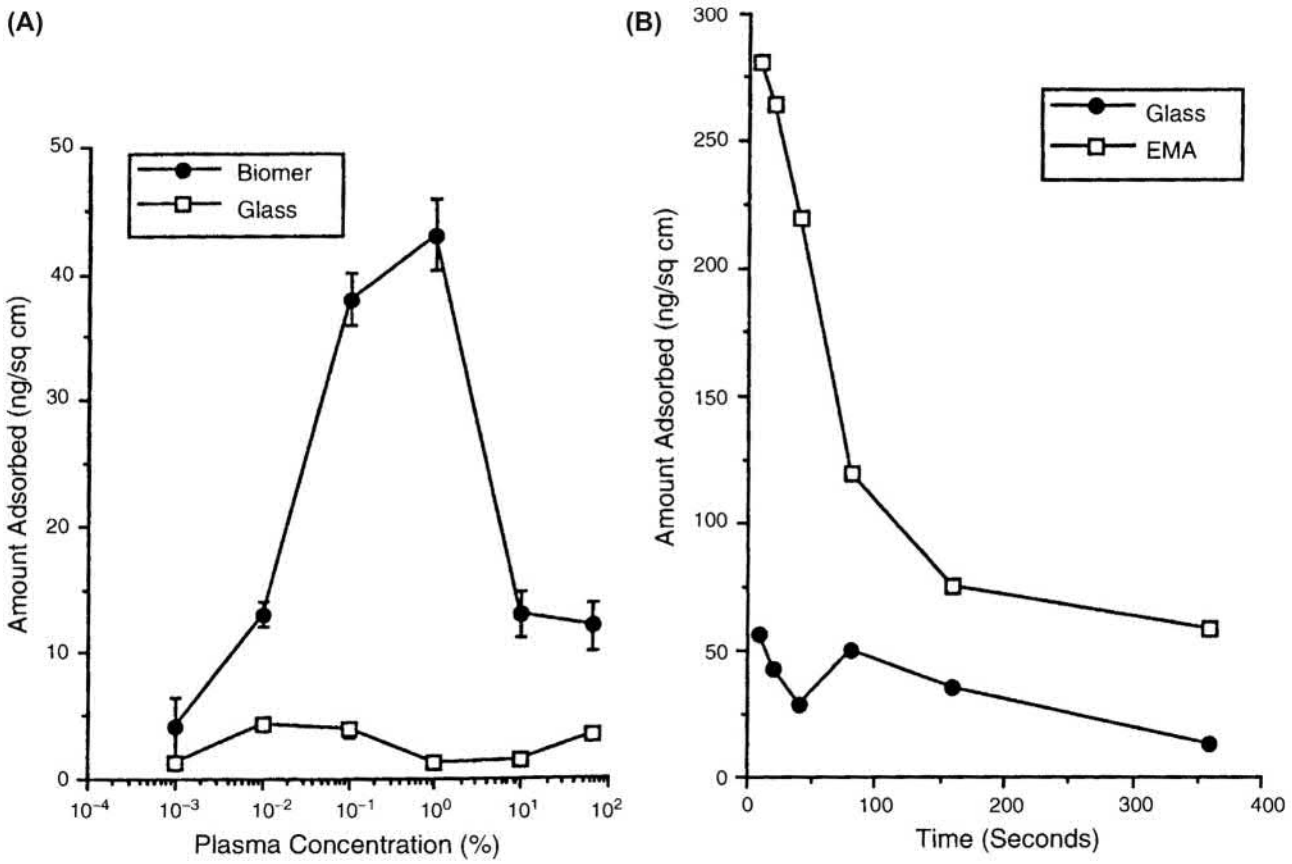
An experimental example of surface chemistry-dependent selective adsorption of proteins from a complex protein mixture is shown in Fig. 2.1.2.11 (Horbett, 1981). In these studies, a radiolabeled protein (e.g., ^{125}I-fibrinogen) added to blood plasma enabled measurement of the protein's adsorption to a series of polymers and copolymers of 2-hydroxyethyl methacrylate (HEMA) and ethyl methacrylate (EMA). This series varies greatly in its surface properties, from water-swollen hydrophilic HEMA to water-repelling hydrophobic EMA. The studies were repeated four times, once each with ^{125}I-labeled fibrinogen, albumin, IgG, or hemoglobin. The dependence of the adsorption of each protein on the changes in surface chemistry in this series is different for each protein, as reflected in the very different shape of lines for each protein. For example, albumin displayed preferential adsorption to both HEMA and EMA, in that adsorption to these polymers was much greater than to any of the HEMA–EMA copolymers. Conversely, fibrinogen adsorption was maximal at intermediate HEMA–EMA compositions. Another behavior is shown by the adsorption of hemoglobin and IgG, both of which display maximal adsorption to EMA, with minimal adsorption on surfaces made with about 20% EMA. Another



• **Figure 2.1.2.11** Differential affinity of proteins to a series of polymers: adsorption of Fg (*green line*); IgG (*purple line*); Alb (*red line*); and Hb (*blue line*) from plasma to hydroxyethyl methacrylate–ethyl methacrylate copolymers. (Redrawn version of a figure from Horbett, T.A., 1981. Adsorption of proteins from plasma to a series of hydrophilic-hydrophobic copolymers. II. Compositional analysis with the prelabelled protein technique. J. Biomed. Mater. Res. 15, 673–695.)

way to look at these data is to consider that the very different trends in adsorption across the series for each protein mean that the relative amount of each protein is unique to each surface, and varies quite a bit among the surfaces. On HEMA, the adsorption is seen to be in the order albumin > hemoglobin > fibrinogen > IgG, while on EMA the order is quite different: IgG, hemoglobin, and albumin are all about the same, but much greater than fibrinogen adsorption. On the 50–50 HEMA–EMA copolymer, the order is also different: fibrinogen and hemoglobin adsorption are about the same, but much greater than albumin or IgG. Examination of the amounts of adsorption for each protein on each surface shows that the overall composition of the adsorbed layer is different on each and every polymer in the series. The differences seen in these studies are typical for many other polymers that have been studied. Namely, the relative enrichment of a given protein when adsorbed from a complex mixture such as plasma is unique to each polymer studied. The effect of surface chemistry in causing differences in the relative enrichment of proteins adsorbed from the complex mixture of proteins in plasma is due to the differences in the relative competitive affinity of the proteins for each of the surfaces that were discussed above in regard to binary competitive adsorption studies.

Other examples of surface enrichment from complex protein mixtures are readily available. The examples presented in this paragraph emphasize protein-affinity differences, in contrast to the surface-affinity examples presented in the previous paragraph. Although fibrinogen is only the third most concentrated protein in blood plasma, after IgG and albumin, biomaterials exposed to plasma are typically enriched in fibrinogen in the adsorbed phase. Hemoglobin is present in very low concentrations in plasma (0.01 mg/mL or less), but it is still adsorbed in amounts similar to the more predominant proteins because of its high surface affinity. Albumin, a lower affinity protein, presents a counterexample. Albumin concentration in plasma is much higher than fibrinogen, yet the surface concentration of albumin adsorbed from plasma is typically about the same as fibrinogen. The high



• **Figure 2.1.2.12** The Vroman effect: (A) fibrinogen adsorption to Biomer and glass from various concentrations of blood plasma; (B) time course of fibrinogen adsorption to glass and poly(ethyl methacrylate) (PEMA) from undiluted plasma. (Reprinted with permission from Slack, S.M., Horbett, T.A., 1995. The Vroman effect: a critical review. In: T.A. Horbett, J. Brash (Eds.), Proteins at Interfaces II: Fundamentals and Applications. ACS Symposium Series (vol. 602, pp. 112–128). Washington, DC: American Chemical Society. Copyright © 1995 American Chemical Society.)

concentration of albumin in the plasma drives it onto the surface according to the law of mass action. Similarly, fibrinogen adsorption is higher from plasmas that contain higher concentrations of fibrinogen. Thus, mass concentration in the bulk solution phase is the second major factor determining competitive adsorption behavior.

The adsorption of fibrinogen from plasma exhibits some unusual behavior. On some surfaces, fibrinogen adsorption is maximal at intermediate dilutions of plasma (see example in Fig. 2.1.2.12A). In addition, fibrinogen adsorption from full-strength or moderately diluted plasma is higher at very early adsorption times than at later times (example shown in Fig. 2.1.2.12B). These are examples of the Vroman effect for fibrinogen. This phenomenon is a clear example of the unique effects of competitive adsorption on both the steady-state and the transient composition of the adsorbed layer that forms from plasma. The Vroman effect appears to involve displacement of initially adsorbed fibrinogen by later arriving, more surface-active plasma proteins, especially high-molecular-weight kininogen, and transitions in the adsorbed fibrinogen that make it less displaceable with adsorption time (reviewed in Slack and Horbett, 1995). Vroman effects, i.e., peaks in adsorption at intermediate dilution, are also observed for fibronectin adsorption from serum, and even for binary protein mixtures under certain conditions.

Molecular Spreading Events: Conformational and Biological Changes in Adsorbed Proteins

Proteins that adsorb to solid surfaces can undergo conformational changes, because of the relatively low structural stability of proteins and their tendency to unfold to allow further bond formation with the surface, which is driven by thermodynamics (i.e., lowering the overall free-energy state of the system) (Latour, 2008). Conformational changes can be detected with many types of physicochemical methods, and also by measuring changes in the biological activity of the adsorbed proteins.

Physicochemical Studies of Conformational Changes

"Soft" proteins are found to adsorb more readily and more tenaciously than "hard" proteins. In this context, a "soft" protein is one with a low thermodynamic stability, while

a "hard" protein is more stable to unfolding in solution in response to denaturing conditions, such as elevated temperature. This concept and the articles supporting the following discussion are presented in detail elsewhere (Horbett and Brash, 1995; Latour, 2008).

Comparison of the adsorptive behavior of different proteins to their molecular properties indicates that less stable proteins are more adsorptive. The important role of structural stability in adsorption is also supported by recent studies with engineered mutant proteins with single amino acid substitutions that vary in stability. Lysozyme adsorption at the solid–liquid interface, and tryptophan synthase occupation of the air–water interface are greater for less stable mutants, and more stable lysozyme variants tend to be displaced by less stable mutants (Lee et al., 2004).

Several studies with differential scanning calorimetry (DSC) methods seemed to indicate that adsorbed proteins may lose much of their structure, depending on how "soft" they are. Heat is taken up at a certain elevated temperature for proteins in solution, due to the unfolding of the native protein at the transition temperature. This phenomenon is analogous to the melting of a crystalline material. An absence or reduction of this effect for a preadsorbed protein suggests that the adsorbed protein has already undergone the transition; i.e., that it has already unfolded upon adsorption. The transition enthalpy of lysozyme preadsorbed to negatively charged polystyrene was much less than for the protein in solution (0–170 kJ/mol for the adsorbed protein vs. about 600 kJ/mol for the native protein in solution depending on the pH). However, for lysozyme preadsorbed on hematite, the unfolding enthalpy is only about 20% less than for the native protein in solution, indicating that changes in the enthalpy of unfolding depend on the adsorbing surface. Furthermore, for lactalbumin the heat released is nearly zero when it is preadsorbed on either the polystyrene or the hematite surface, suggesting complete unfolding of lactalbumin on both surfaces. These observations are consistent with the lower stability of lactalbumin in comparison to lysozyme. Several proteins preadsorbed to pyrolytic carbon do not show any release of heat at the expected transition temperature, suggesting that pyrolytic carbon induces complete unfolding; a result that is consistent with the tenacious binding of proteins to this surface. It has also been shown that albumin and lysozyme preadsorbed to polystyrene exhibit no transitional unfolding enthalpy, while lysozyme preadsorbed to a hydrophilic contact lens still exhibits about 50% of the heat released by the native protein in solution during its thermally induced transition. Streptavidin preadsorbed to polystyrene displays an unfolding enthalpy that is very similar to that for the native protein in solution, probably because of the greater stability of streptavidin in comparison to lysozyme or albumin.

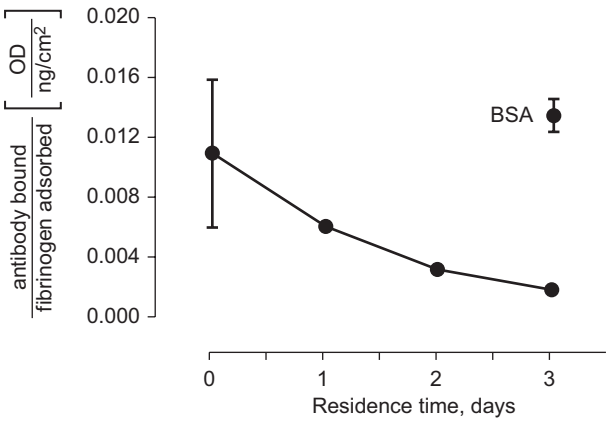
However, more recent studies of adsorbed proteins by the DSC method in conjunction with other, more direct conformational measurements such as circular dichroism (CD), show that at least some adsorbed proteins that appear to be completely denatured, as judged by DSC, still have considerable amounts of their native structure, as measured by CD (Thyparambil et al., 2015). It thus appears that some proteins become somewhat more stable after adsorption, and thus do not show heat release at the normal melting temperature.

The concept of molecular spreading of the adsorbed protein suggested by these observations has been used to explain differences in the amount of IgG adsorbed during stepwise adsorption. When the final concentration of bulk protein in solution is achieved in a series of smaller concentration steps, as opposed to bringing the bulk solution concentration to its final value in one step, adsorption is smaller. This result is thought to be due to spreading and an enlarged footprint of a protein molecule that can occur at lower solution concentrations, which is the same phenomenon that leads to the appearance of Langmuir-like isotherms, as discussed above. Conformational changes upon adsorption of fibronectin to polystyrene beads and Cytodex microcarrier beads have also been detected using electron spin resonance spectroscopy. Many other physicochemical studies are consistent with partial unfolding of the adsorbed proteins (Andrade, 1985; Lundstrom, 1985; Horbett and Brash, 1995; Sivaraman et al., 2009; Sivaraman and Latour, 2010a,b; Thyparambil et al., 2015).

Changes in Biological Properties of Adsorbed Proteins

While physicochemical studies sometimes suggest complete denaturation of adsorbed proteins, most probes for biological activity suggest the changes are more limited (reviewed with citations in Horbett, 1993). Thus, enzymes retain at least some of their activity in the adsorbed state, especially when the enzyme is adsorbed from high solution concentration to minimize adsorption-induced unfolding. Measurements of enzyme activity or retention times during passage over hydrophobic chromatography matrices have shown that the degree of denaturation is highly dependent on the protein, the length of time the protein has spent on the matrix, the solvent, and other conditions, and is not necessarily complete.

Changes in the binding of a monoclonal antibody to fragment D of fibrinogen upon fibrinogen adsorption to polystyrene have been attributed to changes in the conformation of fibrinogen after adsorption. Thus, solution-phase fibrinogen does not bind the antibody raised to fragment D, but the surface-adsorbed fibrinogen does. Furthermore, fibrinogen in solution does not compete for the binding of the antibody to the surface-adsorbed fibrinogen. The RIBS (receptor-induced binding site) antibodies are similar: they bind to fibrinogen only after the fibrinogen has bound to either a solid surface or to the platelet IIb/IIIa receptor. The binding of the RIBS antibodies and others that bind to the platelet-binding regions of fibrinogen varies with the length of time after adsorption of the fibrinogen. Platelet adhesion to polymethacrylates has been correlated with the amount of antifibrinogen binding, suggesting that the adsorbed fibrinogen is in different conformations on the various polymethacrylates.



• **Figure 2.1.2.13** Transitions in adsorbed fibrinogen. The effect of 3-day residence in buffer or buffered albumin solution upon antifibrinogen binding to fibrinogen adsorbed from dilute plasma to Biomer polyurethane is shown. *BSA*, bovine serum albumin. (From: Fig. 3A in Chinn, J.A., Posso, S.E., Horbett, T.A., Ratner, B.D., 1992. Post-adsorptive transitions in fibrinogen adsorbed to polyurethanes: changes in antibody binding and sodium dodecylsulfate elutability. J. Biomed. Mater. Res. 26, 757–778.)

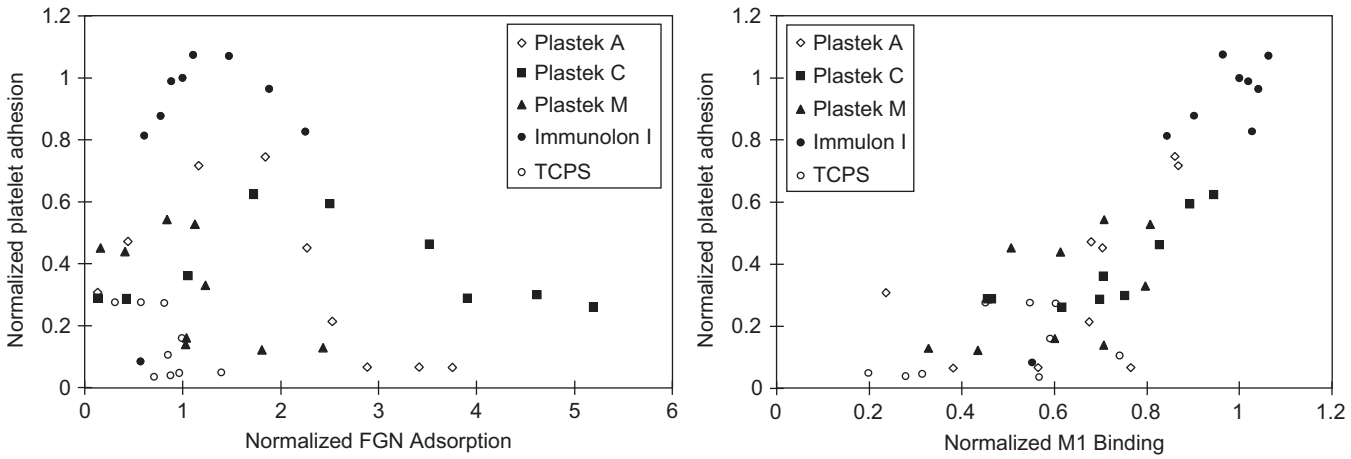
Fibrinogen undergoes a time-dependent transition after its adsorption to a surface that results in reduced platelet and antibody binding to the adsorbed fibrinogen, as well as reduction in the SDS and plasma displaceability, and changes in amide II frequency of the adsorbed fibrinogen. The losses in platelet binding, antibody binding, and SDS elutability are prevented if albumin is included in the storage buffer. An example showing time-dependent losses in antibody binding to fibrinogen and its prevention by albumin is shown in Fig. 2.1.2.13 (Chinn et al., 1992). Vitronectin also appears to undergo conformational changes upon adsorption that affect its ability to bind heparin and its infrared spectra.

Modulation of the biologic activity of fibronectin has been shown in several studies in which the ability of fibronectin adsorbed to various surfaces to support cell attachment or spreading was found to differ. For example, fibronectin adsorbed to tissue-culture-grade polystyrene was able to support cell attachment and spreading, whereas fibronectin adsorbed to ordinary polystyrene does not support spreading very well, unless some albumin is added to the fibronectin solution. Fibronectin adsorbed to self-assembled monolayer (SAM) films with various functional end groups also varies in its ability to interact with cells. On hydrophobic SAMs there is poor cell spreading unless albumin is coadsorbed (albumin "rescuing"). The albumin "rescuing" phenomenon observed for SAMs is similar to the albumin effect on fibronectin's ability to promote cell spreading on polystyrene, and to the effect of albumin addition in preventing losses in platelet adhesion to fibrinogen-adsorbed surfaces discussed above. The ability of fibronectin adsorbed to a series of polymers to support the outgrowth of corneal epithelial cells has also been found to vary a great deal, despite the presence of similar amounts of fibronectin on the surfaces.

The effect of albumin addition in enhancing the adhesivity of fibronectin-coated surfaces is opposite to what one might expect, because the added albumin should reduce the amount of adsorbed fibronectin as albumin competes for sites on the surfaces. The explanation for the albumin effect is thought to be that by adsorbing along with the fibronectin to the surface, the albumin molecules occupy surface sites near the fibronectin molecules. The adsorbed albumin molecules thus keep the adsorbed fibronectin molecules from undergoing structural changes that they would otherwise do in trying to spread into formerly empty surface sites, but they cannot do so if albumin molecules first fill those sites.

Highly uniform SAM surfaces with different terminal functional groups have proved useful in showing how surface chemistry modulates the biologic properties of adsorbed fibronectin. When increasing amounts of fibronectin were adsorbed to SAMs with terminal OH, COOH, NH_2, or CH_3 functional groups, it was found that the amount of adsorbed fibronectin required to cause cell adhesion varied widely. Thus, on the CH_3 surface it took far higher amounts of fibronectin to obtain equivalent maximal adhesion than on the OH surfaces (Keselowsky et al., 2003). Similarly, the binding affinity of antibodies that bind to the cell-binding domain and of the integrin $\alpha_5\beta_1$ was much higher for fibronectin on the OH surface than on the CH_3 surface. Thus, there are significant differences in the functional presentation of the central cell-binding domain of fibronectin upon adsorption to different surface chemistries. The theoretical predictions of differences in preferred orientation of adsorbed molecules on surfaces with different chemistry (see Fig. 2.1.2.7) suggest that these biological effects are also due to orientational effects. With an osteogenic cell line, genes that mark osteoblastic differentiation and actual mineralization were both elevated in the cells on the fibronectin-coated OH and NH_2 surfaces compared with the COOH and CH_3 SAMs (Keselowsky et al., 2005). Myoblast differentiation on fibronectin adsorbed to this same series of SAMs also varied greatly, in the order $OH > CH_3 > NH_2 = COOH$ (Lan et al., 2005). The ability of myoblasts to rearrange adsorbed fibronectin and deposit new fibronectin was also much greater on the CH_3 surface than on the OH surface.

Fig. 2.1.2.14 shows an experimental example of the modulation of the biologic activity of adsorbed fibrinogen, namely its ability to mediate platelet adhesion. In these studies, both fibrinogen adsorption and binding of a fibrinogen-specific antibody were measured from plasma diluted to various degrees on a series of chemically modified polystyrene surfaces. Platelet adhesion to the plasma preadsorbed surfaces was also measured. The left part of Fig. 2.1.2.14 shows that there was no obvious correlation between platelet adhesion and fibrinogen adsorption, despite the fact that we know that fibrinogen adsorption is required for adhesion, as shown in Fig. 2.1.2.3. However, when the availability of the platelet-binding region in fibrinogen adsorbed to these surfaces was measured using a monoclonal antibody (M1)



• **Figure 2.1.2.14** Cross plots of platelet adhesion against the amount of fibrinogen (FGN) adsorption or M1 antibody binding on five different surfaces. (From: Tsai, W.B., Grunkemeier, J.M., Horbett, T.A. 2003. Variations in the ability of adsorbed fibrinogen to mediate platelet adhesion to polystyrene-based materials: a multivariate statistical analysis of antibody binding to the platelet binding sites of fibrinogen. J. Biomed. Mater. Res. 67A, 1255–1268.)

that binds to the C-terminal region of the gamma chain of fibrinogen, it was found to vary greatly. Platelet adhesion was well correlated with the antibody binding, as shown in the right panel in Fig. 2.1.2.14. The poor correlation with total fibrinogen adsorption, and the greatly improved correlation with platelet-binding site availability, is strong support for the idea that the functional activity of adsorbed fibrinogen in supporting platelet adhesion depends on the surface to which it is adsorbed. Thus, fibrinogen's bioadhesive activity is modulated by the surface chemistry.

In another interesting set of studies, Sivaraman and Latour provided evidence that indicates that adsorption-induced unfolding of proteins can actually create platelet-binding sites. Fibrinogen was adsorbed to different surface chemistries from different solution concentrations to obtain a wide range in the degree of unfolding of the protein as determined by circular dichroism (CD) spectropolarimetry. Platelet adhesion to the adsorbed fibrinogen was then found to strongly correlate to the degree of adsorption-induced unfolding (Sivaraman and Latour, 2010a). Surprisingly, platelet adhesion was even found to then occur on surfaces with adsorbed human serum albumin, but only after the albumin unfolded beyond a critical limit, which was measured as a loss in α-helices of more than 33% (Sivaraman and Latour, 2010b). It is hypothesized that this phenomenon occurs by adsorption-induced salt-bridge separation of positively and negatively charged amino acids, causing them to effectively transition from RGE-like to RGD-like motifs, which may be a universal mechanism by which platelets are able to detect denatured proteins on a vascular or biomaterial surface. Further studies are needed to support this hypothesis.

These studies with platelets, fibroblasts, epithelial cells, osteocytic cells, and myoblasts show that substrate properties somehow modulate the ability of adsorbed proteins to interact with cells. These differences may arise, at least in part, from differences in the availability of epitopes on adhesive proteins for the cell surface receptor, which are influenced by factors such as the orientation and conformation of the adsorbed proteins. That is, both the amount of the adsorbed adhesive protein, as well as its "bioreactivity," are actively influenced by the properties of the surface to which it is adsorbed.

The Importance of Adsorbed Proteins in Biomaterials

Table 2.1.2.1 summarizes the principles underlying the influence of adsorbed proteins in biomaterials used in contact with the blood. All of the principles listed also apply in other environments, such as the extravascular spaces, albeit with other proteins and other cell types (e.g., macrophages in the peritoneum adhere via other receptors and other adhesion proteins). The blood platelets therefore provide a "case study," and we close this chapter by considering this case.

The high sensitivity of platelet–surface interactions to adsorbed proteins is fundamentally due to the presence of adhesion receptors in the platelet membrane that bind to certain plasma proteins. There are generally only a few types of proteins in plasma that have native-state motifs that are bound by the adhesion receptors. The selective adsorption of these proteins to synthetic surfaces, in competition with the many nonadhesive proteins that also tend to adsorb, is thought to mediate platelet adhesion to these surfaces, which in turn leads to platelet activation events such as their ability to catalyze the formation of thrombin. However, since the dissolved plasma-phase adhesion proteins do not bind to adhesion receptors unless the platelets are appropriately stimulated, while unstimulated platelets can adhere to adsorbed adhesion proteins, it appears that adsorption of proteins to surfaces accentuates and modulates the adhesion receptor–adhesion protein interaction. The type of surface to which the adhesion protein is adsorbed affects the ability of the protein to support platelet adhesion, due to variations in the amount

TABLE 2.1.2.1 Principles Underlying the Influence of Adsorbed Plasma Proteins on Blood Platelet Interactions With Biomaterials

1. Synthetic foreign materials acquire bioreactivity only after first interacting with dissolved proteins. The principal means by which the transformation from an inert, nonthrombogenic polymer to a biologically active surface takes place is the interaction of the proteins with the surface that then mediates cell adhesion.
2. Platelets are an important example of why and how adsorbed proteins are influential in cell–biomaterials interactions.
3. Sensitivity of platelets to adsorbed proteins is due to:
   a. Some proteins in plasma are strongly adhesive for platelets: fibrinogen, fibronectin, vitronectin, and von Willebrand factor.
   b. Concentrating, localizing, immobilizing effects of adsorbing the proteins at the interface accentuates the receptor–adhesion protein interaction.
   c. Platelets have receptors (IIb/IIIa and Ib/IX) that bind specifically to a few of the plasma proteins, mediating adhesion.
4. Principles of protein adsorption to biomaterials:
   a. Monolayer adsorption and consequent competition for available adsorption sites means that not all proteins in the plasma phase can be equally represented on the surface.
   b. Driving forces for adsorption are the intrinsic surface activity and bulk phase concentration of the proteins.
   c. Surfaces vary in selectivity of adsorption.
   d. Biological activity of the adsorbed protein varies on different surfaces.

of adsorbed fibrinogen (Horbett, 1993), and in the availability of the platelet-binding regions in the fibrinogen molecule (Tsai et al., 2003). The principles that determine protein adsorption to biomaterials include monolayer adsorption, the intrinsic surface activity and bulk solution concentration of the protein, and the effect of different surfaces on the selectivity of adsorption, the conformational stability, and the biologic activity of the adsorbed protein.

More generally, all proteins are known to have an inherent tendency to deposit very rapidly on surfaces as a tightly bound adsorbate that strongly influences subsequent interactions of many different types of cells with the surfaces. It is therefore thought that the particular properties of surfaces, as well as the specific properties of individual proteins, together determine the organization of the adsorbed protein layer, and that the nature of this layer in turn determines the cellular response to the adsorbed surfaces.

Surface Chemistries Highly Resistant to Protein Adsorption

The importance of adsorbed proteins in biomaterials science is also well-illustrated by the amount of effort that has been expended to develop protein "nonfouling" or protein-repellent materials in recent years (see Chapter 1.4.3A; Horbett, 2003; Binazadeh et al., 2012; Thompson et al., 2017b).

Since adsorbed proteins are required for platelet adhesion, an obvious approach to improve blood compatibility is to produce biomaterials that prevent or at least greatly reduce protein adsorption, and thus much recent research has focused on finding protein-repellent materials. For example, many studies show that protein adsorption can be greatly reduced with poly(ethylene oxide) (PEO) or, similarly, poly(ethylene glycol) (PEG) coatings of various types [e.g., PEO/polylactide copolymers, PEO-grafted polyurethanes (PUs), PEO-grafted PU/polystyrene, ethylene glycol-terminated SAMs, or glow discharge deposited polymers of the low-molecular-weight polyether tetraglyme to make PEO-like coatings], and that platelet adhesion is reduced, both in vitro and in vivo (Gombotz et al., 1991; Shen et al., 2002; Binazadeh et al., 2012; Thompson et al., 2017b). However, since even low amounts of adsorbed fibrinogen (c. 5 ng/cm^2; Tsai and Horbett, 1999) are sufficient to support nearly full-scale platelet adhesion, and many of the surfaces tested fail to reduce fibrinogen adsorption to that degree when exposed to undiluted blood plasma, it has proved difficult to make biomaterials that fully achieve this design criterion. In addition, studies have shown that PEO/PEG undergoes hydrolysis over time, thus eventually losing its protein-repellency (Shen et al., 2002; Li et al., 2007), suggesting its suitability for only relatively short-term applications.

Recent studies by Gunkel and Huck (Gunkel and Huck, 2013) and by Riedel et al. (Riedel et al., 2013) investigated the composition of the proteins that nonspecifically bind to PEG-coated surfaces following exposure to undiluted blood plasma and discovered an unusually high percentage of apolipoproteins in the adsorbed protein layer. These proteins were subsequently determined to be deposited on the surfaces via the adsorption of low-density lipoprotein (LDL) particles. These findings were further supported in a recent study by the Brash group (Cornelius and Brash, 2015). In this study, Cornealius and Brash presented the surprising results that while PEO-coated polyurethane surfaces were highly resistant to the adsorption of proteins in solution, they actually adsorbed lipoprotein particles [low-density lipoprotein (LDL), high-density lipoprotein (HDL), and very-low-density lipoproteins (VLDL)] as readily as polyurethane surfaces without a PEO coating. The significance of these findings is that lipoproteins, which are composed of phospholipid membranes encapsulating lipid molecules such as cholesterol, carry apolipoproteins on their surfaces. Thus while being highly resistant to individual proteins in solution, proteins (i.e., apolipoproteins) will still be deposited onto PEO-coated surfaces via HDL, LDL, and VLDL adsorption. The clinical significance of these findings remains to be determined, with the possibility that irreversibly adsorbed apolipoproteins may possibly initiate platelet adhesion and subsequent thrombosis (Chandy and Sharma, 1991), especially as they can be expected to eventually undergo aging-induced unfolding over time (Sivaraman and Latour, 2012).

Another category of highly protein-resistant surface chemistries that shows great potential for biomaterials applications has been provided by zwitterionic betaines [poly(carboxybetaine) (PCB) and poly(sulfobetaine) (PSB)] (Zhang et al., 2006; Jiang and Cao, 2010; Binazadeh et al., 2012; Thompson et al. 2017b). These materials show ultralow protein adsorption properties as well as being much more chemically stable than PEO/PEG functionality. In fact, zwitterionic carboxybetaine hydrogels have been shown to be stable for at least 90 days when subcutaneously implanted in mice without inducing an observable foreign-body response (Zhang et al., 2013). As with PEO/PEG coatings, these surfaces provide resistance to protein adsorption due to their ability to tightly bind water molecules, thus forming hydration layers that proteins in solution are not able to displace. It remains to be determined by further studies how long PCB- and PSB-coated surfaces will be able to maintain their resistance to protein adsorption and whether or not they are also resistant to the adsorption of lipoprotein particles when used for blood-contacting applications.

Concluding Remarks

As presented in this chapter, the adsorption of proteins to biomaterial surfaces is of fundamental importance to the understanding of cellular responses and the subsequent biocompatibility of synthetic materials that are used in implanted medical devices. Because cells do not possess receptors for synthetic materials, their response to different chemically stable materials presenting different surface chemistries is mediated not by the material itself, but by the types of proteins that adsorb to the material surface and the bioactivity of these proteins, which is influenced by their orientation, structure, and packing arrangement on the surface. While much has been learned over the past decades of research to understand and unravel the complexities involved in these processes, the understanding of protein adsorption behavior and its influence on the subsequent biological response to implanted biomaterials is far from complete and remains an important area of ongoing research in the field of biomaterials science and engineering.

Chapter Solutions to Problems

1. What are the three main driving forces that affect the competitive adsorption of proteins to biomaterials from complex mixtures such as blood plasma?
2. Calculate the amount of adsorbed protein in a close-packed monolayer for an average protein of molecular weight 100,000. Assume the protein is spherical and has a partial specific volume of proteins of 0.73 mL/g.
3. When various biomaterials are implanted in the body, the responses often depend on the chemistry of the implanted material. Yet we know that the surface is covered with adsorbed protein and thus the biological response is not due to direct interaction with the surface. How then are the differences in responses explained?
4. What are three methods that show the specific effect of adsorbed proteins on cellular interactions with biomaterials?
5. As illustrated in Fig. 2.1.2.5, polystyrene and other hydrophobic surfaces become more wettable after exposure to protein-containing media. However, for certain materials such as cleaned germanium prisms that initially have low contact angles with water (e.g., 11°) and are thus fairly wettable to begin with, exposure to protein-containing solutions has been reported to cause the contact angle to increase (to around 60°). How can this be explained?
6. Proteins are tightly bound to many biomaterials and adsorption is considered irreversible in that the protein is not washed off in the buffer used for adsorption, even after long soaking periods. Give a molecular explanation of why proteins are so tightly bound.
7. What are the two primary factors that control the kinetics of initial protein adsorption onto a biomaterial surface?
8. Which type of biomaterial surface tends to induce a greater degree of protein unfolding when the protein adsorbs onto the surface: a biomaterial functionalized with nonpolar hydrophobic surface groups (e.g., $-CH_3$ groups) or a biomaterial functionalized with neutral polar hydrophilic groups (e.g., –OH groups)? Explain.
9. Are Vroman effects primarily driven by kinetic or thermodynamic forces?

Chapter Solutions to Problems

1. The three main factors that are believed to control the outcome of competitive adsorption processes are: (1) the intrinsic affinity of each protein for surfaces, meaning that some proteins are more surface active and more adsorptive than others; (2) the chemical nature of the adsorbing surface, due to the fact that the variations in surface affinity among proteins one sees for a given surface are only fixed for that surface, and will differ if another surface is used; (3) the relative bulk concentration of each protein, meaning that even a protein with high affinity for a surface will not be present in high amounts on the surface if it is present in low bulk concentration compared to the other proteins since the excess concentration of the competing proteins will overcome the affinity differences.
2. Close packing means that the molecules touch each other at their boundaries, so the problem can be solved by calculating the cross-sectional area of one molecule of the protein and dividing that into square centimeters of area, which then gives the number of molecules in that area. Using the molecular weight of the protein allows conversion of the number of molecules into the mass of molecules, and thus you end up getting mass per unit area of a close-packed monolayer.

Protein Monolayer Calculation

The specific volume (volume per gram) of a protein can be used to calculate the volume of an individual protein molecule by using the molecular weight and Avogadro's number.

$$V_{\text{molecule}} = V_{\text{specific}} * M / N_{\text{Avogadro}}$$
$$= (0.73\ \text{mL/g}) * (10^5\ \text{g/mole}) / 6.02\times10^{23}$$
$$= 1.22\times10^{-19}\ \text{mL/molecule}$$

The volume of an individual protein molecule can be used to calculate the radius of the molecule r, assuming it is spherical.

$$r = \left(\frac{3}{4\Pi} V_{\text{molecule}}\right)^{1/3}$$
$$= 3.08\times10^{-7}\ \text{cm}$$

(This radius estimate can be compared to dimensions of proteins measured by X-ray crystallography. For proteins in the range of 100,000 molecular weight, average length dimensions are around 70 Å, giving a radius of around 35 Å, fairly close to what we just calculated using the specific volume of proteins.)

The radius of the protein molecule can then be used to calculate the projected areas of an individual protein molecule A_{molecule}, which is the "footprint" or area occupied on the surface by the protein molecules.

$$A_{\text{molecule}} = \Pi r^2$$
$$= 2.97\times10^{-13}\ \text{cm}^2$$

With the footprint area, you then can calculate the number of protein molecules that can be fit into a square centimeter n_{protein}, assuming close packing of circles representing the footprint area occupied by each spherical protein molecule. (This is a small overestimate of the occupiable area, because the tightest packing of circles on a planar surface leaves about 9% area unoccupied, according to a theory by Gauss.)

$$n_{\text{protein}} = 1\ \text{cm}^2 / A_{\text{molecule}}$$
$$= 3.36\times10^{12}\ \text{molecules}$$

Then convert the number of molecules per unit area $n_{protein}$ into mass of protein per unit area $m_{protein}$ using Avogadro's number and the molecular weight of the protein.

$$m_{\mathbf{protein}} = n_{\mathbf{protein}} * M / N_{\mathbf{Avo}}$$
$$= 5.6\times10^{-7}\ \text{g}$$
$$= 0.56\ \mu\text{g}$$

Thus, according to this calculation, there should be around 0.56 μg per square centimeter in a close-packed monolayer of a spherical protein of molecular weight 100,000.

3. Due to differences in relative competitive affinity of proteins for various surfaces, the amount of adsorption of each protein varies with surface chemistry. For example, some surfaces have more adsorbed fibrinogen, and others more adsorbed albumin, and since platelets bind only to fibrinogen, surfaces enriched in fibrinogen are more platelet reactive. Thus, the effect of surface chemistry is to vary the composition of the adsorbed protein and thus this is why the reactivity with cells varies with surface chemistry.
4. Three methods to show the role of adsorbed proteins are as follows.
   a. If surfaces are preadsorbed with various purified proteins, it is found that most inhibit cell adhesion to the surface but a few such as fibronectin, fibrinogen, and vitronectin cause the cell adhesion to be much higher than for other proteins. Proteins that block adhesion are called passivating or blocking proteins, while those that mediate it are called adhesion proteins.
   b. Preadsorption with complex protein mixtures such as blood plasma selectively deficient in only one protein is a more physiologically relevant way to show if a protein is contributing an important role in platelet adhesion in the presence of many other potential adhesion proteins in plasma. If cell adhesion is greatly reduced when the surface is adsorbed with the protein mixture that is missing one protein such as fibronectin, it means this protein is playing an important role in that it is not replaced by the action of other proteins still in the mixture and on the surface.
   c. Addition of antibodies specific to a given adhesion protein or to its receptor to a cell suspension incubating with a biomaterial will result in a decrease in adhesion that is proportional to the concentration of added antibody. Because such antibody-blocking studies can be done with surfaces adsorbed with mixtures of proteins such as plasma, yet they selectively interfere in adhesion mediated by only one adhesion protein, they provide information relevant to the functional role of the adhesion protein under conditions closer to the physiologic situation where biomaterials are exposed to complex mixtures of proteins.
5. An increase in contact angle after exposure to protein-containing media can be explained by adsorption of protein if the adsorbed protein layer is less wettable than the starting surface. For certain solid materials such as cleaned gallium prisms, the interaction is very strong with water and so the contact angle is low. After protein adsorption occurs, the higher contact angle must mean that adsorbed proteins interact with water less strongly than the starting germanium surface. Thus, while proteins are much more wettable than polystyrene, they evidently are not as wettable as some solid surfaces.
6. The irreversible, tight binding of proteins to surfaces is due to the large size of protein molecules so that many noncovalent bonds are formed between the surface and each molecule, i.e., "multipoint attachment" occurs. Although each bond is relatively weak and reversible, the chance that all the bonds would be broken simultaneously is low, so multivalent bonding results in strong bonding.

   R. Latour adds another way to look at this issue. He notes that because of the large number of contacts between functional groups of a protein and a surface, even weak interactions will hold the protein. For example, if the interactions with the surface are equal in energy to their interactions with water in the bulk phase, and we assign the probability of a surface functional group being bonded to a protein versus a water molecule to be 0.5, the probability for all of the functional groups of an adsorbed protein to dissociate from the protein at the same time would be $P = (0.5)^n$, with n being the number of functional group contacts between the protein and surface. So even if n is as small as 20, the probability that they would all dissociate at the same time is very small. Thus, even a hydrophilic surface with OH groups (e.g., OH-SAM) will tend to irreversibly adsorb a large protein, while for hydrophobic surfaces that has favorable thermodynamics of adsorption for a nonpolar amino acid residue versus water the likelihood of desorption is even smaller.
7. Since the rate of adhesion of a protein to a biomaterial surface once it contacts the surface is generally much faster than the rate of diffusion of the protein from solution to the biomaterial surface, the kinetics of the initial process of protein adsorption is typically diffusion limited. The rate of diffusion of a protein in solution is directly proportional to the concentration of the protein in solution and inversely proportional to the square root of the protein's molecular weight. Thus, the concentration of the protein in solution and the size of the protein (i.e., its molecular weight) are the primary factors that determine the initial rate of adsorption of a given protein on a biomaterial surface.
8. Biomaterials functionalized with nonpolar hydrophobic groups will tend to induce a greater degree of protein unfolding than neutral hydrophilic groups. This occurs because proteins tend to be structured with their nonpolar hydrophobic amino acids buried within the protein with the outer surface of the protein largely containing hydrophilic groups, which enable the protein to be soluble in physiological solution. When proteins adsorb to hydrophobic surfaces, strong hydrophobic interactions tend to cause the proteins to unfold with their hydrophobic amino acid

residues tightly adsorbed to the surface. This process is driven by the thermodynamic decrease of system free energy that is caused by reducing the solvent-accessible surface area of the hydrophobic surface. However, when proteins adsorb to a hydrophilic surface, the nonpolar amino acid residues within the protein's core tend to remain buried within the protein with the protein's outer hydrophilic residues forming hydrogen bonds with the surface, thus tending to induce a lower degree of unfolding.

9. Vroman effects represent the displacement of one adsorbed protein by a more strongly adsorbing protein, thus being thermodynamically driven to lower the overall free-energy state of the system.

Introduction

There is no doubt that in vitro methods have been and will continue to be of great value to the progression of medical science. The culture of mammalian cells and the study of their behavior in vitro has led to new understandings of cell physiology, molecular biology, and many disease processes. In many experimental settings, the ability to extract and grow cells from host tissues is a powerful tool since experimental question(s) can be evaluated under standardized conditions without unwanted influences from the host physiology.

As science has progressed, new in vitro techniques have developed beyond the culture of cells in glass or plastic dishes. Cell–substrate interactions are of particular interest since cells interact physically with the extracellular matrix (ECM) and often modify it in response to various stimuli. As a result, efforts to examine and recapitulate the in vivo environment in vitro often require modification of the cell culture substrates. Cell–substrate interactions at the micro- and nano-scales have been facilitated by new techniques, applications, and approaches that have emerged from the combination of engineering and biology. In practice, the chemistry, topography, and elasticity of the culture surface may be altered, or mechanical forces can be applied to cells by physical deformation of the culture substrate.

With respect to tissue engineering and organ regeneration, advances in our understanding of cell–substrate interactions are essential to controlling cell behavior. For example, the ability to pattern cells with micron-scale precision on a variety of substrates presents new opportunities to study and recreate cell–cell interactions required to generate functional tissues in vitro for subsequent implantation in vivo. This is of primary importance since organs contain multiple cell types that are precisely arranged in close proximity to form complex tissue structures.

This chapter provides a basic understanding of in vitro principles beginning with a fundamental overview of the culture of cells and their interaction with surfaces. We then describe a number of techniques employed to manipulate the in vitro environment at the micro- and nano-scales and then discuss how these fundamental techniques can be applied to investigate and influence cell behavior.

A Basic Overview of Cell Culture

Tissue culture is a general term for the harvest of cells, tissues, or organs and their subsequent growth or maintenance in an artificial environment. Mammalian cells cultured in vitro have the same basic requirements as cells growing within an organism. Specialized approaches have been developed to replace a number of mammalian systems essential for life. In vitro, blood is replaced by the culture media, which bathes the cells and provides an energy source (glucose), essential nutrients (salts and amino acids), proteins and hormones (from added serum), and a buffer (to maintain pH balance). During culture, the byproducts of cellular metabolism are released into the media as its constituents are depleted. Since the culture media is not continually circulated and purified, it must be changed regularly to maintain optimal conditions for cell survival and function. Not surprisingly, these culture conditions are also favorable for the growth of unwanted organisms such as fungi and bacteria. Since there is no immune system to control infection in vitro, antifungal agents and antibacterial agents can be added to the culture media on a prophylactic basis. To further reduce the likelihood of contamination by microorganisms, cells are manipulated under a laminar flow hood using strict aseptic technique. Laminar hoods control and direct filtered air to facilitate a sterile working environment by reducing the contact of airborne bacteria and particulates with the culture dish and hood surfaces.

TABLE 2.1.3.1 Examples of Some Commonly Used Cell Lines

Cell Line	Organism	Tissue of Origin	Note
3T3	Mouse	Embryonic fibroblast	Fibroblast
AML-12	Mouse	Liver	Liver
HeLa	Human	Cervical cancer	Epithelium (1st cell line reported)
HUVEC	Human	Umbilical cord vein	Endothelium (stem cells)
MC3T3-E1	Mouse	Calvarial fibroblast	Differentiate to osteoblast

Cells in media are contained in culture dishes or flasks and incubated in a warm (37°C) and humidified chamber (95%). While the lids of the culture dishes cover and protect the media, they are not sealed and enable gas exchange within the incubator. The exchange of gas at the media surface acts like the lungs to maintain gas balance necessary for metabolism. CO_2 is usually added to the incubator at a low concentration (5%). The CO_2 interacts with the bicarbonate buffer in the culture media to help maintain a pH of 7.0–7.4. Buffering counteracts pH changes in the media as it accumulates waste from cellular activity. Phenol red is commonly added as an indicator to monitor pH, and a change in the color of the media is often a sign of poor culture conditions. Since the culture dishes are not sealed, they are prone to evaporation. To reduce evaporation, and prevent a subsequent change in media concentration, a water dish (with an antifungal/antibacterial agent) is usually placed in the bottom of the incubator to maintain a high level of ambient humidity.

Primary Culture

Cells for in vitro studies may be obtained from tissues (primary culture) or from cell lines. Cells for primary culture are obtained from living tissues. Cells can be obtained by passing media through the marrow cavities of the long bones, by collecting cells that grow out from a piece of tissue (*explant culture*) or by enzymatic digestion of tissue that contain cells. Enzymatic digestion of small pieces of tissue immersed in collagenase at 37°C breaks down the surrounding ECM and releases entrapped cells (*enzymatic dissociation*). After harvest, cells may be cultured in suspension or on culture substrates. Anchorage-dependent cells are plated for a few days to remove dead or unwanted (nonadherent) cell types. Cells anchored to the surface of the culture plate are "released" by adding a mixture of trypsin, a protease found in the digestive system and ethylenediaminetetraacetic acid (EDTA). Trypsin degrades proteins, including important cell adhesion proteins (CAPs) that anchor cells to the culture surface. In short applications, trypsin is generally not harmful to cells. EDTA is a chelating agent that binds calcium and magnesium ions. EDTA increases the effectiveness of trypsin and prevents cell aggregation after release from the culture dish.

Harvested cells are often filtered to produce a suspension of single cells. The single cell suspension is counted, and portions of the initial cell population are transferred to new culture dishes for their expansion. Expansion is also referred to as *subculturing* or *passaging* the cells. Passaging cells ensures that cells are plated at a low density, so they have room to proliferate. Under appropriate conditions, most cells proliferate and form a mono-layer on the culture surface. The point at which cells completely cover the culture surface is referred to as *confluence.* At confluence, proliferation will generally cease because cell density or cell–cell contact results in *contact inhibition*. Unlike cell lines, primary cells are often cultured with little to no passaging since serial passaging can result in loss of cell characteristics (phenotype).

Cell Lines

Generating primary cultures by continually harvesting and isolating cells is a time-consuming task. Hence, it is often preferable to utilize cells that are obtained from stock maintained in the lab. Cell lines refer to cells that can be passaged many times without loss of their phenotype. Physiologically, these cells can divide repeatedly, without shortening of their telomeres (Hayflick, 1965). Cell lines differ from other cells in that they have escaped the Hayflick limit and are *immortalized* (Hayflick, 1985). Examples of a handful of commonly used cell lines, from a large number of existing cell lines, are presented in Table 2.1.3.1.

Cell lines also offer an experimental advantage. Primary cells may contain unwanted cell types and heterogeneous populations that are unintentionally collected during harvest. These variations have the potential to significantly impact experimental uniformity and reproducibility. Primary cultures may also contain slight genetic variations due to genetic differences arising from the harvest of cells from different individuals. Since cell lines are derived from a singular cell, all subsequent cells are genetic clones of the parent cell[1]. As a result, experiments using cell lines can be reproduced by different labs using the same cells, which has obvious advantages for collaboration, verification, and reproducibility.

A large number of cell lines are derived from tumors or cells that have undergone spontaneous mutation or some form of manipulation. The HeLa cell line is an example that has been in use since the early 1950s and was derived from cervical cancer cells taken from Henrietta Lacks (Scherer et al., 1953). It is helpful to recognize

[1] If the cell line has not been contaminated or has not undergone spontaneous genetic change.

that while cell lines may behave similarly to normal cells, they have been obtained by repeated culture and selection (Browne and Al-Rubeai, 2007), treating or transforming normal cells (viral, oncogene, radiation, drugs, or chemicals) (Eiges et al., 2001; Groger et al., 2008; Prasad et al., 1994), from transgenic mice (Connelly et al., 1989; Wu et al., 1994) or isolated from tumors (Riches et al., 2001; Yasuda et al., 2009). For example, transformed cells may present different morphologies and altered metabolisms (Priori et al., 1975; Wittelsberger et al., 1981) and often do not exhibit robust contact inhibition (Bell, 1977; Erickson, 1978). These behaviors strongly suggested that cell lines have the inherent potential to demonstrate responses that may not be typical of primary cells (Heckman, 2009; Steele et al., 1991). Therefore, when establishing new experimental protocols using cell lines it is recommended that the results of the protocol be validated with primary cells.

Cell lines can be obtained from nonprofit organizations such as the American Type Culture Collection (ATCC), the European Collection of Cell Cultures (ECACC), and the Coriell Institute for Medical Research (CIMR). The ATCC (www.atcc.org), ECACC (www.hpacultures.org.uk), and CIMR (www.coriell.org) provide high-quality cell lines because of their careful testing and validation. The testing process ensures that cells provided are free of unwanted organisms such as mycoplasma and other unwanted cell types. Cell lines obtained from tissue banks are usually meticulously characterized and preserved to maintain these materials in a manner that permits reproducibility of results across time and among laboratories around the world. In some cases, cell lines can be obtained from other research laboratories; however, caution should be exercised since the possibility exists that the cell lines may be contaminated with microorganisms or unwanted cell types.

Characteristics of Cultured Cells

Cultured cells often display characteristic behaviors and growth patterns. A well-known characteristic is *contact inhibition*. In 1954, Abercrombie and Heaysman proposed that cells form monolayers because they do not move over or under their neighbors (Abercrombie and Heaysman, 1954). Cells exhibiting contact inhibition will preferably migrate to unoccupied areas of the culture substrate and will not use the upper surface of a confluent cell monolayer as substrate. Contact inhibition is closely related to the cessation of cell proliferation (Timpe et al., 1978) and is one reason why most cells cultured in vitro produce monolayers of cells (Garrod and Steinberg, 1973). When cultured cells are in complete contact with each other, plasma membrane ruffling and cell motility are inhibited, resulting in an overall cessation of cell growth (Heckman, 2009). For this reason, cells maintained in culture are frequently replated at lower densities so that growth and proliferation may continually occur.

SIDE BAR: DETECTING CANCEROUS CELLS IN VITRO

The phenomenon of contact inhibition has diagnostic implications for assessing malignancy. A predominant behavior of malignant cells is the loss of contact inhibition and uncontrolled cell growth. The natural phenomenon of contact inhibition has been used as a test to distinguish cancerous from noncancerous cells (Dehner, 1998). Interestingly, unlike normal cells, malignant cells will also proliferate in agar (a three-dimensional [3D] matrix), where no suitable binding sites for cell attachment exist.

Cultured cells also often display characteristic shapes that can be used as visual cues to assess the health and differentiation of a cell culture population. For example, preosteoblastic cells are fibroblastic in shape, possessing a long "drawn-out" morphology. Upon subsequent differentiation into mature osteoblasts, cells display a cuboidal appearance. Dead or nonadherent cells often appear spherical in shape and float in the culture media.

Understanding Cell–Substrate Interactions

In vivo, cell–surface interactions are often explored as a means to enhance or control periimplant tissue formation. Surface chemistry, topography, and elastic modulus (stiffness) of the substrate are all means that can be used to control and guide cell activity and ultimately modulate tissue formation. This triad of substrate properties is important for tissue engineering and organ regeneration, where multiple cell types must be directed to form complex tissue-like structures all in close proximity and often with micron-scale precision. In terms of 3D scaffolds, tuning of scaffold chemistry, topography, and stiffness are all means to selectively guide cell development and differentiation within the bulk material.

Since most cells interact with a substrate (or can be found within the ECM) it is often desirable to control the interaction of cells with substrates in vitro. Modulation of the culture surface by the fabrication of "engineered surfaces" comprised of micro- and nano-sized chemical and topographical patterns or coatings has been used to investigate cell behavior such as adhesion, morphology, migration, proliferation, cell–cell communication, gene expression, differentiation, production of ECM, and responsiveness to extracellular signaling.

Surfaces for Cell Culture

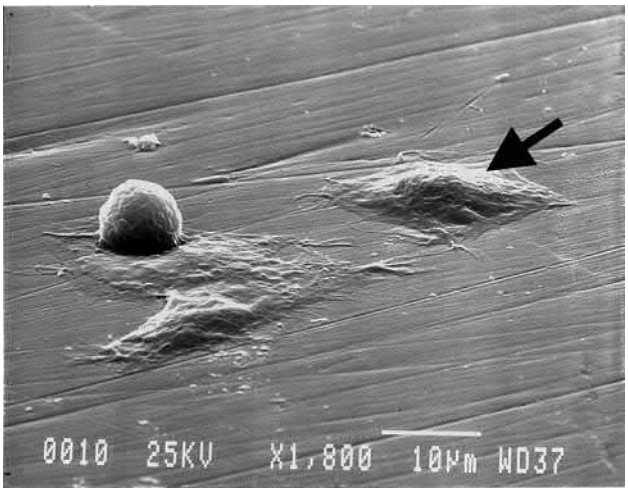
It has long been established that most mammalian cells respond favorably to culture conditions that promote cell attachment. Cell attachment is often characterized by a change in cell morphology. Adherent cells possess a "flattened" appearance, often with an irregular cell shape and the extension of cellular processes (Fig. 2.1.3.1). Regular observation of cells in vitro is essential for successful culture as cell density, state, and contamination can all be readily assessed visually. In this regard, the use of optically clear

materials is practical as it permits simple assessment of cell growth and morphology during culture and it is well suited to many histological techniques that involve staining for quantification of cell activity. Glass, once a common form of cultureware, has been replaced by tissue culture polystyrene (TCP). While TCP is most widely used as a culture substrate, other polymers, such as polyvinylchloride, polycarbonate, and polytetrafluoroethylene, have also been used. The advantages of TCP are that it is inexpensive, clear, easily formed and treated to modify surface groups, and, unlike glass, it can be embedded and sectioned.

Process of Cell Attachment in Vitro

Cell attachment is the initial step in a cascade of cell–biomaterial interactions and it is important to cellular processes such as cell guidance, proliferation, and differentiation. For many adherent cells, cell proliferation can only occur on a substrate. As a result, cell–surface interactions are fundamental to understanding cell behavior and provide an important means to control and quantify cell activity.

The process of cell attachment is largely understood (Garcia, 2005). In vitro, when hydrophilic surfaces, such as TCP, are exposed to culture media containing serum, they are rapidly coated by a thin (~20 nm) layer comprised mainly of proteins (Andrade and Hlady, 1987; Kasemo and Lausmaa, 1994; Nakamura et al., 2007) that adsorb to the culture surface as a monolayer. The process of cell attachment to TCP (and many other materials) is indirect since cells do not bind directly to TCP, but instead bind to the adsorbed proteins (Fredriksson et al., 1998). Cells make contact with and anchor to the adsorbed proteins at discrete regions referred to as focal contacts (Gallant and Garcia, 2007). Cells possess heterodimeric transmembrane proteins composed of α and β subunits called *integrins*. Integrins are receptors that recognize and bind to specific anchoring proteins present on the conditioned TCP surface (Peter and Ma, 2006). The adsorbed proteins present short but specific sequences (Table 2.1.3.2) that are recognized by integrins as binding sites. Integrins recognize and bind to specific ligands such as fibronectin, vitronectin, collagen, and laminin. Over 18 α and 8 β receptor subunit types have been identified and these subunits combine to produce a wide variety of receptor types (Hynes, 2002). Of these combinations, the $\alpha_v\beta_3$ integrin is one of the most abundant. It binds to vitronectin, fibronectin, von Willebrand factor, osteopontin, tenascin, bone sialoprotein, and thrombospondin (Hynes, 2002). For the majority of cells cultured in vitro, fibronectin and vitronectin are important for cell attachment to TCP (Massia and Hubbell, 1991b; Steele et al., 1993).



• **Figure 2.1.3.1** Scanning electron microscopy image of MC3T3-E1 cells at various stages of adherence on polished titanium substrate demonstrating changes in cell morphology during attachment. Attached cells have a flattened morphology and form intimate contact with the substrate. Detached cells are round. SEM × 1800.

TABLE 2.1.3.2 Specific Peptide Sequences on Cell Anchoring Proteins

Peptide Sequence	Derived From ECM Protein	Conjugate Receptor	References
RGD	Fibronectin, laminin α-chain, collagen, vitronectin	Multiple integrins	(Massia and Hubbell, 1990a, 1991b; Erkki Ruoslahti, 1996; Ruoslahti and Pierschbacher, 1987)
YIGSR	Laminin β1-chain	β_1 integrins	(Boateng et al., 2005; Weber and Anseth, 2008; Weber et al., 2007)
IKVAV	Laminin α-chain	LBP110	(Tashiro et al., 1989; Weber and Anseth, 2008; Weber et al., 2007)
REDV	Fibronectin	$\alpha_4\beta_1$ integrin	(Hubbell et al., 1991)
DGEA	Collagen type I	$\alpha_2\beta_1$ integrin	(Staatz et al., 1991; Weber and Anseth, 2008; Weber et al., 2007)
KQAGDV	Fibronectin γ-chain	β_3 integrins	(Gobin and West, 2003; Mann and West, 2002)
VAPG	Elastin	Elastase receptor, $\alpha_5\beta_3$ integrin	(Gobin and West, 2003; Mann and West, 2002)

While integrins mediate the physical interactions of binding, they also act as receptors that regulate cellular functions. Integrins play an important role in controlling various steps in the signaling pathways that regulate processes such as cytoskeletal organization, cell proliferation, differentiation, apoptosis, and migration. In most cell types certain biochemical signals necessary for cell survival, function, and growth are triggered by integrins upon attachment. Without attachment, the cell eventually undergoes *apoptosis,* i.e., programmed cell death (Ruoslahti and Reed, 1994).

Commercial and Experimental Modifications of Culture Surfaces

Polystyrene is a hydrophobic material that is not well suited to the attachment of most mammalian cells (Curtis et al., 1983). For the culture of nonadherent cells, untreated TCP is routinely used. As previously described, most cells require modified surfaces that are suitable for protein adsorption before cell attachment can occur.

A variety of treatment methods have been employed to improve cell attachment and growth on TCP surfaces (Table 2.1.3.3). TCP treatment methods used to enhance cell adhesion are often proprietary and vendor specific, but some of them, such as chemical treatment in sulfuric acid (Curtis et al., 1983), chemisorption (Bain and Hoffman, 2003a; Shen and Horbett, 2001), ionizing radiation (Callen et al., 1993), or exposure to plasma-based ionizing processes (such as glow discharge) (Amstein and Hartman, 1975; Koller et al., 1998), have been described in the literature. It is generally understood that these treatments impart a charge to the TCP surface that enhances its ability to interact with and bind specific CAPs present in the serum added to the culture media (Jacobson and Ryan, 1982; Lee et al., 1997).

It is important to recognize that the preparation of culture surfaces can have profound effects on the behavior of cultured cells (Bain and Hoffman, 2003b; Shen and Horbett, 2001). For some cell types, commercially available surfaces may be far from optimal and identification of optimized substrates can be a laborious task, especially for cells that are difficult to culture in vitro. One approach has been the generation of culture surfaces comprised of mixtures of protein-adhesive and "protein-repellant" molecules or groups. Bain et al. used a combination of protein-adhesive diamine groups (N2) and repellant trifluoropropyl groups (F3) to generate a large number of culture surfaces by varying the ratio of monomers in a silanization bath (Bain and Hoffman, 2003a). The different surfaces produced possessed varying affinities for proteins and, as a result, cells. A surprising finding of the work was that the growth and activity of insulin-secreting cells was best supported by the most hydrophobic (F3) surfaces in the study (Bain and Hoffman, 2003b).

More direct approaches to tune substrate chemistry can be achieved by anchoring specific adhesion molecules to the culture substrate. In such investigations, it is often advantageous to retain only the molecule(s) of interest while reducing or excluding nonspecific protein adhesion that might occur with cells grown in normal serum-enriched media (Koepsel and Murphy, 2009). Self-assembled monolayers (SAMs) are versatile and valuable tools that have been used to study protein adhesion (Li et al., 2007; Prime and Whitesides, 1991). SAMs are comprised of long alkanethiols anchored at one end to a gold-coated substrate and at the other to small functional groups such as cell adhesion peptides or "repellant" oligo (ethylene oxide) sequences. These terminal functional groups can also be used to tether specific proteins, such as monoclonal antibodies, or can interact with proteins in the media. SAMs can be tailored to achieve a certain degree of adsorption by controlling the composition of the monolayer (mixture of functional groups).

The control of ligand density and type provides another means of modifying substrate chemistry and cell behavior. Gradients of immobilized ECM components and growth factors have also been shown to direct cell migration and shape (Byambaa et al., 2017; Inoue et al., 2009). Such experimental

aspects can also be explored efficiently with microfluidic systems where the facile and reproducible generation of gradients utilizing small reagent volumes has been applied to the study of cell behavior in vitro (Du et al., 2009).

Dynamic Control of Cell Culture Surfaces

Controllable surfaces for cell culture have been generated to enable a predictable change in the adhesive or morphological characteristics of the surface. Changes in surface characteristics may be achieved by mechanical or physicochemical methods, and the latter are the focus of this section. A wide variety of dynamic surfaces have been fabricated from SAMs with specific functional groups that are responsive to thermal, chemical, electrical, or electromagnetic (UV or visible light) stimuli. Dynamic culture surfaces can be used as a means to control cell adhesion. More sophisticated applications have been used to selectively pattern surfaces to generate a culture environment with multiple cell types specifically arranged in groups in close proximity to each other.

Dynamic culture surfaces have also been used to detach cells from substrates. Cell sheets have been spontaneously detached by cooling a thermally sensitive, radiation- or plasma-polymerized poly(N-isopropylacrylamide) (poly[NIPAAm]) polymer (Cheng et al., 2004). Okano's group in Japan has pioneered in this method, using electron beam radiation grafting of NIPAAm monomer on the surfaces of cell culture dishes. At temperatures suitable for cell culture (above 32°C) poly[NIPAAm] surfaces are hydrophobic and readily adsorb CAPs, leading to the growth of a cell monolayer to confluence. However, when the temperature is reduced below a critical temperature (32°C) poly[NIPAAm] surfaces become hydrophilic, and the cell sheet detaches as a contiguous, confluent monolayer, carrying with it the CAP monolayer. Such dynamic thermal control of cell adhesion can be particularly useful for the safe removal of intact cell sheets by avoiding the use of proteolytic enzymes (trypsin) that can disrupt natural cell–cell networks and compromise cellular integrity. Cell sheets have a variety of applications in tissue engineering (Elloumi-Hannachi et al., 2010) but are perhaps most recognized clinically by the Okano group work to provide layers of corneal cells for repairing damaged or diseased cornea of the eye.

Methods that convert surfaces from cell-adhesive to nonadhesive have also been reported using photo-responsive SAMs. These approaches generally modify the presentation of CAPs making them less accessible to the cell. Upon exposure to UV light, surfaces based on a combination of azobenzene groups and RGD ligands will "hide" the RGD groups by UV-induced conversion of the azobenzene functional group from polar to nonpolar character (Auernheimer et al., 2005). Exposure to UV light reduces the exposed length of the azobenzene-RGD segments, and thus, reduces cell adhesiveness. Nitrospiropyran and methyl methacrylate polymer coatings have also been employed as photo-responsive surfaces (Higuchi et al., 2004). Nitrospiropyran is a photo-responsive polymer that switches from a cell adhesive to a nonadhesive (hydrophilic) state upon exposure to UV light.

Investigating Cell–Substrate Interactions

The cellular microenvironment consists of a myriad of signals arising from surrounding cells, ECM, and soluble molecules. The ability to control and modulate cell behavior, through the cell microenvironment, is important for understanding cell behavior as well as controlling a wide range of cell–biomaterial interactions. In general, cell behavior can be modified by controlling substrate chemistry, topography, and elasticity, and investigations have traditionally focused on broad changes to the culture surface such as those obtained by the application of a coating. However, cell–cell and cell–ECM interactions occur over very small (micro- and nano-) length scales.

New insights into cell behavior and physiology have been gained by utilizing and extending a variety of techniques and materials that can be used to influence the cell environment at the microscale. The following sections examine some of the fundamental concepts learned from examining cell behavior in response to different substrate chemistry, topography, elasticity, and strain conditions, alone or in combination at macro, micro-, and nano-scales.

SIDE BAR: LIMITATIONS OF BIOMATERIAL EVALUATION IN VITRO

It is important to recognize that the in vitro evaluation of biomaterials is subject to specific constraints, namely arising from the reduced natural complexity of the in vitro environment. First and foremost, there is no immune or inflammatory response in vitro. Nor is there the same cascade of events that normally occur with implantation, namely the interaction with components of the blood, clot formation, angiogenesis, and recruitment of a variety of cells that participate in wound healing.

Cell Response to Substrate Chemistry

Surface chemistry is perhaps the most obvious, and, in some cases, the most accessible parameter to control when modifying in vitro conditions to assess their effects on cell behavior. At the macroscale, a variety of strategies can be employed to modify cell culture surface chemistry. Most coating strategies aim to increase cell adhesion or to preferentially select for the adhesion of certain cell types. Uniform coatings may be achieved by simple application of the material of interest by either spin coating the substrate or by immersion in a solution of interest. Substrates have been coated with a variety of organic and inorganic compounds, such as collagen (Kataropoulou et al., 2005), fibronectin (Klein-Soyer et al., 1989), gelatin (Aframian et al., 2000), and poly-L-lysine (Jensen and Koren, 1979). Culture surfaces have also been broadly coated with specific adhesion-related peptides. The peptide sequence arginine-glycine-aspartate (RGD) has been immobilized on a number of materials as a means to enhance cell attachment in 2D (Cutler and Garcia, 2003; Massia and

Hubbell, 1990a, b, 1991a; Petrie et al., 2008). Studies suggest that the minimal effective density of RGD is 1 pmol/mm^2 (Chollet et al., 2009) and that increasing RGD density (up to a limit) is generally beneficial to cell attachment (Massia and Hubbell, 1991b). Similarly, the spatial organization of various cell ligands has been achieved by controlling their density. This approach has been used to enhance the initial number of attached cells, to increase their proliferation or to preferentially select for specific cell types (Zemljic Jokhadar et al., 2007).

There are, however, instances where substrate coatings are of limited benefit and examples of such situations include cultures where the applied coating may rapidly degrade or detach from the culture substrate. A common strategy to enhance cell adhesion is to modify the substrate chemistry to encourage the adsorption and presentation of certain cell-adhesive proteins or ligands (Keselowsky et al., 2003). Ligands are present in the serum added to culture media. As previously discussed with TCP, a number of processes have been developed to enable modification of large culture surface areas to enhance protein adsorption.

Micrometer-Scale Chemical Patterns

Patterning at the microscale is associated with the control of cell shape, position, and density, and presents a powerful tool to examine and control the cell microenvironment. A common approach is to generate a pattern of CAPs on a two-dimensional (2D) surface and then deliver cells that adhere preferentially to the patterned, adhesive regions on the substrate. Usually, the nonadhesive regions are treated with polyethylene glycol (PEG), i.e., PEGylated. A multitude of patterns in various configurations have been attained using printing methods as well as methods including dynamic surfaces as previously discussed.

Cells and proteins have been previously patterned on various substrates using SAMs (Mrksich and Whitesides, 1996), metal templates (O'Neill et al., 1990), stamped proteins, peptides (Hyun et al., 2001) and biopolymers (Bhatia et al., 1997), microfluidic channels (Takayama et al., 1999), membranes (Ostuni et al., 2000), polysaccharides (Khademhosseini et al., 2004), and cross-linked PEG (Khademhosseini et al., 2003). Noncontact methods can also be used to generate protein patterns and include films that are cross-linked by photolithography that can selectively promote or exclude cell adhesion (Chien et al., 2009). In this manner, nonspecific biological molecules can be used to create patterns of adhesive and/or nonadhesive regions. Short chains of PEG have been assembled on surfaces to form a brush-like layer that resists protein adsorption and as a consequence, cell attachment.

Protein patterning has also been used to produce regions of preferential adhesion for specific cell types, to alter cell shape, to cluster cells together, to restrict their proliferation, or to position different cell types in close proximity. Components of the ECM, that participate in cell adhesion in vivo, are general candidates for studies involving chemical patterning in vitro. Fibronectin, laminin, vitronectin, and collagen are examples of ECM molecules commonly used for patterning cell-adhesive regions.

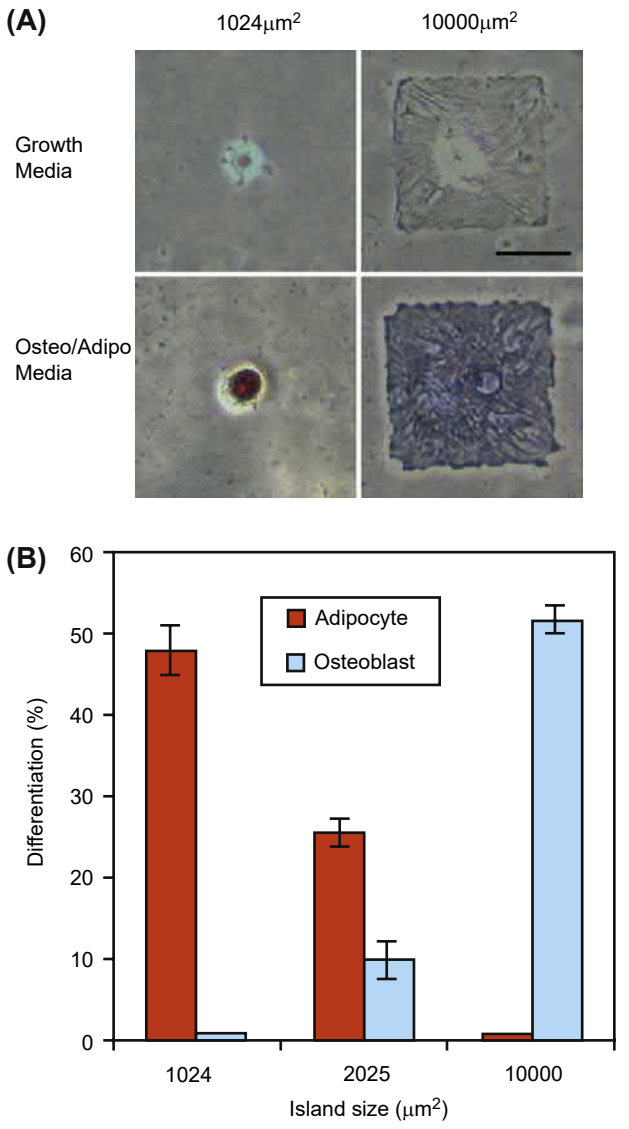
Direct transfer of proteins or cells from a stamp to the substrate can also be used to generate micro- and nanoscale patterns. Microstamping or microcontact printing (μCP) is a technique in which polydimethylsiloxane (PDMS) molds are used to pattern substrates by the selective transfer of materials of interest (Mrksich and Whitesides, 1996). In one approach, the relief patterns on a PDMS stamp can be used to form patterns of SAMs on the surface of a substrate through conformal contact. Alkanethiols are used to pattern gold-coated surfaces by forming densely packed SAMs. The sulfur end-groups strongly interact with the metal surfaces, and the rest of the molecule can then be used to control surface chemistry, wetting, and protein and cell adhesion. For example, alkanethiols can be PEGylated at the opposite end from the thiol (–SH) group to render gold-coated surfaces "nonfouling," or protein and cell resistant. To micropattern surfaces using alkanethiols, a variety of methods have been employed such as μCP. In this approach, PDMS molds are "inked" with the alkanethiol solution and transferred to the gold surface by conformal contact between the relief pattern and the substrate. Using μCP, micropatterns of SAMs terminated with PEG chains have been generated. These micropatterns have been used to immobilize proteins and cells on specific regions of a surface by selectively modifying surfaces with the nonfouling PEG patterns.

Using micropatterned fibronectin islands, Chen et al. reported that cell shape and the area available for cell adhesion governed whether individual cells grow or die, regardless of the type of matrix protein or antibody to integrin used to mediate adhesion (Chen et al., 1997; Dike et al., 1999) (Fig. 2.1.3.2). For bovine capillary cells, apoptosis significantly increased as fibronectin island size was reduced below 400 μm^2. Using micropatterned fibronectin, McBeath et al. demonstrated that cell shape regulated the differentiation of human mesenchymal stem cells (hMSCs) (McBeath et al., 2004). hMSCs that were permitted to adhere, spread, and flatten differentiated into osteoblasts, while those that were not permitted to attach formed spherical cells and resulted in adipocytes.

Nonfouling Surfaces in Cell Culture

As previously described, nonfouling surfaces may be created with PEGylated alkane thiols in SAMs. Other approaches include the generation and application of nonfouling coatings or films such as plasma-deposited triglyme and tetraglyme films of the Ratner group (Johnston et al., 2005), plasma-deposited tetraglyme, and fluorocarbon-based films (Cao et al., 2007; Goessl et al., 2001).

PEG has been used in many chemical variations to generate nonfouling surfaces. Polymerization of PEG monomers to form brush-like nonfouling coatings has been investigated. Beginning with surface-initiated atom transfer radical polymerization, Lavanant et al., grew robust brush-like polymers of



• **Figure 2.1.3.2** Cell shape modulates hMSC differentiation. (A) Brightfield images of hMSCs plated onto small (1024 μm²) or large (10,000 μm²) fibronectin spots after 1 week. Fibronectin spots were patterned on a mixed SAM substrate by microcontact printing. Large fibronectin spots supported osteogenesis (blue), while small fibronectin spots supported adipogenesis (red). Scale bar 50 μm. (B) Differentiation of hMSCs on 1024, 2025, or 10,000 μm² islands after 1 week of culture. Small fibronectin spots resulted in adipogenesis, medium fibronectin spots supported both adipogenesis and osteogenesis, and large fibronectin spots resulted in osteogenesis. (Reprinted from McBeath, R., Pirone, D. M., Nelson, C. M., Bhadriraju, K., & Chen, C. S. (2004). Cell shape, cytoskeletal tension, and RhoA regulate stem cell lineage commitment. Dev. Cell, 6(4), 483-495., with permission from Elsevier.)

PEG methacrylate (PEGMA) on low-density poly ethylene by photobromination followed by polymerization (Lavanant et al., 2010). Functionalization of the peptide brushes with the RGD-containing peptide ligand, GGGRGDS, increased cell adhesion compared to the polymerized PEGMA surface.

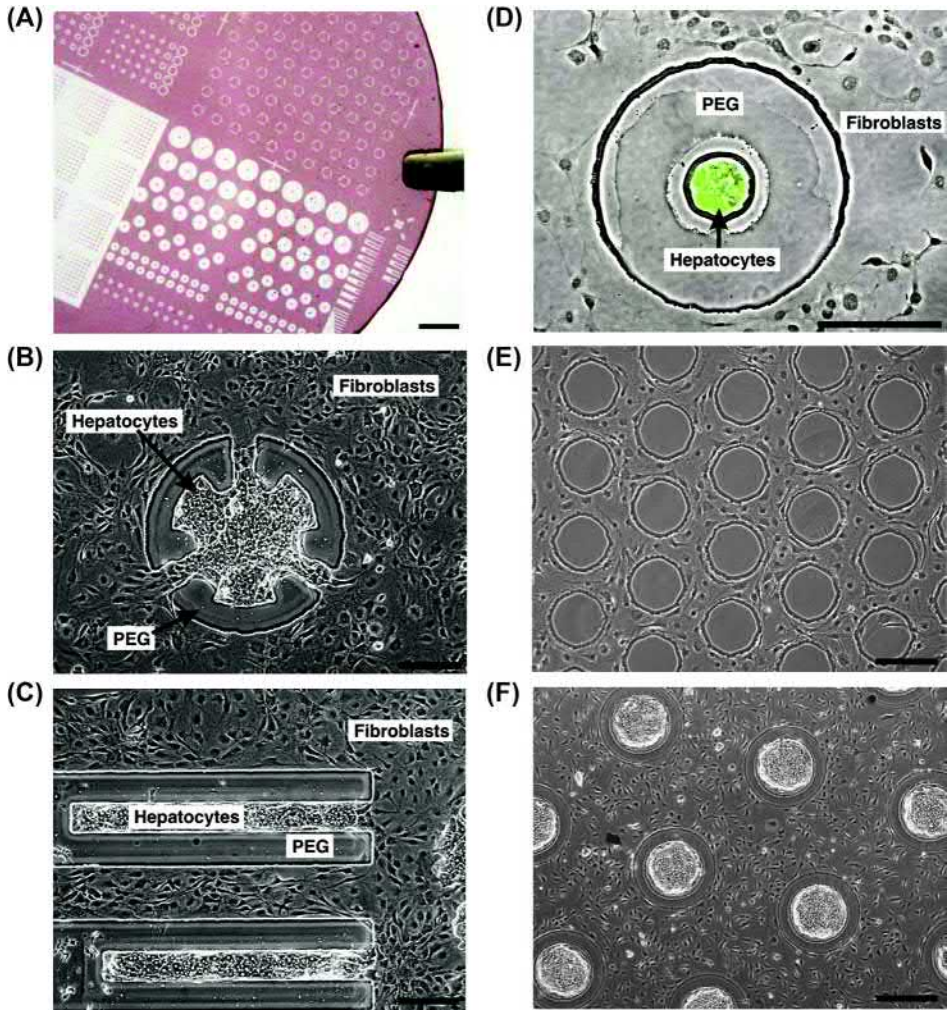
Changes in the structure of the component molecules of SAMs can also reduce cell adhesion. For example, SAMs comprised of oligo(ethylene glycol) (OEG) with variable ethylene glycol side chain lengths of 4, 9 and 23 were grafted onto titanium to create a nonfouling surface. After 4 h of exposure to 3T3 fibroblasts, there was no cell adhesion to any of the SAMs. At 35 days after seeding, it was observed that longer side chains resulted in reduced adhesion. This was further supported as complete cell coverage of the Ti surface was observed at 7, 10 and 11 weeks for samples with side chain lengths of 4, 9 and 23, respectively (Fan et al., 2006).

For many patterning applications, the ability to isolate or sequester cell-adhesive regions by surrounding them with surfaces that resist cell attachment is of great interest. The practical applications include the fabrication of arrays of cells for high-throughput testing as well as patterned cocultures for investigating complex interactions between different groups of homogeneous cell populations. Microarrays of captured molecules surrounded by nonfouling backgrounds are one approach that has been used to identify and screen combinations of CAPs to develop bioactive surfaces. Monchaux et al. grafted RGD and RGE (a nonadhesive control), as well as other known endothelial ligands (REDV and SVVYGLR), on a low-fouling carboxy-methyl-dextran background (Monchaux and Vermette, 2007). They concluded that RGD was necessary for cell adhesion and that endothelial cells could discriminate against and would not adhere to arg-gly-glu (RGE) sequence. Coimmobilization of the RGD peptide with vascular endothelial growth factor (VEGF) or an osteopontin-derived peptide SVVYGLR significantly enhanced endothelial cell adhesion while coimmobilization of RGD with either REDV or SVVYGLR induced a reduction in endothelial cell spreading.

The development of nonfouling surfaces from biodegradable or biologically relevant compounds is of great interest. Biodegradable ultra-low fouling peptide surfaces have been generated from natural amino acids that offer new and innovative means to control cell adhesion (Chen et al., 2009). Amino acids (H2N–CH-R-COOH) are molecules that possess an amine group (H2N), a carboxylic acid group (COOH), and an organic side chain (R) of varying length and composition. Amino acids are the building blocks of proteins and are the ubiquitous components of many organisms. Amino acids are *zwitterionic* at physiologic pH, meaning that they have both positive and negative charges on different atoms but possess no overall net charge. Ultra-low fouling surfaces based on zwitterionic molecules have been developed that can "catch and release" molecules of interest (Mi et al., 2010), potentially enabling a new generation of in vitro surfaces for diagnostic and assay-based testing.

Chemical Patterning for the Coculture of Cells

Cell–cell interactions are important for tissue development and function. During embryogenesis, the temporal and spatial signaling between cells of different origins is part of the cascade of events that support natural tissue growth and development (Yu et al., 2008). However, the process of harvesting tissues and isolating cells as well as the purification of specific cell types disrupts many of the cell–cell interactions found in in vivo cell–cell contact, signaling, structure, and general heterogeneity.



• **Figure 2.1.3.3** Examples of patterned cocultures. (A) Glass coverslip with patterned photoresist. Scale bar is 2 mm. Control of cell organization via patterned surface chemistry. (E) 3T3-J2 fibroblasts excluded from islands of PEG-disilane (day 5). (F) Hepatocytes and 3T3-J2 fibroblasts patterned on a combination of collagen and PEG-disilane, (day 2). (E,F) Scale bars 500 μm. (Reprinted in part with permission from Hui, E. E., & Bhatia, S. N. (2007). Microscale control of cell contact and spacing via three-component surface patterning. Langmuir, 23(8), 4103–4107. https://doi.org/10.1021/la0630559. Copyright 2007 American Chemical Society.)

The coculture of different cell types is one approach to enhance the in vitro environment and maintain cell phenotype in vitro (Nandkumar et al., 2002). Cocultures can be established by simply mixing two or more cell populations prior to plating, however this provides little control over cell–cell contact, spacing, or interaction. Greater control can be obtained through the use of patterned cocultures, which primarily allow to control homotypic and heterotypic cell–cell contact. Using patterning techniques, cocultures can be established where cell–cell contact, spacing, and interaction can be controlled with high resolution. Both cells and cell-adhesive proteins may be patterned using selective adhesion to micropatterned substrates (Folch and Toner, 2000; Hui and Bhatia, 2007), by flow through a microfluidic channels (Chiu et al., 2000; Takayama et al., 2001), by stamping with a stencil-based approach (Chen et al., 1998; Folch and Toner, 2000) or by seeding on surfaces that dynamically switch from cell-adhesive to cell-repulsive (Edahiro et al., 2005; Kikuchi et al., 2009). A common requirement of most coculture (and patterning) applications is the ability to selectively control and limit cell adhesion to specific areas of the substrate. As a result, nonfouling surfaces can be of considerable benefit.

A practical application of coculturing is the study of liver cells (hepatocytes). Hepatocytes rapidly lose their ability to generate a characteristic protein (albumin) when they are cultured in vitro. Using mask-to-mask registration and photolithography, Hui and Bhatia (Hui and Bhatia, 2007) generated surfaces with three distinct chemistries for the cocultures of hepatocytes and 3T3-J2 fibroblasts. Hepatocytes preferentially adhered to collagen-coated regions and fibroblasts to serum-coated glass regions (Fig. 2.1.3.3).

A nonfouling PEG region was included that separated the two cell types and controlled the amount of contact or interaction between cocultured populations for up to 7 days (Fig. 2.1.3.3). At 8 days, hepatocytes retained the ability to produce albumin.

High-Throughput Screening

Microarrays represent a specific type of chemical patterning. The arrays consist of a large number of small spots, each with defined location and unique chemical composition. This approach is suitable for testing biomaterials and microenvironments to enable the screening of a large number of chemical combinations in a high-throughput manner. A high-throughput microarray that probes the cell–cell, cell–ECM, and cell–biomaterial interactions can be useful for studying cell adhesion, proliferation, and differentiation (Khademhosseini, 2005; Khademhosseini et al., 2006).

Typically, cell–ECM interactions are studied using purified matrix proteins adsorbed to cell culture substrates. This approach requires large amounts of protein per 96- or 384-well plate and can be prohibitively expensive. To address these challenges, new methods have been developed using pin tools (Cleveland and Koutz, 2005), piezo tips (Niles and Coassin, 2005), ultrasound (Strobl et al., 2004), and microarray (Flaim et al., 2005) technology for nanoliter liquid handling. Recently, robotic spotters capable of dispensing and immobilizing nanoliters of materials have been used to fabricate microarrays, where cell–matrix interactions can be tested and optimized in a high-throughput manner. For example, synthetic biomaterial arrays have been fabricated to test the interaction of stem cells with various extracellular signals (Anderson et al., 2004). Using this approach, thousands of polymeric materials were synthesized and their effect on differentiation of human embryonic stem cells (ESCs) (Anderson et al., 2004) and hMSCs (Anderson et al., 2005) were evaluated. These interactions have led to unexpected and novel cell–material interactions. Although the molecular mechanisms associated with the biological responses have yet to be clarified, such technology may be widely applicable in cell-microenvironment studies and in the identification of cues that may induce desired cell responses. Also, the materials which yield desired responses could be used as templates for tissue engineering scaffolds. Such an approach is a radical change from traditional methods of developing new biomaterials, where polymers have been individually developed and tested for their effect on cells. In addition to the screening of libraries of synthetic materials, the effect of natural ECM molecules on cell fate can similarly be evaluated using a high-throughput method. In one example, combinatorial matrices of various natural ECM proteins were tested for their ability to maintain the function of differentiated hepatocytes and to induce hepatic differentiation from murine ESCs (Flaim et al., 2005). A peptide and small-molecule microarray made by a DNA microarray spotter were also used to study high-throughput cell adhesion (Falsey et al., 2001). A microarray of immobilized ligands was analyzed with three different biological assays such as protein-binding assay, functional phosphorylation assay, and cell adhesion assay. This array can be used to rapidly screen and analyze the functional properties of various ligands.

Nanometer-Scale Chemical Patterning

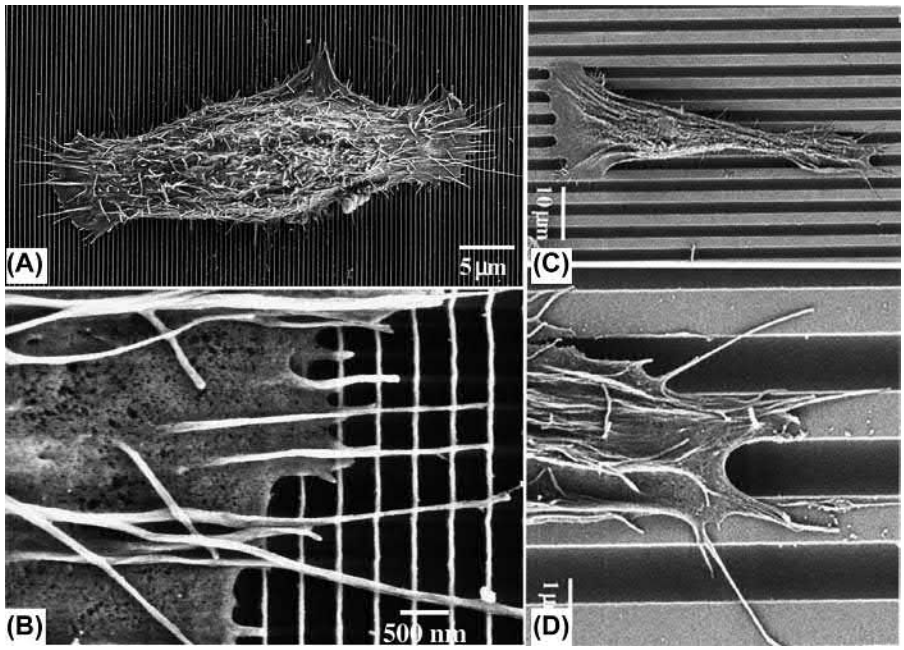
Nano-sized chemical patterns generally do not direct cell shape or orientation as a result of their extremely small size relative to the cell. Surfaces with chemical features on the nano-scale modulate cell functions such as adhesion, proliferation, migration, differentiation, and gene expression.

Cell Response to Substrate Topography

All cells are exposed to some type of physical environment in vivo. Cell–cell interactions, the ECM, and biomaterials all present a surface to the cell that is quantifiable in terms of its surface features (Liliensiek et al., 2009). As a field of study, surface topography defines the specific morphological characteristics of a surface. Surface topography may be generally described as isotropic (uniformity in all directions) or anisotropic (uniformity in one direction). Surface topography may be quantified by a number of techniques such as atomic force microscopy (AFM) or white light interferometery (WLI).

Unlike periodic surfaces typically fabricated for in vitro investigation (Clark et al., 1987), most biological surfaces present nonordered features at the macro- and micro-scales, which generally become more ordered at the nano-scale (Fratzl, 2008). Fibers in the ECM and pores in basement membranes are just a few examples of prevalent and quantifiable topographical features (Abrams et al., 2003; Liliensiek et al., 2009). Thus, it is not surprising that cells respond to topographical cues and that surface topography of the culture surface presents another means to control and study cell behavior in vitro. Micro- and nano-sized features are known to influence cell behavior, and both generally coexist in many biological surfaces. Accurate quantification of these surfaces is challenging since most tools are optimized for quantifying micro or nano features individually, but not both at the same time (Sosale et al., 2008).

In terms of cell activity, surface topography has been reported to affect proliferation, gene expression (Carinci et al., 2003), cell adhesion (Hamilton et al., 2006), motility (Clark et al., 1987), alignment (Clark et al., 1991), differentiation (Martinez et al., 2009), and matrix production (Hacking et al., 2008). In sensing and interacting with the topographical environment, evidence suggests that cells extend fine processes termed *filopodia*. While the specific mechanisms are poorly understood, changes in cell activity resulting from interaction with surface features have been linked to changes in cytoskeletal arrangement (Wojciak-Stothard et al., 1995) including actin filaments (Gerecht et al.,



• **Figure 2.1.3.4** Effect of micro- and nano-patterns on corneal epithelial cell alignment. (A) Cells were aligned perpendicularly to ridges that were 70 nm wide and 330 nm apart. (B) Expanded view of (A) showing filopodia also aligned perpendicularly to the patterns. (C) With increasing width and spacing (1900 nm ridge width, 2100 nm spacing), cells were aligned with the ridges and (D) filopodia were guided by the topographic pattern. (Reprinted from Teixeira, A.I., McKie, G.A., Foley, J.D., Bertics, P.J., Nealey, P.F., Murphy, C.J., 2006. The effect of environmental factors on the response of human corneal epithelial cells to nanoscale substrate topography. Biomaterials 27 (21), 3945–3954, Copyright (2006), with permission from Elsevier.)

2007), nuclear shape (Dalby et al., 2003), and ion channels (Tobasnick and Curtis, 2001). It is likely that these effects represent a small portion of the cellular events relating to interactions with surface topography and different mechanisms or combinations of mechanisms may be activated by different feature sizes and shapes (Ball et al., 2007).

Micrometer-Scale Topography

Investigations concerning the response of cells to precisely patterned, microfabricated surfaces began decades ago. Fibroblasts (Brunette, 1986a), osteoblasts (Hamilton and Brunette, 2007), macrophages (Wojciak-Stothard et al., 1996), neutrophils (Tan and Saltzman, 2002), epithelial cells (Brunette, 1986b), endothelial cells (Bettinger et al., 2006), cardiomyocytes (D. Kim et al., 2005), and neuronal cells (Clark et al., 1991) have all demonstrated a reproducible response to surface texture. Polarization or cell alignment along the direction of ridged surfaces is a phenomenon that is commonly observed when cells are cultured on linearly patterned substrates. Cell alignment to topographical features is referred to as contact guidance (Wood, 1988). With microscale-sized features, cell alignment generally increases with increasing groove depth and decreasing groove spacing (Bettinger et al., 2006), however cell response to topography is highly dependent upon cell type (Fig. 2.1.3.4). For example, epithelial cells and fibroblasts are differentially affected by surfaces with micron-sized grooves (Clark et al., 1987, 1990). Neutrophils (Clark et al., 1987) are largely unaffected by step topographies but large differences in responses exist between fibroblastic, epithelial, and neuronal cells (Clark et al., 1990, 1991).

Nanometer-Scale Topography

It has been demonstrated that cells can sense and respond to features as small as 10–30 nm (Dalby et al., 2002; Wojciak-Stothard et al., 1996). Compared to the micron-scale, where cells may be profoundly affected by a single feature, at the nano-scale a repetition of similar features has the greatest effect and provides the most predictable results regarding cell behavior (Ball et al., 2007; Curtis et al., 2004). Once again, cell response to topography is highly dependent upon cell type. Using surfaces of aligned ridges possessing a constant ridge spacing of 260 nm and depths varying from 100 to 400 nm, Clark demonstrated that neuronal cells were highly oriented in the ridge direction for all depths, epithelial-like cells were highly oriented for all depths, whereas the orientation of fibroblast-like cells increased with increasing depth from 50% orientation at 100 nm to nearly 95% orientation at 400 nm (Clark et al., 1991).

At the microscale, increasing the depth and decreasing the width of grooved or stepped surface features increases the probability of cell alignment with the topographical

feature(s). At the nanoscale, it appears that a finite limit in feature sizes exists with respect to cell alignment to surface topography. By culturing fibroblasts on linearly patterned surfaces fabricated by e-beam lithography, it was determined that groove depths below 35 nm or ridge widths smaller than 100 nm did not result in cell alignment and that 35 nm may be the threshold for whole-cell fibroblast alignment (Loesberg et al., 2007). Similarly, Teixeira et al. demonstrated a finite limit in the response of human corneal epithelial cells to surfaces with linearly patterned surfaces with groove spacing ranging from 400 to 4000 nm (groove width 330–2100 nm) (Teixeira et al., 2006). At groove spacings greater than 400 nm, cells were oriented in an increasingly parallel manner to the linear pattern (Fig. 2.1.3.4), however at groove spacings less than 400 nm, cells were perpendicularly arranged. These findings further demonstrate a cell-specific sensitivity with regard to cell alignment to surface topography as well as imply that a limit exists in feature sizes that cells are able to recognize.

The effects of nano-topography on cell differentiation have also been reported. Proteomic-based studies have shown that cells respond to nano-sized pits and pores in irregular patterns, leading to increased differentiation and matrix production by human osteoprogenitor cells (Kantawong et al., 2009). Likewise, studies with surfaces fabricated by the arrangement of titanium nanotubes have demonstrated that nano tube diameter affects both hMSC differentiation and adhesion (Oh et al., 2009). Smaller diameter nanotubes (30 nm) increased cell adhesion, while larger diameters (100 nm) increased cell differentiation. Other authors using different cell lines and culture conditions have reported optimal nanotube diameters and spacing as low as 15 nm (Park et al., 2007). Topography at the nano-scale can also be used to effectively reduce cell adhesion. Kunzler et al. generated a constant gradient of nanofeatures (65 nm diameter and height) with the spacing as the only changing parameter along the gradient (Kunzler et al., 2007). This study demonstrated that the spacing or density of nonadhesive nano-scale features can disrupt cell adhesion, likely by restricting receptor–ligand interaction.

High-Throughput Screening of Surface Topography

Analogous to microarrays used to test many chemical compounds at one time in a high-throughput manner, topographical arrays have been developed to assess the effects of systematic variances in surface topography. Lovmand et al. developed a topographical array consisting of 504 topographically distinct surface structures fabricated on silicon wafers that were coated with tantalum prior to cell seeding (Lovmand et al., 2009). Each structure consisted of a topographical pattern comprised of a series of circles, squares, or rectangles that varied systematically in height from 0.6 to 2.4 μm, and feature size and spacing from 1.1 to 6.6 μm. Murine osteoblast cells (MC3T3-E1) were cultured on the array for up to 28 days to assess proliferation, cell area, and mineralization. It was determined that the height of the features had the greatest effect on mineralization, followed by feature size, then the gap size. The combined effects of feature size and gap size became important as feature height decreased.

SIDE BAR: CLINICAL APPLICATIONS OF SURFACE MORPHOLOGY

Osteoblasts are substrate-dependent cells that have been widely used for investigating responses to surface topography. A considerable amount of work has been produced concerning the response of osteoblast cells to surface topography, and the end result of this work is widely applied clinically to enhance the long-term osseointegration of dental and orthopedic implants (Hacking et al., 1999, 2003). Mechanical fixation of an implant by the direct apposition of bone is referred to as osseointegration (Albrektsson et al., 1981; Branemark et al., 1977). Irregularly textured surfaces on titanium implants have been created by blasting the surface with small hard particles (Al_2O_3) that deform the relatively ductile titanium surface and produce a distinctly unordered micron-sized surface texture. It is common with dental implants that their surfaces are further processed by immersion in acid that superimposes a finer secondary nano-sized structure upon the textured surface and increases their osseointegration.

SIDE BAR: A NOTE ABOUT CELL LINES IN THE STUDY OF SURFACE TOPOGRAPHY

To enhance optical clarity, the TCP surface is very smooth (R_a~1.2 nm) (T. Y. Chang et al., 2007) and this has certain ramifications for the growth and development of cells in vitro. Adherent cell lines are selected preferentially for their ability to proliferate and differentiate on glass or tissue culture plastic. As a result, many cell lines have been selected based on their behavior on smooth, flat surfaces that are rarely found in vivo. Studies comparing the response of primary cells to cell lines derived from similar tissue sources have reported significant differences in cell activity (Fisher and Tickle, 1981; McCartney and Buck, 1981). This point becomes especially salient when working with surfaces where the effects of surface topography are the subject of primary interest (Clark et al., 1991; Hacking et al., 2008).

Cell Response to Substrate Elasticity

While surface chemistry and topography modulate cell function, it is increasingly evident that cells also respond to the physical or mechanical properties (stiffness) of the substrate. Stiffness can be described as the resistance of a solid material to deformation and is commonly defined by elastic modulus (E) and reported in "Pascals" (Pa). Excluding bone ($10–20 \times 10^9$ Pa), most tissues have elastic moduli in the range of 10^1–10^6 Pa, substantially lower than the elastic moduli of most culture surfaces such as TCP ($3–3.5 \times 10^9$ Pa).

Hydrogels are well suited to the study of cell substrate interactions since their stiffness can be varied by modifying the polymer concentration or the relative extent of cross-linking. Hydrogels can also be made from a variety of natural and synthetic materials such as hyaluronic acid (HA), fibrin, alginate, agarose, chitosan, polyacrylamide, and PEG. In

addition, natural materials can be modified to obtain hydrogels with new properties, e.g., gelatin methacryloyl (Yue et al., 2015). In terms of collagen hydrogels, gel stiffness may be increased by increasing the collagen concentration (Brigham et al., 2009) or reducing the thickness of the gel and immobilizing it on a glass substrate (Arora et al., 1999).

The stiffness of the substrate affects cell adhesion, spreading, and migration. In 2D cultures, cells preferentially migrate toward surfaces of greater stiffness, a phenomenon referred to as mechanotaxis (Lo et al., 2000). In 2D systems endothelial and fibroblast cells cultured on collagen-coated substrates that were classified as compliant ($\sim 5 \times 10^3$ Pa) or stiff ($\sim 70 \times 10^3$ Pa) demonstrated remarkably different behaviors (Opas, 1994). Cells cultured on compliant substrates had reduced spreading, increased lamellipodia activity, and greater migration. Cells cultured on stiffer substrates generally increased proliferation, however the specific preference is cell-type dependent (Pelham and Wang, 1997). There is substantial evidence that substrate stiffness also affects cell proliferation in 2D as well as 3D culture systems (Wong et al., 2003).

Substrate elasticity can also be used to direct the differentiation of certain cell types. MSC's cultured on collagen-coated substrates of varying stiffness can be directed toward neuronal, myogenic, and osteogenic lineages (Engler et al., 2006). For example, adult neural stem cells will selectively differentiate to neurons on softer substrates (1×10^2–5×10^2 Pa) or glial cell types on stiffer substrates (1×10^3–1×10^4 Pa) (Saha et al., 2008). These findings suggest that stem cells are able to recognize and differentiate according to physiologically relevant substrate stiffness. In general, stiff substrates favor myogenic differentiation, while rigid matrices favor osseous differentiation and soft ones favor neural cell differentiation (Engler et al., 2006).

Cell Response to Mechanical Deformation (Strain)

There has been considerable work assessing the response of cells to mechanical strain or deformation (Buckwalter and Cooper, 1987). Forces can be applied directly to adherent cells in vitro by either elongation or compression of their substrate (2D) or matrix (3D). With respect to cyclic tensile loads, in both 2D and 3D cultures, cells predominantly align in the direction of the applied load and assume an elongated morphology (Haghighipour et al., 2007; Henshaw et al., 2006; Toyoda et al., 1998).

Because of its load-bearing function and well-known adaptation to load, cells of the musculoskeletal system have been evaluated under conditions of tensile and compressive strain. For example, the extent of mineralization of bone and its mineral density is load dependent (Rodionova and Oganov, 2003). In vitro, cyclic strain in both tensile (Hanson et al., 2009) and compressive (Goldstein, 2002) loading enhances osteoblast mineralization. Thus, strain appears to be an important stimulus for the generation of mineralized and tendon-like tissues in vitro.

Toyoda et al. cultured cells harvested from the anterior cruciate ligament (ACL) and synovium (Toyoda et al., 1998). Cells were subjected to cyclic tensile load for 24 h via culture plates with flexible rubber bases. For both cell types, tensile load increased cell alignment and elongation, however tensile load only increased the production of collagen type I in cells derived from the ACL (Toyoda et al., 1998). These results have been supported by similar studies where fibroblasts subjected to cyclic tensile strain increased the formation of organized ECM, increased collagen production, and increased metabolic activity compared to unloaded controls (Hannafin et al., 2006; Joshi and Webb, 2008).

These findings have led to the fabrication of bioreactors that can apply physiologic loads to developing tissue to enhance the production and alignment of extracellular matrix in a number of tissues including cardiac (Kortsmit et al., 2009), bone (van Griensven et al., 2009), cartilage (Preiss-Bloom et al., 2009), and tendon (Riboh et al., 2008).

Comparison and Evaluation of Substrate Cues

As previously discussed, cells respond to a number of surface cues such as chemistry, topography, elasticity, and strain. Evaluating cell response to multiple cues is inherently difficult since substrate properties are often interrelated. In many in vitro investigations of biomaterials it may be difficult to effectively separate the effects of surface chemistry from those of morphology and elasticity. This is particularly problematic in cases where the unique properties of a material may arise from the manufacturing process (Bobyn et al., 1999; Hacking et al., 2002). In such investigations, it is important to recognize that subtle changes in biomaterial properties can have profound effects on cellular response and ultimately in vivo function. This is especially true, for example, of implant coatings where responses to surface morphology need to be dissociated from other factors such as surface chemistry. Experimental controls must not just approximate surface morphology, but match it precisely, since subtle changes in surface morphology have the potential to confound experimental findings. In many cases however, it may not be practical or even possible to produce an exact morphological control from a different biomaterial. A morphological control may be generated by coating the surface of interest with a thin film that is dense, durable, homogeneous, and does not alter the surface morphology. There are a variety of thin-film deposition techniques collectively referred to as physical vapor deposition (PVD) that have been employed by several research groups (Hacking et al., 2002, 2007; Meredith et al., 2007). While other coating methods exist, PVD is advantageous since samples can be processed at lower temperatures in a relatively inert environment.

Control of substrate elasticity can be achieved by varying the precursor components and curing conditions. PDMS, for example, can be prepared with a range of elasticity

(2.8–1882 kPa) by varying the ratio of base to curing agent (Cheng et al., 2009). Since PDMS can be cast into many shapes, patterned surfaces with varying elasticity can be created. These surfaces can be subsequently coated to achieve uniform and comparable surface chemistry. Similarly, by progressively reducing the thickness of a gel to a thin film, chemical composition can be maintained while substrate elasticity changes.

While the contributions of topography, chemistry, elasticity, and strain to cell behavior have been evaluated and documented for a wide variety of cell types, much of the literature has evaluated the effects of only one stimulus in each experimental setting. In vivo however, it is reasonable to expect that cells experience a wide range of stimuli simultaneously. Since physical cues such as chemistry, topography, elasticity, and strain can produce both synergistic and opposing effects on cell behavior, it is of interest to evaluate their simultaneous effect on cell behavior and, if possible, describe a hierarchy of cellular cues. However, since the cellular response to physical stimuli is often dependent upon cell phenotype and further subject to effects by soluble factors, broad exploration of these phenomena presents a challenging combinatorial experimental environment. Organ-on-a-chip platforms have the potential to model more complex experiments for studying cell–substrate interactions (Ashammakhi et al., 2019).

Chemistry and Topography

Using a combination of patterning techniques including photolithography, Curtis established that fibroblasts respond to both chemical and topographic patterns (Curtis and Wilkinson, 1999). However, when both chemical and topographical stimuli were combined and orthogonally opposed on the same surface, cells aligned with nanometer-sized topographical patterns. Curtis coined the term "topographic reaction" to describe these events (Curtis and Wilkinson, 1999). Similarly, a preference of cellular alignment to topographic cues in the presence of both topographic and chemical patterns has been demonstrated in a number of studies (Charest et al., 2006; Gomez et al., 2007).

Chemistry and Strain

Hyun et al. developed a system to evaluate the combined effects of chemical patterning and strain on cell alignment (Hyun et al., 2006). Thin paraffin films were patterned with adhesive regions of fibronectin to which NIH 3T3 fibroblasts adhered and aligned. After cells aligned in the direction of the chemical patterning, the paraffin films with the adherent cells were subjected to cyclical stretch. Mechanical force was applied perpendicular to the cell alignment resulting from chemical patterning and the actin cytoskeleton realigned along the axis of applied mechanical stress. Stretched cells showed altered gene expression of cytoskeletal and matrix proteins in response to mechanical deformation.

Topography and Strain

Cheng et al. (Cheng et al., 2009) fabricated patterned PDMS substrates consisting of parallel microchannels (2 μm wide, 2 μm separation, and 10 μm deep) that were subjected to cyclic compressive strain applied perpendicular to the direction of the channels. After 6 h of compression, fibroblasts cultured on the patterned PDMS substrate aligned in the direction of the microchannels (topographical cue) and perpendicular to the direction of compression. Elastic microgrooved surfaces have also been utilized to maintain the cellular orientation of mesenchymal stem cells (MSC's) while subjected to cyclic tensile strain (Kurpinski et al., 2006).

Organ-on-a-Chip 3D culture

Because 2D culture cannot mimic 3D in vivo environment and lack many aspects of native tissue such as microfluidic flow, organ-on-a-chip models were developed (Zheng et al., 2016). An organ-on-a-chip system comprises a 3D culture system that has dynamic flow through microchannels, thanks to advances made in microfluidics, microfabrication, and knowledge gained from research into bioreactors. Microfluidic work by Whitesides (Whitesides, 2006) makes the early basis for lab-on-a-chip and organ-on-a-chip systems. The platform offers several advantages over the conventional 2D culture in studying various physiological and pathological conditions. An entirely different approach is embodied in organ-on-a-chip systems where cells can be subjected to flow stress, topographical cues, and possible stimulation by embedded biomolecules and microelectrodes, and the effect can be monitored using microsensors.

In some organ-on-a-chip models, not only cells are cultured and exposed to flow, but other physiological effects are included in the system for creating movement that mimics in vivo effects. For example, by moving the membrane between alveolar and vascular space in the lung-on-a-chip (Huh et al., 2010), the mechanical cues can be recreated. Similar models were developed for the gut (Kim et al., 2012). These 3D models were used to study various diseased and pathological conditions including cancer and its metastasis (Bersini et al., 2014). In organ-on-a-chip systems, sensors can also be integrated (Shin et al., 2017) and various changes can be detected and monitored on a continuous basis making real-time follow-up and analysis possible (Ashammakhi et al., 2018, 2019). More recently, multiorgan-on-a-chip systems were developed by linking different tissue units together (Zhang et al., 2017) and the interaction between substance and cells was evaluated. The use of 3D models of organ-on-a-chip was found to be more representative to in vivo events than 2D. Cells cultured in these systems were observed to polarize in a biomimetic way (Jang and Suh, 2010) and the curvature of channels was found to influence cell function (Ferrell et al., 2012). Cell functionality was correlated to diameter, with smaller diameter resulting in increasingly functional cells.

(Normal renal tubules have a small diameter at about 50 μm [Jameson and Loscalzo, 2010]). These findings suggested that the cells could sense structural and spatial cues and that surface curvature might have a positive effect on distal tubular cell function (Ferrell et al., 2012). Thus, the system allows the manipulation and study of various material properties on cells, such as the effect of stretch (Kilinc et al., 2011), peristaltic movement (Kim and Ingber, 2013; Kim et al., 2012), as well as shear stress (Jang et al., 2013). Also, sensors and electrodes for the measurement of transepithelial electrical resistance (TEER) can be integrated to monitor renal epithelial cell growth, and the integrity of tight junctions (Ferrell et al., 2010). Jang et al. cultured primary human proximal tubular epithelial cells on microchannels comprised of collagen type IV-coated polyester membranes (Jang et al., 2013). Compared to control systems not exposed to fluid shear stress, tubular cells in microfluidic systems regained normal columnar shape, polarity, and primary cilia. They also displayed an increase in cellular uptake of albumin and an increased recovery from cisplatin-induced damage (Jang et al., 2013). Jang et al. also cultured primary rat renal collecting duct cells on a multilayer microfluidic device created from thin fibronectin-coated porous polyester membranes situated in a PDMS microchamber (Jang and Suh, 2010). Shear stress was maintained at 1 dyn/cm^2 by accounting for fluid flow rates, viscosity, and channel size in this system. At this stress level, cytoskeletal rearrangement, number of cell junctions, and cell polarity increased.

Classically, PDMS is used for the fabrication of organ-on-a-chip systems because it is transparent, has low toxicity, and high permeability to O_2 and CO_2 and (Whitesides, 2006). However, PDMS can absorb hydrophobic compounds which limits its application in for drug testing (Halldorsson et al., 2015). Other materials such as polycarbonate, polystyrene, and poly(methyl methacrylate) (PMMA) (Chan et al., 2015), can be used because they have low absorption of hydrophobic compounds (Nge et al., 2013). In addition, natural and synthetic hydrogels may be added to microfluidic devices, to better mimic the natural physiologic environment (Hasan et al., 2015). Microchannel surfaces can be coated with various biomaterials that enhance cell attachment and function. For example, Sciancalepore et al. cultured hPC progenitor cells on porous polycarbonate membranes coated with either fibronectin, laminin, or Matrigel that separated PDMS microchannels (Sciancalepore et al., 2014). In this study, fibronectin was associated with the highest number of metabolically active cells.

Summary

In vivo, cells are responsive to a myriad of substrate-related signals within the environment. At the micro- and nano-scales, interactions with the ECM expose the cell to a variety of chemical moieties and topographical features. Micro- and nano-scale technologies have provided many new tools to manipulate the in vitro environment. Cell behavior may be modified by patterns of cell-adhesive ligands and topographical features. Further modification of cell behavior can be achieved by altering the mechanical properties of the substrate, such as elasticity or by deformation of cell shape. With respect to generating complex tissue structures, substrate cues like topography, chemistry, and matrix elasticity are promising candidates for controlling cell differentiation. Unlike soluble factors, substrate cues can provide specific information for directing and controlling cell behavior. The combination of multiple physical cues presents new and potentially useful methods to direct and control cell development and behavior. With respect to physical stimuli, evidence suggests that a hierarchy exists among cell responses to substrate characteristics.

2.1.4

Functional Tissue Architecture, Homeostasis, and Responses to Injury

RICHARD N. MITCHELL, FREDERICK J. SCHOEN

Department of Pathology/Brigham and Women's Hospital and Harvard Medical School, Boston, MA, United States

It is reasonable to ask why a chapter that covers concepts of tissue anatomy, physiology, and pathophysiology should be included in a book on biomaterials science. In the current era of sophisticated biomaterials development, there are at least three key reasons that merit emphasis:

1. The safety and effectiveness of biomaterials will be enhanced by design and testing informed by a deep understanding of the architecture, function, and dysfunction of the tissue ecosystem into which they are placed.
2. The surgical or other interventional procedure by which biomaterials are implanted into the body disrupt and induce some injury and associated physiological responses in the surrounding tissues. Consequently, inflammation and healing are superimposed on and may significantly influence biomaterials–tissue interactions.
3. Optimal development of increasingly interactive, regenerative and tissue-engineered biomaterials demands a knowledge of both functional tissue organization and how cell phenotypes and tissue adaptation and remodeling processes are controlled by their mechanical and biochemical environment.

Tissue Constituents, Organization, and Integration

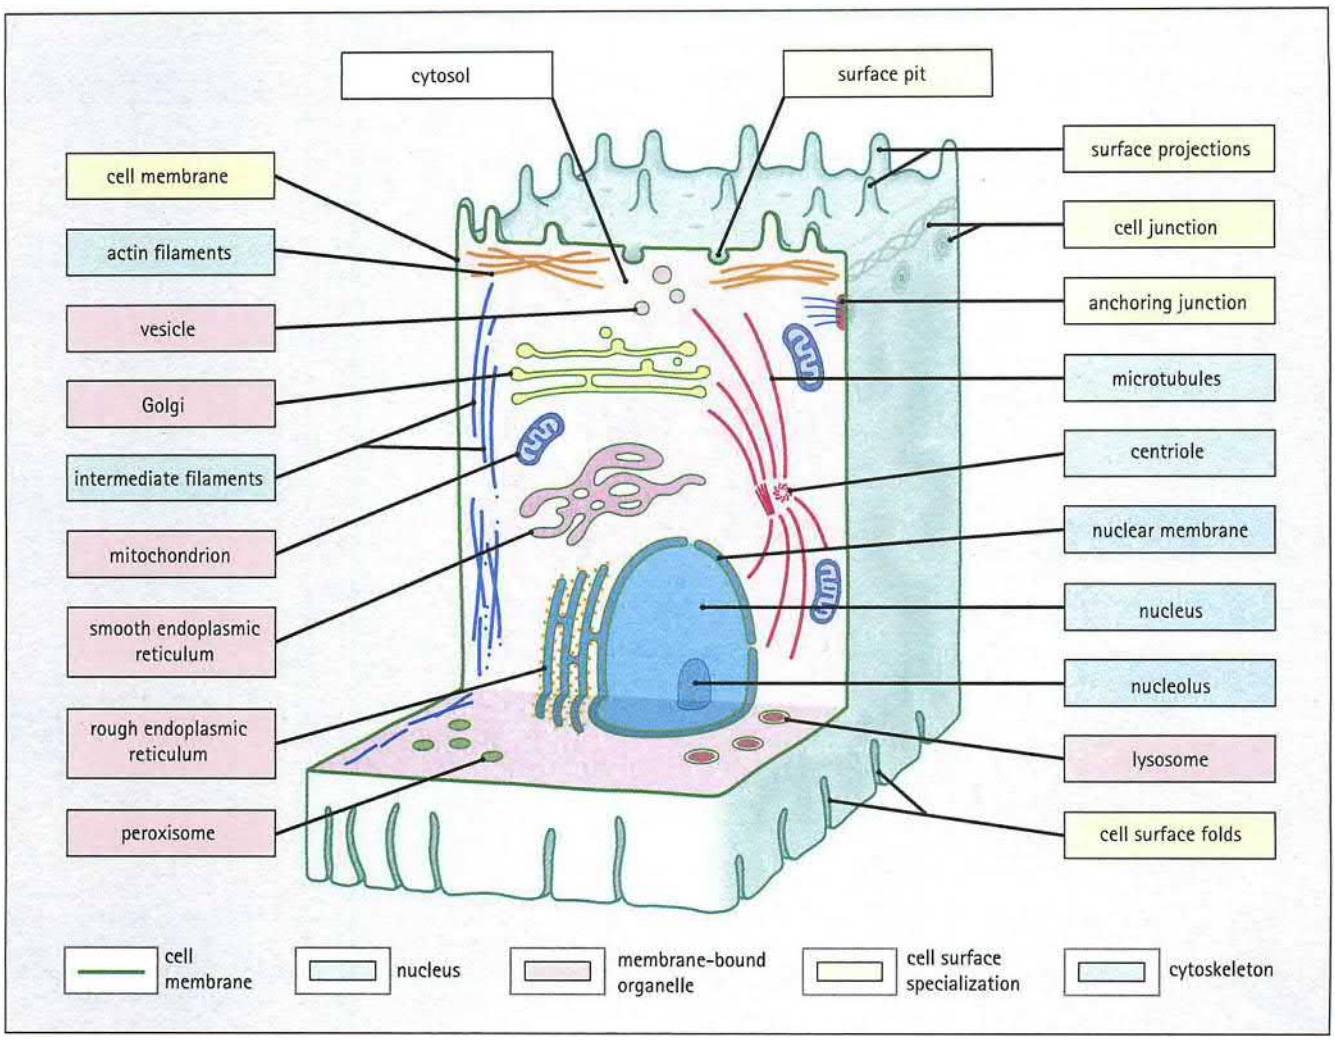
A major goal in this first section is to describe how *biological structure is adapted to perform physiologic function*. This general and overarching concept extends from cells (and their *subcellular* constituents) to the organization of tissues and organs. Beginning with the smallest subunits of cellular organization we will build to progressively more complex systems. We also provide an introduction to the physiologic responses to environmental stimuli, and the mechanisms of and responses to cell injury and tissue–biomaterials interactions. For additional detail, see Lodish et al. (2016).

The Essential Role of Cells

Cells constitute the basic structural building blocks of all living matter. Each cell is a structurally highly ordered and functionally integrated assembly of signal transduction molecules, enzymes, cytoskeletal proteins, and organelles—all of which are discrete, specialized structures within a cell. Virtually all cells share the same core functional attributes, including nutrient uptake, metabolism, waste removal, organellar turnover, and proliferation (Fig. 2.1.4.1).

Except for the circulating blood elements, cells are joined via cell–cell junctions to form *tissues* that comprise a handful of general types: *epithelium*, *connective tissue*, *muscle*, and *nerve*. *Hematopoietic and lymphoid tissues*—responsible for generating erythrocytes, granulocytes, monocytes, platelets, and lymphocytes—also exhibit similar features as they proliferate and differentiate into their final circulating progeny. *Organs* are assembled from the basic tissue types and are "glued" together within an *extracellular matrix* (ECM) composed of myriad proteins, glycoproteins, *mucopolysaccharides* (sugar polymers), and *proteoglycans* (polymeric sugars attached to a protein core) synthesized by the individual cells. For information on the specific constituents of the ECM, Chapter 2.1.5. Organs are self-contained collections of several different types of tissues arranged into a functional unit with a specific vital function (e.g., the heart, liver, or a joint). Collectively, the organs—often grouped in physiologic systems (exemplified by the cardiovascular and respiratory systems, the gastrointestinal tract, the bones and joints, and the internal and external genitalia)—perform the various functions required by the intact living organism, including circulation, respiration, digestion, excretion, movement, and reproduction, respectively.

The basic functional attributes of cells include protection, signaling, nutrient absorption and assimilation, energy generation, macromolecule synthesis, growth, and reproduction. Without these basic activities, cells cannot live. However, most cells also exhibit specialization—that is, they have additional capabilities, such as irritability, conductivity, contraction, absorption, or



• **Figure 2.1.4.1** General schematic of a typical mammalian cell, demonstrating the overall organization and major organelles. (James, S.L., Peter, G.A., 2015. Stevens & Lowe's Human Histology, fourth ed.)

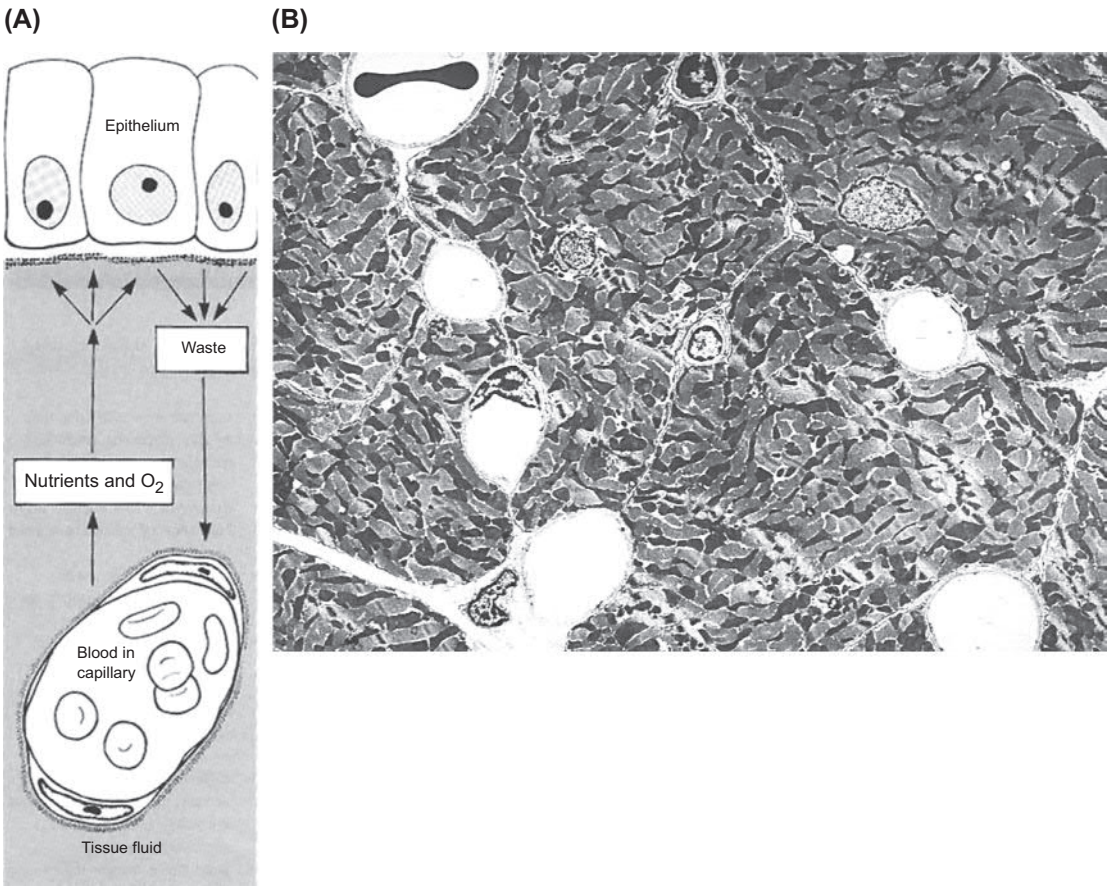
secretion of molecules. *Multicellular organisms are thus composed of individual cells with marked specialization of structure and function.* Differentiated cells allow a division of labor in the performance and coordination of complex functions carried out in architecturally distinct and organized tissues. It is also important to note that cells are not only the fundamental building blocks of the body, but that injury at the cellular level is the underlying basis of virtually all disease (see Rubin et al., 2014; Kumar et al., 2015).

Parenchyma and Stroma

Organs are broadly organized into *parenchyma*—the cells that provide the specific function of a tissue (e.g., neurons in the brain, cardiac myocytes in the heart, hepatocytes in the liver, etc.), and the *stroma* (also called *mesenchyma*)—the surrounding support tissues. Stroma can be conceptualized as the maintenance core or infrastructure (support members, plumbing, electrical, communications, etc.) in a large building—while the parenchyma can be thought of as the specialized office or living space. Like the structural support of a building, the stroma will also provide the framework for tissue reconstruction in the event of damage. Stroma in tissues characteristically includes the blood vessel vascular supply, as well as nerves, supportive fat (*adipose tissue*), and fibrous connective tissue (*including ECM*) synthesized by adipocytes and fibroblasts, respectively.

Vascular Supply: Tissue Perfusion

To maintain baseline cellular function (through ATP synthesis), as well as sustain the ongoing turnover of subcellular structures, cells require a continuous supply of oxygen and nutrients; in the setting of *increased demand* (e.g., exercise or increased cell proliferation), baseline oxygen consumption can increase 10- to 20-fold. In addition, metabolic by-products (e.g., CO_2) must be constantly removed to prevent tissue acidosis. Consequently, most tissues have a dense arborizing network of blood vessels (*vasculature*) to deliver oxygenated nutrient-rich arterial



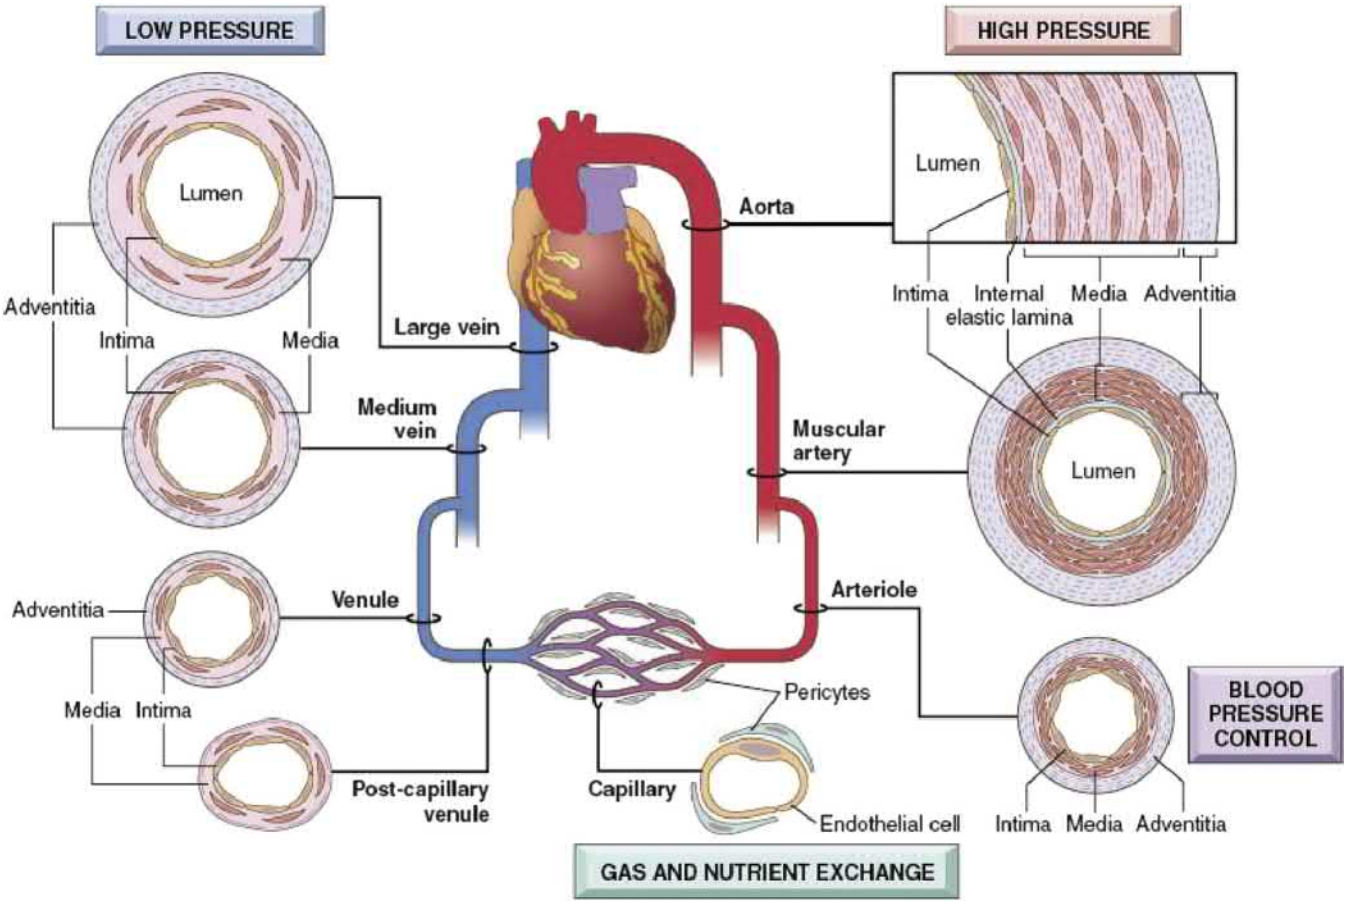
• **Figure 2.1.4.2** Role of the vasculature in tissue function. (A) Schematic of the route by which cells in a tissue obtain nutrition and oxygenation by diffusion from underlying capillaries. Metabolic waste products diffuse in the reverse direction and are removed into the circulation. In each case, diffusion occurs through the fluid that permeates the extracellular matrix. (B) Myocardium, a highly metabolically active tissue, has a rich capillary network, as demonstrated by transmission electron microscopy. The six open round spaces are capillaries, with a red blood cell seen on cross-section in the capillary in the upper left corner. ((A) Reproduced by permission from Cormack, D.H., 1987. Ham's Histology, ninth ed. Lippincott, Philadelphia, PA.)

blood and remove depleted venous blood (Fig. 2.1.4.2). In virtually all tissues there is also a parallel series of *lymphatics*, responsible for draining excess water and electrolytes (as well as inflammatory cells) that have accumulated in the extravascular spaces.

Perfusion of (i.e., delivery of blood to) a tissue or an organ is accomplished through the cardiovascular system, composed of a pump (the *heart*) and a closed loop of distributing and collecting tubes in series: *arteries* → *arterioles* → *capillaries* → *venules* → *veins* (Fig. 2.1.4.3). The extensive system of thin-walled *capillaries* ultimately permits the efficient and rapid exchange of substances between the blood and the tissues. Since blood exits the heart at high pressure, the proximal vasculature (arteries and arterioles) must buffer pulsatile flow to ensure steady low-pressure flow within the capillaries. On the venous side, distensibility of the vasculature provides a high capacitance storage of excess volume. Other functions of the circulation include regulation of body temperature and the distribution of various regulating substances (e.g., hormones, inflammatory mediators, growth factors). Most of the time, the vasculature must maintain blood in a liquid form; however, when vessels are injured, the vessel walls contribute to *hemostasis*—that is, preventing severe hemorrhage by a coordinated response of vasoconstriction, plugging vascular defects by platelet clumps, and activating the coagulation cascade. Moreover, the circulatory system distributes inflammatory cells to their sites of action. The regulation of coagulation, vascular pressure, and the egress of inflammatory cells and mediators is accomplished through the function of *endothelial cells* that line the entire cardiovascular system and interface with the circulating blood elements.

Extracellular Matrix (See also Chapter 2.1.5)

ECM comprises the biological material produced by, residing in between, and supporting cells; it is synthesized, remodeled, and otherwise maintained by the cells associated with the ECM. ECM, stromal, and parenchymal cells, capillaries and nerves are physically and functionally integrated in tissues and organs (Fig. 2.1.4.4). The ECM provides physical support and a matrix to which cells can adhere, signal each other, and interact. However, the ECM is more



• **Figure 2.1.4.3** Regional structural variations in the cardiovascular system. Although the basic organization of vessels is constant, the thickness and composition of the various layers differ as a functional response to varying hemodynamic forces and tissue metabolic requirements. (Reproduced by permission from Mitchell, R.N., Schoen, F.J., 2010. Blood Vessels. In: Kumar, V., Abbas, A.K., Fausto, N., Aster, J.C. (Eds.), Robbins and Cotran Pathologic Basis of Disease. eighth ed. Saunders, Philadelphia, PA.)

than a scaffold that maintains tissue and organ structure. Indeed, the ECM regulates many aspects of cell behavior:

- mechanical support for cell anchorage;
- determination of cell orientation (cell polarity, e.g., what is up and down);
- control of cell growth;
- cell differentiation;
- scaffolding for orderly tissue renewal;
- establishment of tissue microenvironments;
- sequestration, storage, and presentation of soluble regulatory molecules.

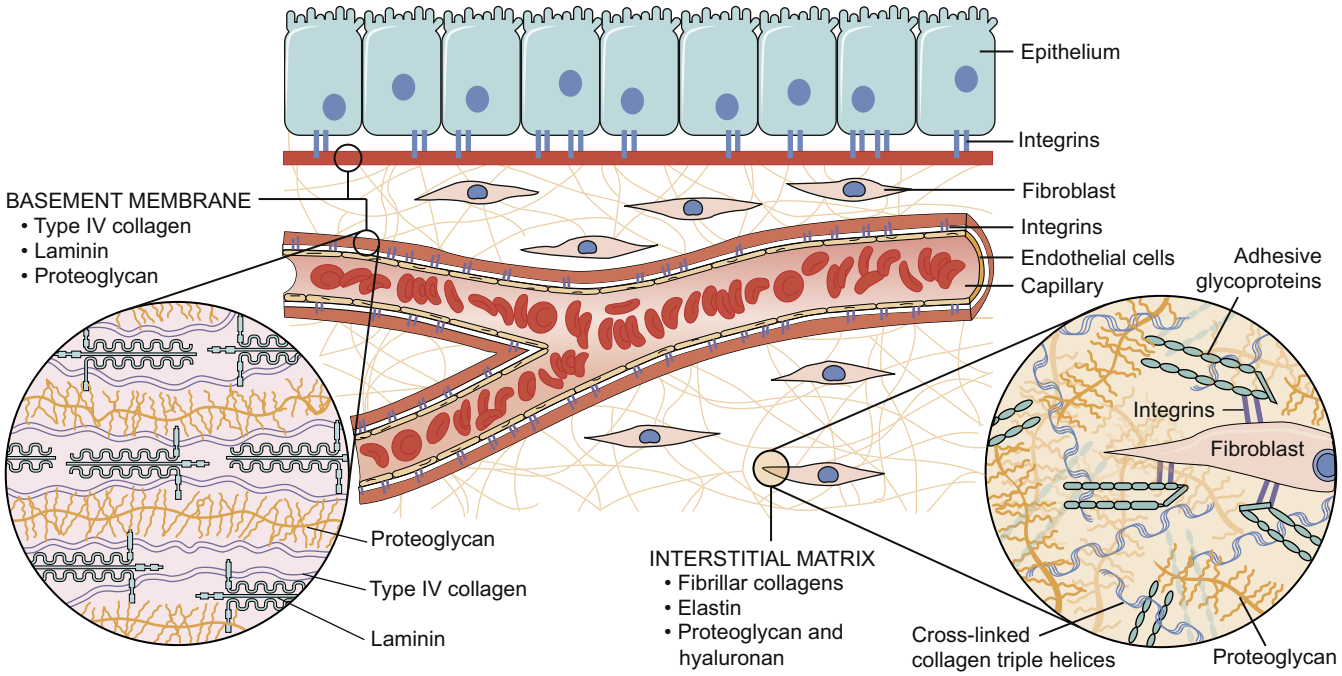
Some ECMs are also specialized for a particular function, such as strength (tendon), filtration (the basement membranes in the kidney glomerulus), or adhesion (basement membranes supporting most epithelia). To produce additional mechanical strength in bones and teeth, the ECM is calcified. Even in a tissue as "simple" as a heart valve leaflet, the coordinated interplay of several ECM components and the spatial and temporal dynamics of ECM interactions are critical to function. Importantly, the scaffolds used in tissue-engineering applications are intended to replicate the several functions of natural ECM.

ECM components are synthesized, secreted, and remodeled by cells in response to environmental cues. Virtually all cells secrete *and degrade* ECM to some extent (see later). Certain cell types (e.g., fibroblasts and smooth muscle cells) are particularly active in the production of interstitial ECM (i.e., the ECM between cells). Epithelial cells also synthesize the ECM of their basement membranes (Fig. 2.1.4.4).

The mechanical forces that cells experience from their surroundings markedly influence cellular phenotypes, including cell shape, orientation, and differentiated function; this occurs though the interaction of cell surface receptors (Kumar et al, 2017; Mammoto et al, 2013) (such as *integrins*) with ECM molecules (Fig. 2.1.4.5). The resultant changes in cytoskeletal organization and in the production of second messengers can modify gene expression (Fig. 2.1.4.6).

Organ Structure

Organs have a composite structure with epithelial, lymphoid or other specialized tissues, called *parenchyma*, performing specific functions of the organ, while *stroma* consists of connective tissue and blood vessels that provide support and nourishment



• **Figure 2.1.4.4** Main components of the extracellular matrix (ECM), including collagen, proteoglycans, and adhesive glycoproteins. Both epithelial cells and fibroblasts interact with ECM via integrins. Basement membranes and interstitial ECM have differing architecture and general composition, although there is some overlap between them. Some ECM components (e.g., elastin) are not included for the sake of simplification. (Reproduced by permission from Kumar, V., Abbas, A.K., Fausto, N., Aster, J.C., 2010. Robbins and Cotran Pathologic Basis of Disease, eighth ed. Saunders, Philadelphia, PA.)

to the specialized tissues (Figs. 2.1.4.7 and 2.1.4.8). Although parenchymal cells are generally more sensitive to chemical, physical, or ischemic (i.e., low blood flow) injury than is stroma, when an organ is injured, orderly repair and regrowth of parenchymal cells requires an intact underlying stroma.

There are two basic organ patterns: tubular (or hollow) and compact (or solid) organs. Tubular organs include the blood vessels and the digestive, urinary-genital, and respiratory tracts; they have similar architectures in that each is composed of layers of tissue arranged in a specific sequence. Each has an inner coat consisting of a lining of epithelium, a middle coat consisting of layers of muscle (usually smooth muscle) and connective tissue, and an external coat consisting of connective tissue typically covered by epithelium. Compact, solid organs (e.g., liver, lymph node or spleen) have an extensive connective tissue framework, surrounded by a dense, connective tissue capsule.

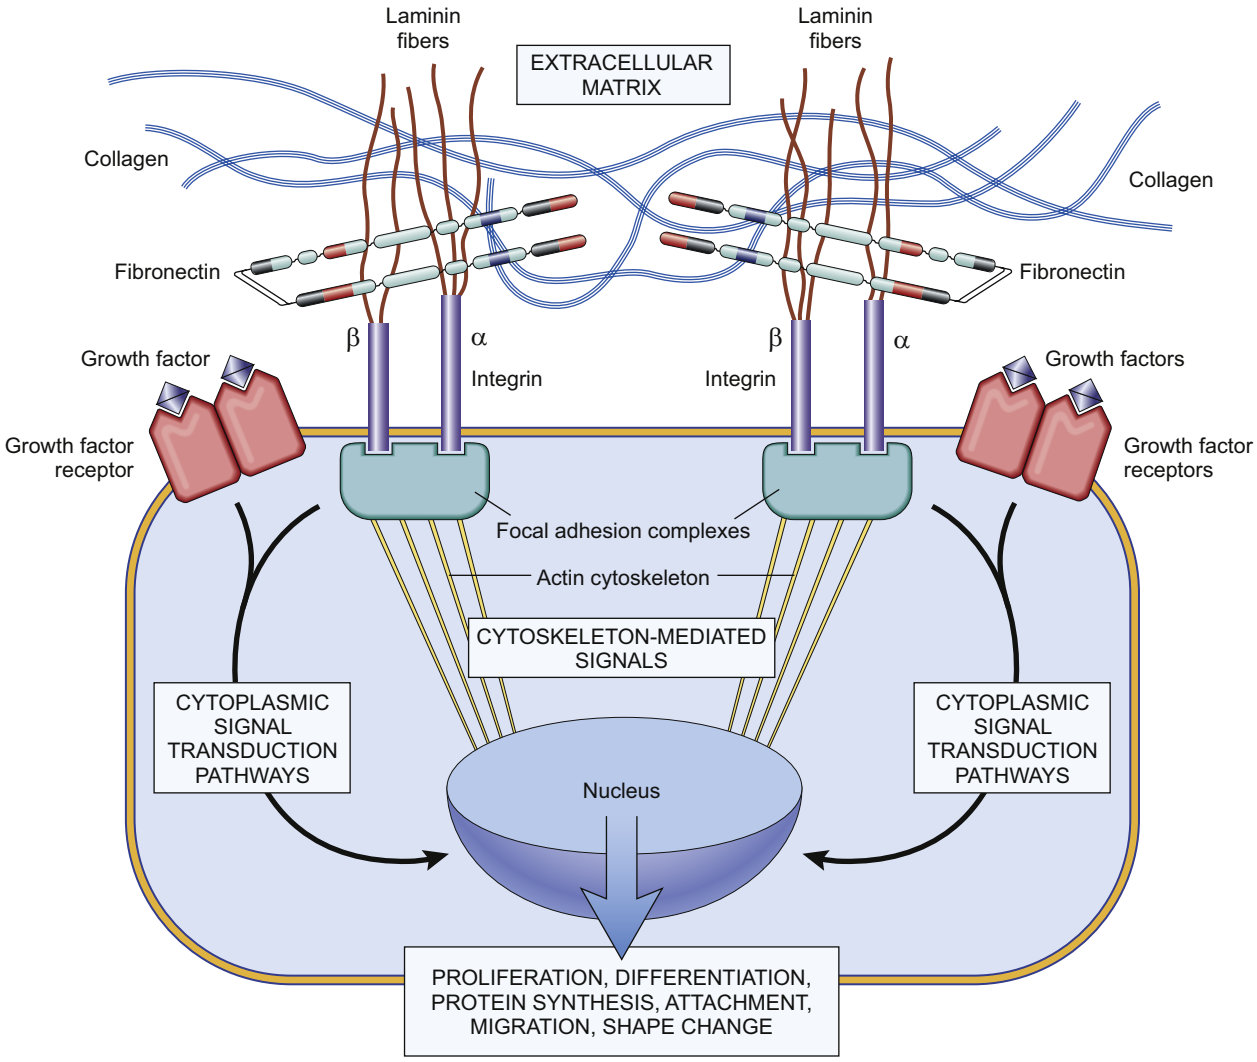
Blood vessels are also *organs*. Blood vessels have three layers: an *intima* (the *endothelium*, which is an epithelium), a *media* (primarily smooth muscle and elastin), and an *adventitia* on the outside (primarily collagen). The amounts and relative proportions of layers of the blood vessels are influenced by mechanical factors (especially blood pressure, which determines the amount and arrangement of muscular tissue), and metabolic factors (reflecting the local nutritional needs of the tissues). The histologic composition and organization as well as the thickness of these three layers varies characteristically with the specific physiologic functions performed by the different segments of the cardiovascular system (Fig. 2.1.4.3).

The blood supply of an organ comes from its outer aspect (Figs. 2.1.4.7 and 2.1.4.8). Compact organs have a hilus or area of thicker connective tissue where blood vessels and other conduits enter the organ. In tubular organs, large vessels penetrate the outer coat, perpendicular to it, and give off branches that run parallel to the tissue layers. These vessels divide yet again to give off penetrating branches that course through the muscular layer, and branch again in the connective tissue parallel to the layers. The small blood vessels have junctions (*anastomoses*) with one another in the connective tissue. These junctions may provide *collateral* pathways that can allow blood to bypass obstructions.

Cell and Tissue Differentiation, Phenotype, and Maintenance

Structure–Function Correlation

As cells differentiate, they become increasingly specialized, and develop well-defined structural and functional characteristics. For example, striated muscle cells have well-organized actin and myosin filaments that slide over one another, facilitating cellular contraction. Gastric (stomach) epithelial cells have large numbers of mitochondria to generate the ATP necessary to pump hydrogen ions out of the cell against a concentration gradient and acidify the stomach contents. Skin keratinocytes function as a protective barrier by undergoing autophagic programmed cell death and becoming scale-like structures composed of durable, nonliving keratin (an intermediate filament). Specialized phagocytic cells of the immune system detect infectious



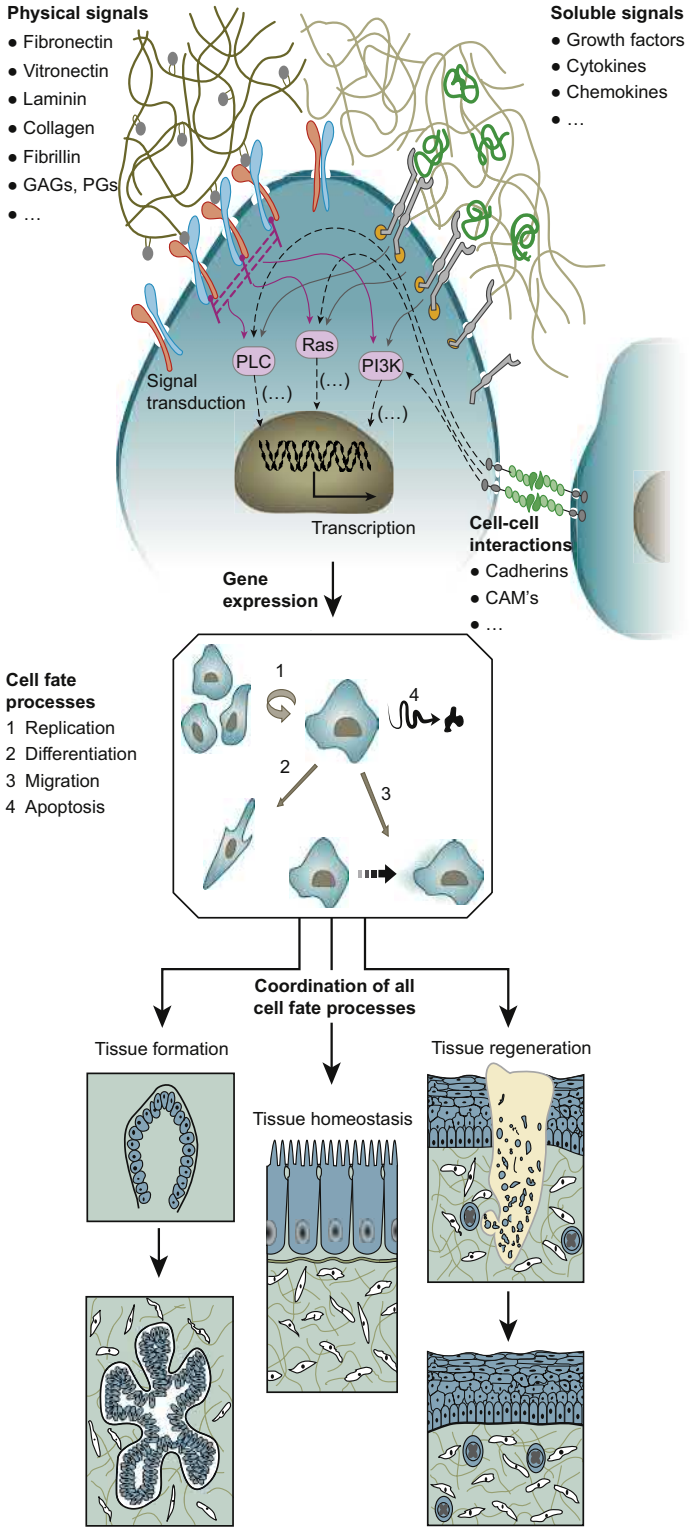
• **Figure 2.1.4.5** Soluble and mechanotransduction pathways by which a variety of cell behaviors, e.g., proliferation, differentiation, protein synthesis, locomotion, or shape change, can be modified. Note that soluble mediators can act through plasma membrane receptors (or intracellular receptors, not shown) to affect changes in nuclear transcription. Extrinsic mechanical forces can also impact cellular phenotypes through protein–protein interactions linking ECM proteins (e.g., fibronectin and laminin) with cell surface integrins that are in turn connected to the nucleus through cytoskeletal elements such as actin microfilaments. Integrins are important components of *focal adhesion complexes*, which can provide secondary signaling (e.g., by driving protein phosphorylation) when external mechanical forces are applied to proteins connected to them. *EGF*, Epidermal growth factor; *IL-1/TNF*, interleukin-1/tumor necrosis factor; *PDGF*, platelet-derived growth factor; *TGF-β*, transforming growth factor-β; *TIMPs*, tissue inhibitors of metalloproteinases. (Reproduced by permission from Kumar, V., Abbas, A.K., Fausto, N., Aster, J.C., 2010. Robbins and Cotran Pathologic Basis of Disease, eighth ed. Saunders, Philadelphia, PA.)

microorganisms (e.g., bacteria, parasites, and viruses), actively migrate to them, and then ingest and destroy them. *Polymorphonuclear leukocytes* (also called *PMNs* or *neutrophils*) are particularly active against bacteria, while *macrophages* react to other types of organisms and foreign material. B lymphocytes are not phagocytic but contribute to immunity by producing antibodies that can bind and neutralize infectious agents.

Stem Cells

Cells with the capacity to both divide and yield differentiated cells of one or more types are called *stem cells*. *Stemness* can be functionally understood as the capacity for *asymmetric division*: one progeny cell maintains *totipotency* or *pluripotency* (it can still potentially become any [or many] cell type[s]), while the other daughter cell transcribes selected subsets of genes to become more differentiated.

Thus the stem cells in early embryos (found only rarely in adult cell populations) are totipotent with virtually limitless replicative capacity. As the fetus grows and develops, subsets of these totipotent cells *differentiate* and assume specific functions that will eventually lead to the formation of mature tissues, e.g., bone, muscle, liver, skin, and brain (Fig. 2.1.4.9).

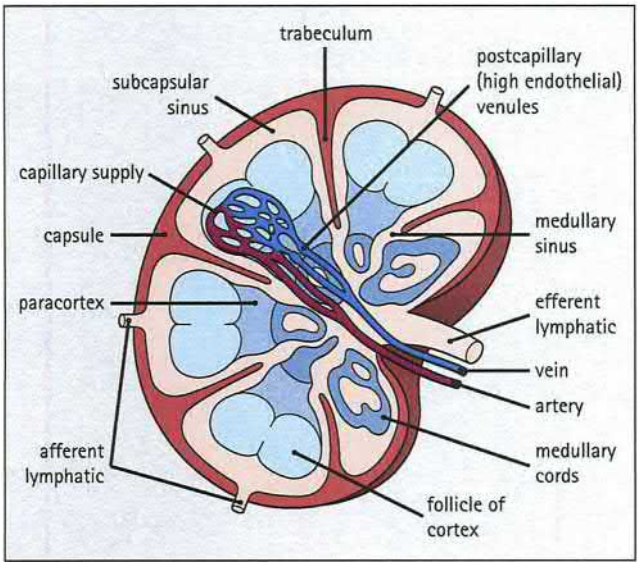


• **Figure 2.1.4.6** Individual cell behaviors and the dynamic states of multicellular tissues are regulated by reciprocal molecular interactions between cells and their environment. (Reproduced by permission from Lutolf, M.P., Hubbell, J.A., 2005. Synthetic biomaterials as instructive extracellular microenvironments for morphogenesis in tissue engineering. Nat. Biotechnol. 23, 47–55.)

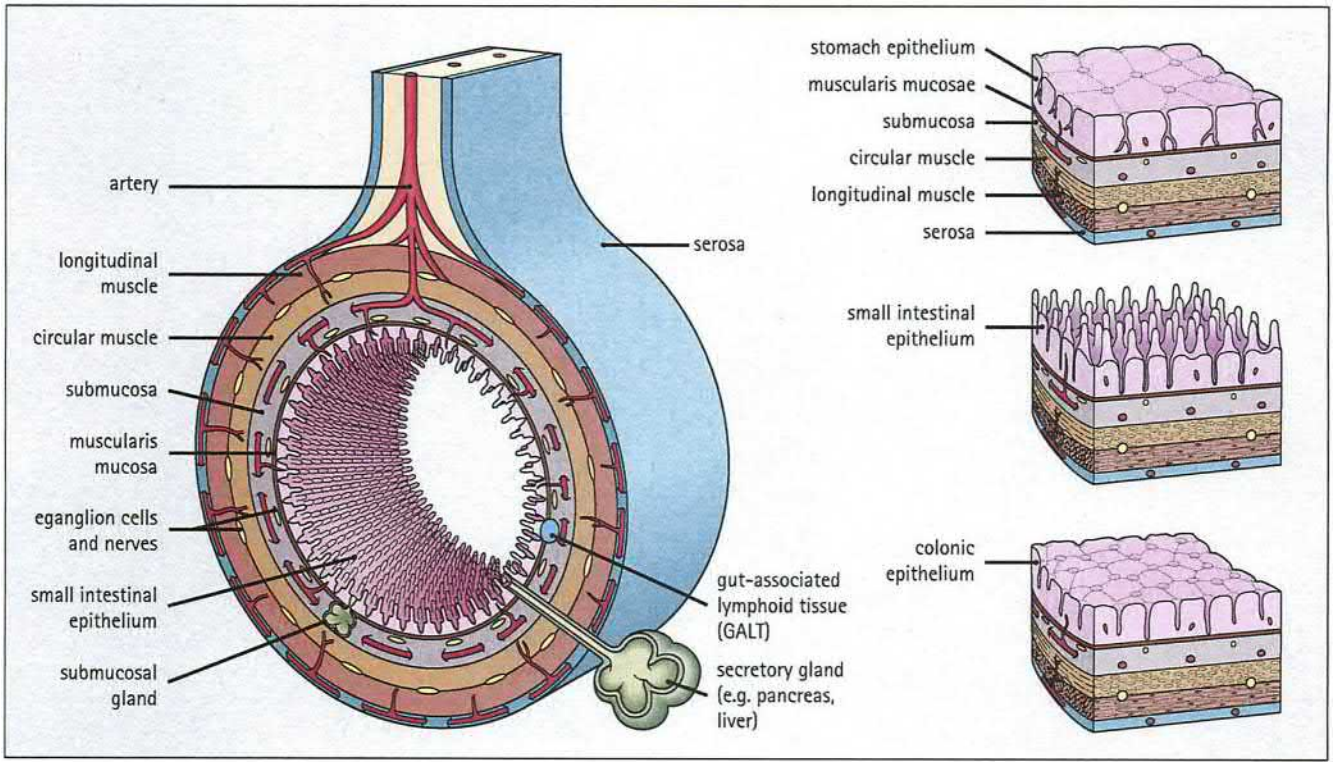
As cells differentiate along particular specialization or tissue pathways, they lose the ability to interconvert and develop into all cell types, although they may be able to form most or all the cells *of a particular tissue*. Thus gastrointestinal stem cells in the small bowel can differentiate into absorptive epithelial cells, mucus-producing epithelial cells, and Paneth crypt cells that produce bacteriocidal proteins; however, they cannot differentiate into smooth muscle cells or even other types of epithelium. Stem cells in these lineages are said to be *pluri-* or *multipotential*; they may also have slightly limited replicative capacity. With further differentiation, cells may lose replicative capacity altogether.

Therefore the various stem cell populations *downstream of the totipotential stem cells* are not all created equal; each type of stem cell has a repertoire of cells that it can potentially differentiate into. For example, pluripotent stem cells such as hematopoietic stem cells can form only circulating blood elements (red cells, platelets, leukocytes, etc.); with progressive maturation, even those lineages will develop into populations that become progressively more restricted in their differentiation capacity (i.e., capable of making only red cells or lymphocytes).

It is also important to recognize that differentiated cells cannot typically *transdifferentiate* into other cell types—that is transform from one mature somatic cell into another without an intermediate pluripotent or progenitor cell (also called *lineage reprogramming*). Thus a keratinocyte in the skin does not naturally become an absorptive epithelial cell like those in the gastrointestinal tract. An apparent exception to this is seen in certain tissues where one mature adult cell type is replaced with another (called *metaplasia*; see later in the chapter). In reality, this occurs through a reprogramming of a precursor stem cell to generate a different cellular phenotype. Moreover, it is now possible to experimentally genetically reprogram mature, differentiated cells by the addition of certain transcription factors; this is the basis for generating inducible progenitor stem cells from adult end-stage cells.



• **Figure 2.1.4.8** Lymph node structure. Blood vessels enter and efferent lymphtics emerge from the hilum. Lymphoid follicles comprise the parenchyma. (Reproduced from James, S.L., Peter, G.A., 2015. Stevens & Lowe's Human Histology, fourth ed.)

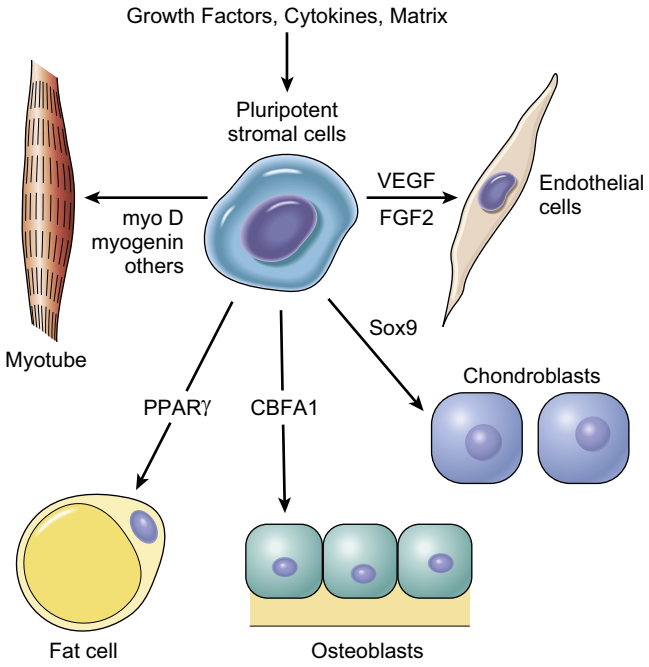


• **Figure 2.1.4.7** Vascularization of a hollow organ, as exemplified by the digestive tract. The specialized epithelium differs from region to region (stomach, small intestine and colon, as indicated) but the essential wall architecture remains the same throughout, as in the cadiovascular system (recall Figure 2.1.4.3). (Reproduced from James, S.L., Peter, G.A., 2015. Stevens & Lowe's Human Histology, fourth ed.)

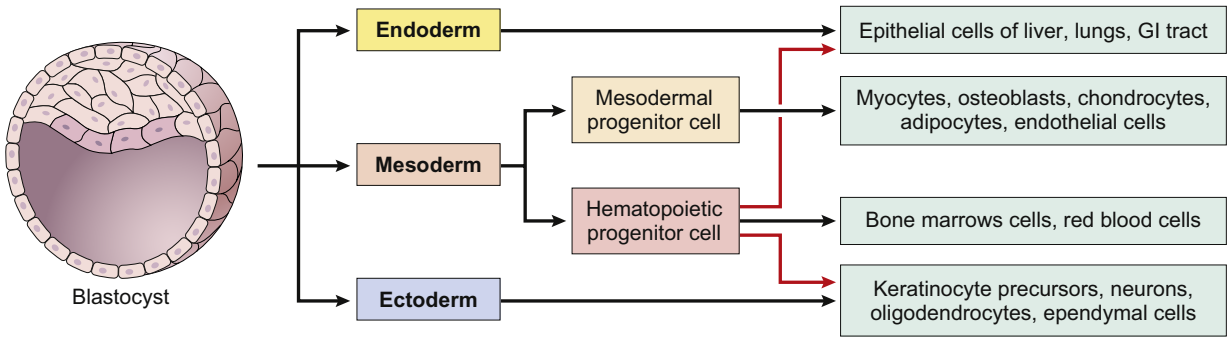
Cellular Differentiation and Gene Expression

Every cell in the body has the same complement of genes (called the *genotype*). When selected subsets of genes are preferentially expressed, yielding a distinct biological profile (called the *phenotype*), progressive differentiation occurs. As cells progressively specialize, more and more of the "unnecessary" genes in the differentiating cell are turned off (usually irreversibly). Some genes are active at all times (*constitutively expressed*); others may be selectively activated or *modulated* depending on external influences (e.g., injury). Thus from one type of pluripotent cell, differential activations of specific genes can engender the development of endothelial cells, skeletal muscle, fat, bone, or cartilage (Fig. 2.1.4.10).

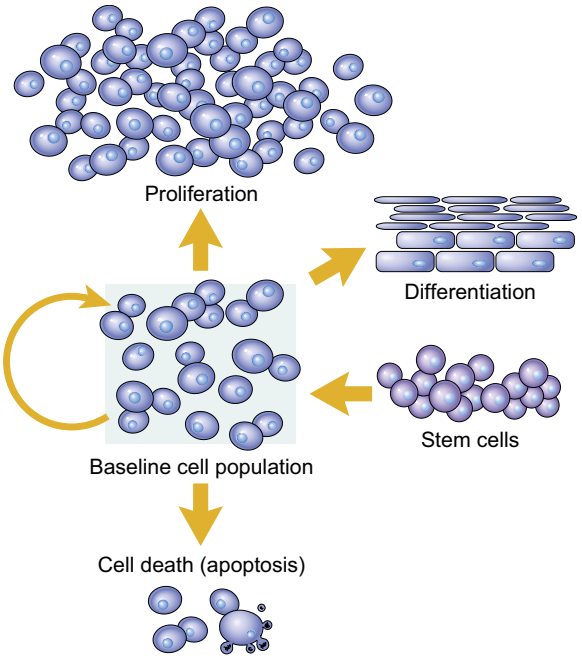
The specific function(s) of a given cell are reflected by the relative amount and types of organelles it contains. The relative predominance of specific types of organelles can often be inferred by examination of tissue sections prepared by standard histologic techniques and can be confirmed by transmission electron microscopy. For example, cells with substantial energy requirements need a significantly greater capacity to generate adenosine triphosphate (ATP), the energy currency of the cell. Thus kidney tubular epithelial cells (which reabsorb sodium and chloride against concentration gradients) and cardiac myocytes (which rhythmically contract 50–100 times per minute) have a generous complement of mitochondria. In comparison, cells specifically adapted to synthesize and export selected proteins (e.g., insulin in a pancreatic islet cell, or antibody produced by a plasma cell) have a well-developed rough endoplasmic reticulum (the key site of protein synthesis). A corollary to this general concept is that the nutritional and extracellular structural needs of a cell can also be inferred from the organellar constituents and the presumed cellular function. Thus cells with substantial energy demands but little in the way of intracellular energy reserves (e.g., cardiac muscle cells) will need a continuous source of oxygen and glucose—provided by a dense capillary network with minimal diffusion distance from blood to cardiomyocyte mitochondria.



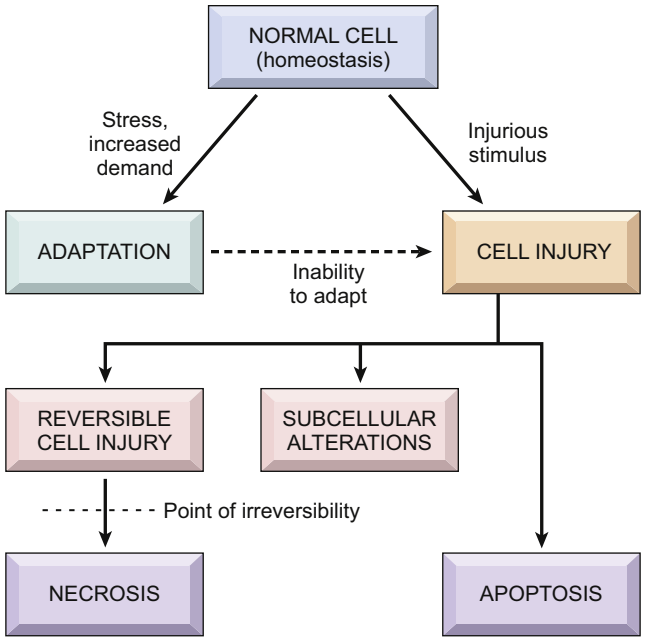
• **Figure 2.1.4.10** Differentiation of pluripotent mesodermal progenitor cells. The same stromal cell can differentiate in different developmental pathways depending on the activation of specific genes; this can occur through exogenous soluble factors or via mechanical cell–matrix interactions. Thus, vascular endothelial growth factor (VEGF) and fibroblast growth factor-2 (FGF-2) are two (of many) soluble signaling molecules that induce endothelial differentiation. Sox9, CBFA1, PPARγ, and myoD are all intracellular transcription factors whose activities will induce the specific lineages shown. (Reproduced by permission from Kumar, V., Abbas, A.K., Fausto, N., 2005. Robbins and Cotran Pathologic Basis of Disease, Seventh ed. Saunders, Philadelphia, PA.)



• **Figure 2.1.4.9** Differentiation of mature cell lineages from the *totipotential* blastocyst. Cells in the early embryo have the capacity to proliferate and differentiate into all adult tissues. As the embryo expands, distinct layers (*endoderm*, *ectoderm*, and *mesoderm*) from the original sphere become three general *pluripotential* lineages—now with more limited cellular differentiation repertoires. Eventually, after multiple rounds of replication and additional differentiation, the final adult tissues develop. *Adult stem cells* derived from the original pluripotential lineages will persist within the organs they formed, with the capacity to regenerate cells specifically of that tissue. In addition, adult hematopoietic progenitors from the original mesoderm have the relatively unique capacity to generate tissues of the endoderm and ectoderm—in addition to making marrow-derived blood cells. (Reproduced by permission from Kumar, V., Abbas, A.K., Fausto, N., 2005. Robbins and Cotran Pathologic Basis of Disease, Seventh ed. Saunders, Philadelphia, PA.)



• **Figure 2.1.4.11** Achieving steady-state populations of cells. Total cell numbers in a baseline tissue population can be regulated by changes in stem cell output, loss of cells through programmed cell death (*apoptosis*), cellular proliferation, or differentiation. (Reproduced by permission from Kumar, V., Abbas, A.K., Fausto, N., 2005. Robbins and Cotran Pathologic Basis of Disease, Seventh ed. Saunders, Philadelphia, PA.)



• **Figure 2.1.4.12** General overview of potential cellular responses to stressors and injurious stimuli. (Reproduced by permission from Kumar, V., Abbas, A.K., Fausto, N., Aster, J.C., 2010. Robbins and Cotran Pathologic Basis of Disease, eighth ed. Saunders, Philadelphia, PA.)

Tissue Homeostasis

Tissues function best when maintained within certain physiologic ranges of pH, temperature, nutrition, pressure, etc. Reflecting that in reality, the body—and organs, tissues, and even individual cells—strives to achieve *homeostasis* (i.e., an optimal range of conditions) in the face of variations in the internal and external environments. This dynamic adaptation of biologic structure and function may require increased or decreased function, and requires signaling through soluble molecules (e.g., hormones, cytokines, etc.), as well as cell–cell and cell–ECM interactions (Fig. 2.1.4.5). Even extracellular mechanical forces (e.g., torsion or tension) can be translated into intracellular signaling or transcription events. Thus tissue homeostasis can also critically depend on cellular interactions with the surrounding ECM. (Smith et al, 2018)

Cell Turnover

A fundamental concept is that structural and functional specialization is typically associated with large-scale loss of the capacity for cellular replication; for example, neutrophils, cardiac myocytes, and neurons are all end-stage cells and cannot proliferate. In the small bowel, the terminally differentiated absorptive cells actually divide no further and undergo programmed cell death within 3–4 days of their genesis. Consequently, maintaining cell numbers or repairing sites of injury require multipotent stem cells to proliferate and differentiate. Thus, even in fully developed organisms, populations of multipotential cells capable of repopulating adult tissues persist—providing the balance between cellular proliferation, programmed cell death (*apoptosis*), and *differentiation* into specialized end-stage cells that have lost the ability to reproduce (Fig. 2.1.4.11).

Matrix Remodeling

In most tissues, the ECM is constantly turning over and being remodeled in a coordinated, regulated manner. Although matrix turnover is generally quite low in normal mature (i.e., stable) tissues, rapid and extensive remodeling characterizes embryological development, adaptation to changing environmental conditions, and wound repair. Tissue remodeling is a major goal of many tissue-engineering approaches, and an understanding of cell–substrate interactions and matrix remodeling are central to the application of biomaterials technology, tissue engineering, and regenerative therapeutics.

Connective tissue remodeling, either physiological or pathological, is typically a highly organized process involving the coordinated action of a group of enzymes that can collectively degrade most proteins of the ECM. Called *matrix metalloproteinases* (MMPs), these are synthesized by macrophages, fibroblasts, and epithelial cells; 28 MMPs have been described, each with a distinct specificity for the various types of collagens and other ECM components. MMP enzymatic activities are counterregulated by *tissue inhibitors of metalloproteinases* (TIMPs); these are multifunctional proteins with both MMP inhibitor activity and cell growth modulating properties. Distortion of the balance between matrix synthesis and turnover may result in altered matrix composition amounts and organization. Particularly important in tissue remodeling are *myofibroblasts*, cells with features of both smooth muscle cells

(i.e., contractile proteins such as α-actin) and fibroblasts (i.e., synthesis of ECM proteins such as collagen).

Cell and Tissue Injury, Adaptation, and Other Responses (Fig. 2.1.4.12)

For more detail, see Rubin et al. (2014) and Kumar et al. (2015). As noted previously, cells and tissues attempt to maintain their milieu and function within a relatively narrow range of physiologic parameters (*homeostasis*). However, as cells and tissues encounter more challenging physiologic stresses or pathologic stimuli, they undergo more extensive changes (*adaptations*) designed to achieve a new steady state but in all cases to preserve viability. Usually, if the stressors recede, the cells and tissues will revert to their prestressed state. However, if the stressors persist and a cell's adaptive capability is exceeded, *cell injury* develops. Up to a point, cell injury itself is reversible, and with normalization of the stimulus, the cell returns to its baseline state. However, with severe or persistent stress, the cell suffers irreversible injury and dies. For example, when heart muscle cells are subjected to diminished blood flow due to an occluded coronary artery, there is an imbalance between blood supply and energy demand (a physiological condition called *ischemia*); fortunately, the cells may be only *reversibly injured* if the occlusion is incomplete or sufficiently brief. Alternatively, cardiac myocytes may undergo *irreversible injury* (i.e., cell death, also called *necrosis*, as in *myocardial infarction*) if there is complete or prolonged ischemia caused by arterial occlusion. Other types of responses may be initially adaptive and protective but eventually progress to pathologic states; as described later, these include *atrophy* (i.e., a decrease or organ or tissue size or function); *hypertrophy* (i.e., an increase in cell size and function); or *hyperplasia* (i.e., an increase in cell number).

Cell Regeneration and Proliferation

At a tissue level, the ability to regenerate is a function of the level of differentiation of the stem cells within that tissue and their overall replicative potential. These fall into three broad general categories: *labile*, *stable*, and *permanent* tissues.

Labile tissues have pluripotent stem cells that are constantly in cell cycle and thus constantly generating new cells that will differentiate into the final population comprising the parenchyma of that particular organ. As those final differentiated cells senesce, they typically undergo programmed cell death (*apoptosis*, discussed later); nevertheless, they are continuously being replaced by cells of the "next generation," and thus the integrity of the tissue is maintained. These tissues include many epithelia that cover the skin, oral cavity, vagina, and cervix; the linings of the ducts draining exocrine organs (e.g., salivary glands, pancreas, biliary tract, gastrointestinal tract, uterus, fallopian tubes, and the urinary tract). The hematopoietic cells of the bone marrow are also continuously replenishing the circulating peripheral blood cell elements. As a corollary of their ongoing proliferation, labile tissues typically repopulate sites of injury relatively quickly. However, they are also most sensitive to extrinsic insults such as radiation or chemotherapy for tumors—which is why patients being treated for cancer lose their hair (hair follicle epithelium), malabsorb food (gastrointestinal epithelium), and are anemic and prone to infections and bleeding (bone marrow).

Stable tissues have pluripotent stem cells that typically rest in a quiescent stage of the cell cycle and are not actively turning over. However, these cells have substantial regenerative capacity when stimulated by injury or surgical cell loss; these include the parenchymal cells of the liver and kidney, as well as endothelial cells, fibroblasts, and smooth muscle.

Permanent tissues include neurons and cardiac myocytes. Classically, cardiac muscle cells and neurons are considered as terminally differentiated cells without the ability to reproduce. Skeletal muscle has a limited regenerative capacity, largely due to the proliferation and transformation of a small population of stem cells. Moreover, we are also learning that terminally differentiated permanent cells—previously thought to be irreplaceable once destroyed (e.g., nerve and cardiac muscle)—may be potentially repopulated by bone marrow-derived stem cells or even small populations of tissue-endogenous stem cells. While exciting, the extent to which we can utilize this replacement process appears to be very limited; for all practical purposes (for now), dead permanent cells are repaired by scar formation (Buja, 2019; Talman and Ruskoaho, 2016). There is also accumulating evidence to suggest that cells of end-stage, highly differentiated tissues can, under very limited conditions (e.g., some forms of injury), dedifferentiate into multipotent stem cells (Ma et al, 2017; Brumbaugh et al, 2019).

These concepts have important ramifications not only for embryogenesis, but also for the tissue engineer. For applications that require large numbers of differentiated cells, expansion of terminally differentiated cell populations may work for some cell types (e.g., skin). However, cells such as heart or nerve will probably require directed differentiation from expanded stem cells.

Reversible versus Irreversible Injury

Whether a specific form of stress induces adaptation or causes reversible or irreversible injury depends not only on the type of injury, its duration, and the severity of the stress, but also on several other cell-specific variables, including vulnerability of the type of cell being injured, degree of differentiation, blood supply, nutrition, and the previous state of health of the cell. For example, skeletal muscle in the leg can tolerate complete ischemia for 2–3 h without suffering irreversible injury, while cardiac muscle will die after only 20–30 min, and central nervous system neurons are dead after 2–3 min. Within limits, cells can compensate for disturbance of any of these, and if the injurious stimulus abates, will return to normalcy. Persistent or excessive injury, however, causes cells to pass the threshold into *irreversible injury*. In other words, they die;

in pathology jargon, the cells are said to become *necrotic* or undergo *necrosis*. The specialized activities relating to cell function may shut down relatively early in the setting of injury, and in most cases long before there is any cell death. For example, myocardial cells become noncontractile after 1–2 min of ischemia, although they will not die until 20–30 min of ischemia have elapsed. Consequently, if the injury can be halted before cells become irretrievably damaged then restoration of function can be anticipated. Of course, lack of cardiac function may lead to death of other important structures (e.g., the brain) even before the heart cells themselves reach the "point of no return."

Adaptation

As cells and tissues encounter more chronic physiologic stresses or pathologic stimuli, they undergo adaptations designed to achieve a new steady state, but in all cases to preserve tissue function. The principal significant adaptive responses are:

hypertrophy: an increase in size of individual cells;
hyperplasia: an increase in cell number;
atrophy: a decrease in size, without appreciable change in cell number;
metaplasia: transformation from one mature cell type to another.

For example, when heart muscle cells are subjected to persistent increased load (e.g., high blood pressure), the cells adapt by undergoing *hypertrophy* (enlargement of the individual myocytes and eventually the entire heart) to compensate for the higher pressures they must pump against. Conversely, in periods of prolonged starvation (as can happen in prolonged illness or with malignant tumors), all myocytes (and thus the heart) will undergo *atrophy*. Hypertrophy and hyperplasia are closely related and often develop concurrently in tissues, so that both may contribute to an overall increase in organ size in organs whose cells can proliferate (i.e., the gravid uterus).

Hyperplasia Can Be Physiologic or Pathologic

Physiologic hyperplasia is divided into (1) hormonal hyperplasia, exemplified by proliferation of the glandular epithelium of the female breast at puberty and during pregnancy, and (2) compensatory hyperplasia, that is, hyperplasia that occurs when a portion of the tissue is removed or diseased—driven by local growth factor expression. Hyperplasia is also a critical response of connective tissue cells in wound healing, by which growth factor-stimulated fibroblasts and blood vessels proliferate to facilitate repair.

Atrophy, Proteasomes, and Autophagy

Loss of cell substance will result in reduction in cell size—denoted as atrophy. When a sufficient number of cells are involved, the entire tissue or organ diminishes in size, becoming atrophic. It should be emphasized that *although atrophic cells may have diminished function, they are not dead*. Atrophy represents a reduction in the structural elements of the cell; the biochemical mechanisms underlying this process are varied but ultimately affect the balance between synthesis and degradation. Causes of atrophy include decreased workload (for example, immobilization of a limb to permit healing of a fracture), loss of innervation, diminished blood supply, inadequate nutrition, loss of endocrine stimulation, and aging. Although some of these stimuli are physiologic (e.g., loss of hormone stimulation in menopause) and others pathologic (e.g., denervation), the fundamental cellular changes are identical. They represent a retreat by the cell to a smaller size at which survival is still possible; a new equilibrium is achieved between cell size and diminished blood supply, nutrition, or trophic stimulation.

Mammalian cells contain two systems that serve distinct degradative functions:

- The *ubiquitin–proteasome pathway* is responsible for the degradation of many cytosolic and nuclear proteins.
- *Lysosomes* contain proteases and other enzymes that degrade *endocytosed molecules* and *phagocytosed particles* from the extracellular environment, as well as catabolize cellular components such as *senescent organelles.*

Metaplasia

Metaplasia is a reversible change in which one adult cell type (epithelial or mesenchymal) is replaced by another adult cell type. This is a cellular adaptation whereby cells sensitive to a particular stress are replaced by other cell types putatively "better" able to withstand the adverse environment. Metaplasia is thought to arise by genetic *reprogramming* of stem cells.

Neoplasia

Beyond adaptive responses, environmental stimuli can also induce genetic changes that can trigger abnormal proliferation and differentiation. Such behavior is uncoordinated relative to normal tissues, has lost its responsiveness to normal growth controls, and persists after cessation of the stimuli that initiated it. This condition is called *neoplasia*; in its malignant form, it is more commonly called *cancer* (see Chapter 2.5.11).

Causes of Cell Injury

Hypoxia and Ischemia

The efficient production of ATP by mitochondria—and therefore the energy needed to run all cell activities—is critically dependent on oxygen. *Hypoxia* is decreased O_2 supply relative to the needs of a particular cell or tissue. *Anoxia* is the complete absence of oxygen. Tissue hypoxia can occur in any setting where there is reduced oxygen tension, including causes as diverse as high altitude, anemia, and carbon monoxide poisoning (the latter diminishes the oxygen-carrying capacity of hemoglobin). However, the most common cause of tissue hypoxia is diminished blood flow, called *ischemia.* Irreversible tissue injury (*necrosis*) due to ischemia is called *infarction*

(as already discussed). It is also important to note that diminished blood flow will also affect the ability to remove waste products from a metabolizing tissue, so that, all things considered, *ischemia is far worse than simple hypoxia.*

Toxic Injury and Trauma

Chemical agents include components of food, naturally occurring toxins, hormones, neurotransmitters, synthetic drugs, environmental pollutants, poisons, ethanol, tobacco, and even toxic biomaterials. Chemicals induce cell injury by one of two general mechanisms:

- By combining directly with a critical molecular component or cellular organelle and thereby inhibiting its normal activity.
- Chemicals that are not intrinsically biologically active may be converted to toxic metabolites during normal physiologic breakdown.

Injury can also result by direct mechanical force (trauma, pressure), temperature extremes (burn, frostbite), electric shock, or ionizing radiation.

Infection and Inflammation

Infectious agents run the gamut from virus and bacteria to fungi, protozoans, and helminths (worms). There is generally a preferred cell or tissue of invasion (called a *tropism*), and therefore each agent tends to have a defined spectrum of potential injury. *Viruses* multiply intracellularly, appropriating host biosynthetic machinery in the process; cell lysis may occur directly, or as a result of the immune system's recognition and destruction of infected cells. *Bacteria* have toxic cell wall constituents (e.g., endotoxin), and can release a variety of exotoxins. Moreover, the very process of eradicating infections by the host immune system can also cause injury—and in many cases constitutes the bulk of the pathology.

Pathogenesis of Cell Injury

There are three basic mechanisms of cell injury:

- *Loss of adequate ATP production.* Ischemia, hypoxia, or mitochondrial dysfunction will all cause a precipitous drop in ATP synthesis.
- *Oxygen and oxygen-derived free radicals.* Lack of oxygen (and loss of ATP production) obviously underlies the pathogenesis of ischemic cell injury. In addition, *partially reduced, activated oxygen species* are important mediators of cell death. *Free radicals* are chemical species with a single unpaired electron in an outer orbital; they are extremely unstable and readily react with inorganic or organic chemicals. When generated in cells, free radicals cause single-strand breaks in DNA, fragment lipids in membranes via lipid peroxidation, and fragment or cross-link proteins leading to accelerated degradation or loss of enzymatic activity.
- *Failure of intracellular calcium homeostatic mechanisms.* Cytosolic free calcium is normally maintained by ATP-dependent calcium transporters at extremely low concentrations (less than 0.1 μM), while extracellular calcium and sequestered mitochondrial and endoplasmic reticulum calcium stores are typically at roughly 10^4-fold higher concentrations. Consequently, any cell ischemia or injury potentially opens a floodgate of calcium. Increased cytosolic calcium in turn activates a variety of *phospholipases* (promoting membrane damage), *proteases* (catabolizing structural and membrane proteins), *ATPases* (accelerating ATP depletion), and *endonucleases* (fragmenting genetic material).

Ischemia-Reperfusion Injury

If cells are reversibly injured in ischemic circumstances, restoration of blood flow should theoretically result in cell recovery. However, in many cases, restoration of blood flow to ischemic but otherwise viable tissues results in paradoxically exacerbated and accelerated injury.

Cell Death

Necrosis

Two phenomena consistently characterize irreversible injury. The first is the *inability to reverse mitochondrial dysfunction* (lack of oxidative phosphorylation and ATP generation) even upon restoration of oxygen; the second is the development of *profound disturbances in membrane function.* Massive calcium influx into the cell occurs, particularly if ischemic tissue is reperfused after the point of irreversible injury, with broad activation of calcium-dependent catabolic enzymes. Precipitation of calcium salts in cells (*calcification*) is discussed in detail in Chapter 2.4.4.

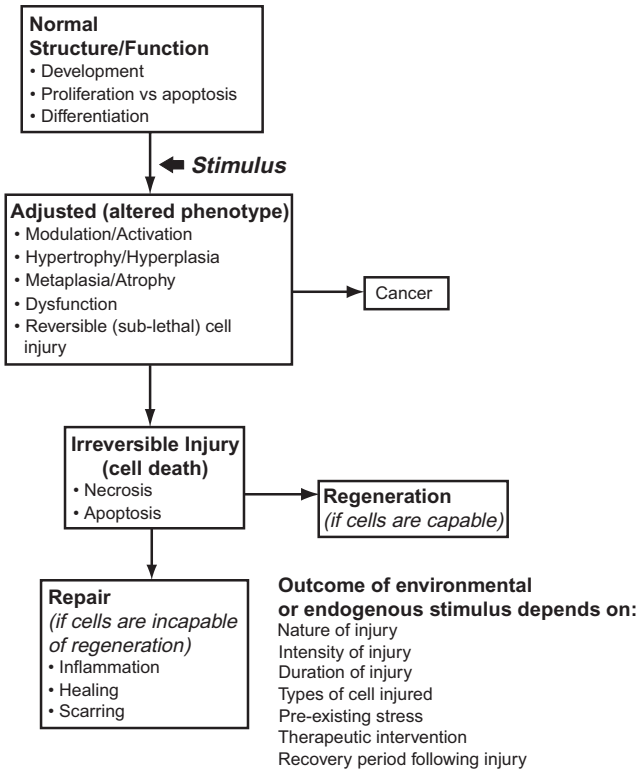
Since necrotic tissue is a potential nidus for secondary infections, the body rapidly mobilizes inflammatory cells to remove the resulting debris and initiates the process of either rebuilding the dead tissue or laying down a fibrous scar (see Chapter 2.2.2). As mentioned previously, the recruited inflammation can in itself be a cause of further local injury. Moreover, having to replace a specialized tissue with a nonfunctional matrix scar is also a less than optimal outcome.

Apoptosis

The cell death that has been thus far described is the consequence of irreversible injury; in a way, this can be thought of as cellular "homicide." However, there is also an important form of controlled or *programmed* cell death that can be conceptualized as cellular "suicide." Apoptosis is responsible for programmed cell death in several important physiologic (as well as pathologic) processes, including:

- the programmed destruction of cells during embryogenesis, including implantation, organogenesis, and developmental involution;
- hormone-dependent physiologic involution, such as the endometrium during the menstrual cycle, or the lactating breast after weaning; or pathologic atrophy, as in the prostate after castration;

- cell deletion in proliferating populations such as intestinal crypt epithelium, or cell death in tumors;
- deletion of autoreactive T cells in the thymus, cell death of cytokine-starved lymphocytes, or cell death induced by cytotoxic T cells;



• **Figure 2.1.4.13** Cellular mechanisms of disease, emphasizing the general concept that stressor stimuli induce altered cell behaviors (reversible cell injury with phenotypic alterations) to compensate and maintain viability; notably, such changes can also lead to malignancy. Failure to successfully adapt to stressors leads to irreversible cell injury (death) with the downstream outcomes of regeneration and/or scarring, depending on cell type and other variables.

- a variety of mild injurious stimuli (heat, radiation, cytotoxic cancer drugs, etc.) that cause irreparable DNA damage that in turn triggers cell suicide.

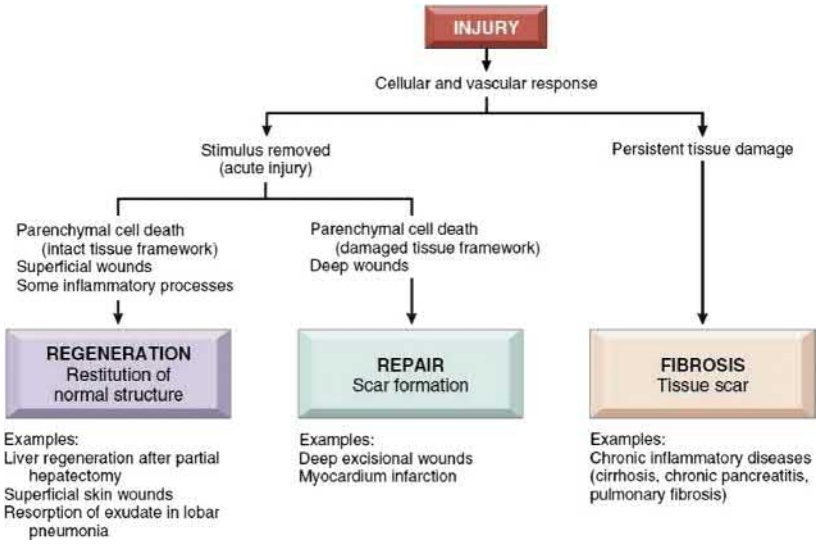
Apoptotic cells and their fragments have marker molecules on their surfaces that signal uptake and disposal by adjacent cells or phagocytes. This (and other) alterations allow the early recognition and phagocytosis of apoptotic cells without release of proinflammatory mediators. The process is so efficient that dead cells typically disappear without leaving a trace, and inflammation is virtually absent.

The general framework of cell injury (and subsequent responses to injury) is summarized in Fig. 2.1.4.13.

Response to Tissue Injury and Biomaterials

A key protective response of an organism is its ability to eliminate damaged tissues and foreign invaders, such as microbes or exogenous nonbiological materials (examples of the latter ranging from splinters to inhaled environmental particulate pollutants to therapeutic biomaterials). The goal of this response is to rid the organism of both the cause of injury (especially if it is microbial) and ameliorate potential adverse consequences (i.e., secondary infection). Without this protective process, tissue wounds would not heal and infections would go unchecked. However, inappropriately triggered or inadequately controlled inflammation can also be harmful. Inflammation usually is a highly coordinated sequence of events involving local and circulating proteins, leukocytes, and phagocytic cells (macrophages) that are recruited to a site of injury.

The outcome of tissue injury depends primarily on the tissue type and the extent and persistence of the injury (Fig. 2.1.4.14). When tissue injury is transient or short-lived, tissue destruction is small, the tissue is capable of regeneration, and the outcome is typically (and happily) restoration of normal structure and function. When an infection or foreign material cannot be eliminated, (Singer and Clark, 1999)



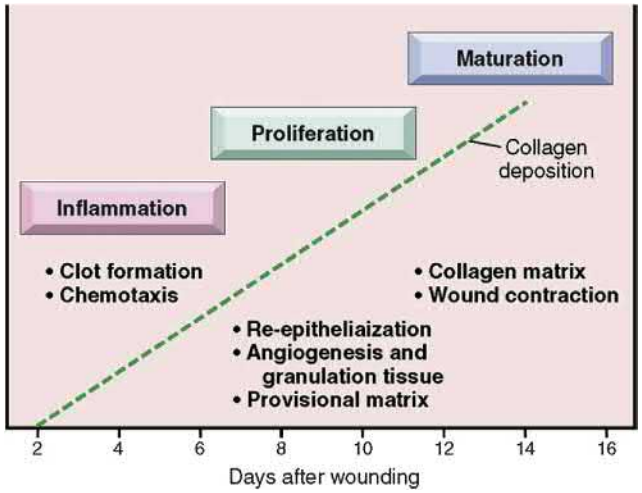
• **Figure 2.1.4.14** Regeneration, repair, and fibrosis after injury and inflammation. (Reproduced by permission from Kumar, V., Abbas, A.K., Fausto, N., Aster, J.C., 2010. Robbins and Cotran Pathologic Basis of Disease, eighth ed. Saunders, Philadelphia, PA.)

when the injury is extensive, or occurs in tissues that do not regenerate, inflammation and scarring occur. In those situations, the body often "controls" the foreign body or infection by creating a wall around it (see Chapter 2.2.2).

In the case of most "inert" materials, the late tissue reaction involves *encapsulation* by a fibrous tissue capsule (composed of collagen and fibroblasts). Encapsulation is largely a result of the healing of the wound engendered by the implantation of a biomaterial. If a superimposed infection occurs that cannot be easily eliminated, an abscess (i.e., localized collection of acute inflammation and infectious organisms) is the outcome, adding yet an additional component of injury.

Inflammation and Innate Immunity

As described earlier, inflammation and repair follow cell and tissue injury induced by various exogenous and endogenous stimuli, both eliminating (i.e., diluting, destroying, or isolating) the cause of the injury (e.g., microbes or toxins) and degrading necrotic cells and tissues that occur as a result of the injury. In doing so, the inflammatory response initiates the process that heals and reconstitutes the tissue, replacing the wound by native parenchymal cells, or by filling up the defect with fibroblastic scar tissue, or some combination of both. Although *lymphocytes (B and T cells)* may eventually be involved in responses to various forms of injury (so-called *antigen specific* or *adaptive immunity*), the initial response to cell and tissue damage is the cells of innate immunity, *neutrophils* and *macrophages*. In the vast majority of cases, these innate cells (and their mediators) are sufficient to resolve the original injury and drive the regenerative or scarring process. As described later, these cells lack the exquisite specificity of lymphocytes, but nevertheless do have a reasonable repertoire of receptors that allow them to recognize pathogens and damaged tissues (for additional information, see Chapter 2.2.3).



• **Figure 2.1.4.15** Phases of cutaneous wound healing: inflammation, proliferation, and maturation. (Reproduced by permission from Kumar, V., Abbas, A.K., Fausto, N., Aster, J.C., 2010. Robbins and Cotran Pathologic Basis of Disease, eighth ed. Saunders, Philadelphia, PA.)

Inflammation and repair constitute an overlapping sequence of several processes (Fig. 2.1.4.15):

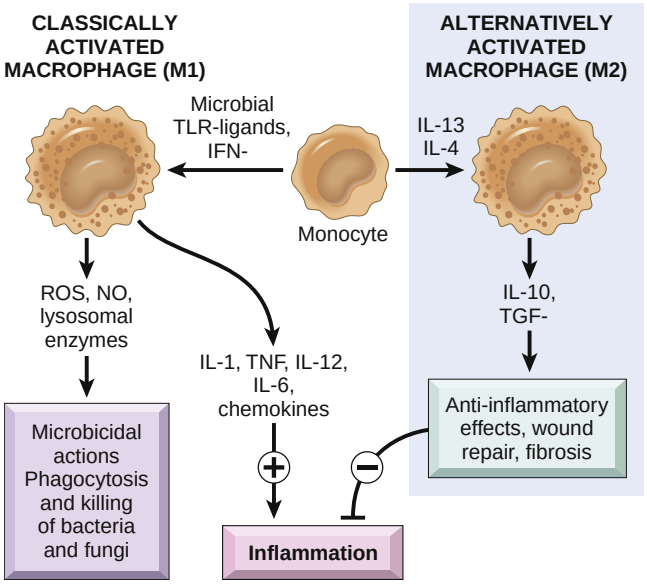
- Acute inflammation is the immediate early response to injury. It is of relatively short duration (usually 1–3 days) and is characterized by fluid and plasma protein exudation into the tissue, as well as by the accumulation of the innate immune cells called *neutrophils* (*PMNs*). Neutrophils are recruited to sites of inflammation through the increased adhesiveness of endothelium in the postcapillary venules at those sites, and by the local elaboration of several chemotaxic mediators (*chemokines*).
- Chronic inflammation: This next phase (days to weeks after injury) involves macrophage recruitment (these are also cells of *innate immunity*), and later—in some cases—lymphocytes (cells of *adaptive immunity*); there is often concurrent tissue destruction. The chronic inflammatory response is responsible for driving the subsequent *repair* mechanisms, representing some combination of host tissue *regeneration* versus *scarring*.

A special type of chronic inflammation characterized by activated macrophages and often multinucleated giant cells is called a *granuloma* or *granulomatous inflammation*. Granulomatous inflammation characteristically occurs when the inciting agent cannot be degraded, including in the setting of implanted foreign bodies.

- Scarring: In situations where repair cannot be accomplished by complete tissue regeneration, scarring will ensue. This occurs through three sequential processes: (1) formation of new blood vessels (*angiogenesis*), (2) deposition of collagen (*fibrosis*), and (3) maturation and remodeling of the scar (*remodeling*). The early healing tissue—called *granulation tissue* (not to be confused with granuloma, above)—exhibits a dense network of new capillaries and proliferating fibroblasts (synthesizing new ECM). The ECM deposition in scarring is usually well developed by 4–6 weeks, although full scar remodeling may require much longer. (Gurtner et al, 2008; Rodriguez et al, 2019; Wynn and Vannella, 2016).

Macrophage Recruitment and Polarization

Tissue macrophages—and their bone marrow-derived circulating precursors, (Caputa et al, 2019; Kim and Nair, 2019) the *monocytes*—are the central figures in chronic inflammation. The half-life of circulating monocytes is about 1 day; they begin to emigrate at the site of injury within the first 24–48 h after onset of acute inflammation. However, once they have transmigrated into the tissues and assumed the identity of macrophages, these cells are impressively long-lived, and in fact may persist for the lifetime of the host organism. Transmigrated macrophages may become "activated," a process resulting in increased cell size, increased content of lysosomal enzymes, more active metabolism, and greater ability to kill ingested organisms. Activation signals include cytokines secreted by sensitized T lymphocytes (in particular interferon-γ), bacterial endotoxins (lipopolysaccharide), various mediators produced during acute inflammation, and



• **Figure 2.1.4.16** Classical and alternative macrophage activation. Different stimuli activate monocytes/macrophages to develop into functionally distinct populations. Classically activated (M1) macrophages are induced by microbial products (via toll-like receptors [TLRs]) and cytokines, particularly interferon-γ (IFN-γ). M1 macrophages phagocytose and degrade microbes and necrotic material, as well as augment inflammatory reactions through the production of additional cytokines (e.g., interleukin [IL]-1, tumor necrosis factor [TNF], etc.) and mediators such as reactive oxygen species (ROSs), lysosomal enzymes, and nitric oxide (NO). Alternatively activated macrophages (M2) are induced by a different set of cytokines (e.g., IL-13 and IL-4); they are critical for coordinating tissue repair and the resolution of inflammation. *TGF-β*, Transforming growth factor-β. (Reproduced by permission from Kumar, V., Abbas, A.K., Aster, J.C. (Eds.), 2018. Robbins Basic Pathology, tenth ed. Elsevier, Philadelphia, PA.)

ECM proteins such as fibronectin. In the usual histologic preparations, "activated" macrophages are enlarged and have pale pink granular cytoplasm with indistinct cell boundaries, so-called *epithelioid* macrophages (because they resemble the cells that comprise squamous epithelium).

Following activation, *macrophages secrete a wide variety of biologically active products* important in mediating subsequent tissue destruction, angiogenesis, and the fibrosis characteristic of chronic inflammation. *Steroids* have their profound salutary effects on chronic inflammation and subsequent scarring largely due to their inhibition of macrophage activation.

Products synthesized by activated macrophages are:

- *Acid and neutral proteases*, which can digest and/or remodel the ECM.
- *Complement components and coagulation factors.* Although hepatocytes are the major source of these proteins in plasma, activated macrophages make locally significant amounts of these proteins in the ECM.
- *Reactive oxygen species and nitric oxide.*
- *Prostaglandins and leukotrienes.*
- *Cytokines*, such as interleukin-1 and tumor necrosis factor, as well as a variety of *growth factors* that influence proliferation and ECM production by smooth muscle cells and fibroblasts.

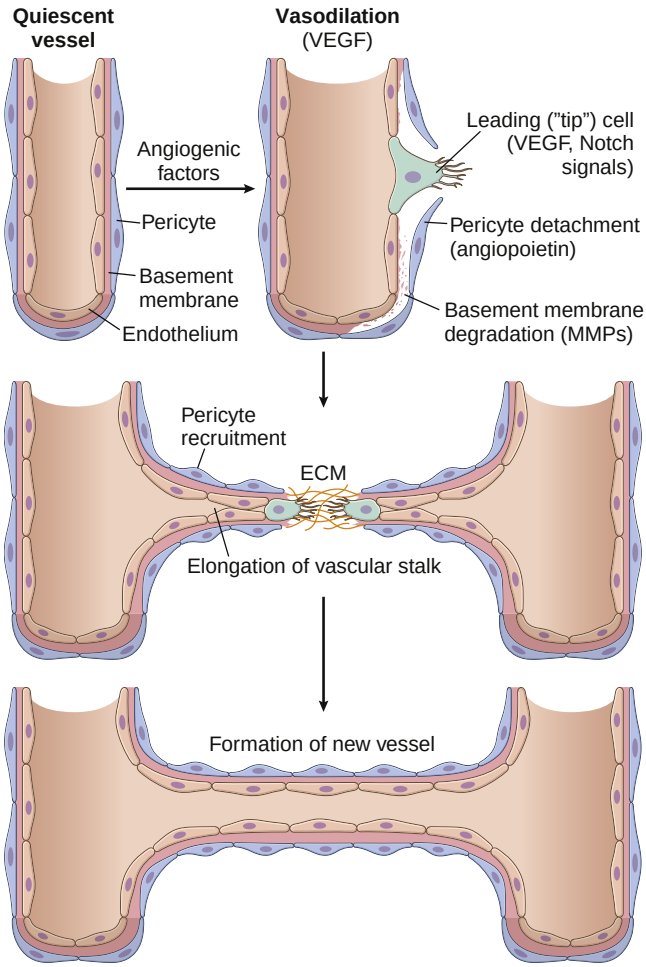
Macrophages comprise at least two distinct subsets with distinct functions, depending on the pathways by which they are activated (Fig. 2.1.4.16) (Adams et al, 2019). The classically activated M1 macrophage—induced by interferon-γ and toll-like receptor pathways—that is initially induced at a site of injury is typically proinflammatory; it not only recruits and activates additional inflammatory cells, but also exhibits increased cytotoxic features. Alternatively, the M2 macrophage subset (induced by interleukins-4 and -13, or by hemoglobin in sites of hemorrhage) develops later in the response to injury, and tends to turn off inflammation, producing cytokines and enzymes that drive fibrosis. Recent experiments suggest that M1 macrophages can differentiate into M2 macrophages (and vice versa), depending on the cytokine milieu, and that the gradual transition from predominantly M1 to M2 at the sites of wound healing are not necessarily due to differential recruitment of the two subsets.

Regeneration Versus Fibrosis (Scar)

In terms of healing and reparative potential, the mitotic capability of a cell population, *or* the capacity of immature precursor cells to divide and differentiate to fill an injured void, will ultimately decide the outcome of tissue destruction. As discussed previously, not all cells are equally capable of such proliferative expansion. In labile and stable cells capable of regeneration, the cell proliferation process is regulated by a combination of *cell–ECM interactions* and *growth factors* (Fig. 2.1.4.5). ECM provides a substratum for cell adhesion, and critically regulates the growth, movement, and differentiation of the cells living within it. Importantly, although labile and stable cells are capable of complete regeneration, *reconstitution of normal structure requires an intact ECM*. In particular, the basement membrane directs cell polarity and is required for the orderly renewal of an epithelial tissue; in the absence of an intact basement membrane, cells proliferate in a haphazard fashion, producing disorganized masses bearing no morphologic and—more importantly—no functional resemblance to the original tissue.

Growth Factors

For the most part, these are polypeptides that can act on a variety of cell types, or may have a rather circumscribed target population. Besides promoting growth, these mediators also influence cell locomotion, contractility, protein synthesis, and differentiation (i.e., almost *any* cellular activity), all of which can affect repair and wound healing. The various growth factors typically work via cell-to-cell communication over short distances. For example, wound healing and repair in connective tissues are most commonly achieved by one cell in a tissue secreting a factor that regulates the activities of adjacent cells (*paracrine pathways*). Cells that carry receptors for their own endogenously produced factors will also exhibit *autocrine stimulation*, important in compensatory epithelial hyperplasia at sites of injury (e.g., hepatic regeneration). In addition to specific signals that stimulate and positively regulate growth, cells and tissues are also maintained by a number of *negative growth inhibitory signals.*



• **Figure 2.1.4.17** Angiogenesis. In tissue repair, angiogenesis primarily occurs through the sprouting of new vessels, driven by vascular endothelial growth factor (VEGF) and other soluble mediators. The process involves basement membrane degradation, endothelial proliferation, chemotaxis, and differentiation, as well as the recruitment of pericytes to form mature vessels. (Reproduced by permission from Kumar, V., Abbas, A.K., Aster, J.C. (Eds.), 2018. Robbins Basic Pathology, tenth ed. Elsevier, Philadelphia, PA.)

When cells are not capable of complete proliferative regeneration or when the ECM is not entirely preserved, the outcome will be scar. This involves the progressive degradation of the originally damaged tissues, the generation of new blood vessels to provide a path for delivering nutrients and cells to make the scar, and eventually remodeling of the deposited matrix.

Vascular Response

New vessels in the evolving site of repair originate by budding from preexisting vessels, a process called *angiogenesis* or *neovascularization* (Fig. 2.1.4.17). There are several different proangiogenic mediators (many synthesized by activated macrophages), although *vascular endothelial growth factor* (VEGF) and *basic fibroblast growth factor* are probably the most important. These factors induce the following vasculogenic effects:

- proteolytic degradation of the parent vessel basement membrane allowing formation of a capillary sprout;
- migration of endothelial cells toward the angiogenic stimulus;
- proliferation of the endothelial cells behind the leading front of migrating cells;
- maturation of endothelial cells and organization into capillary tubes.

These new vessels have incompletely formed interendothelial junctions, resulting in the leakage of proteins and red cells into the extravascular space. VEGF also profoundly increases endothelial transcytosis, which will augment fluid leak across the vessel wall. Indeed, this leakiness explains why *granulation tissue is often edematous*, and accounts for much of the edema that persists in healing wounds long after the acute inflammatory response has resolved. Subsequent long-term vessel stabilization of the new vessels requires *angiopoietin-1* binding to Tie2 receptors on endothelial cells to induce perivascular *pericyte* (perivascular smooth muscle-like cells) recruitment.

Wound Healing in the Presence of Biomaterials

For biomaterials and medical device implantation, two sources of injury are important: that caused by the surgery itself, and that secondary to the implanted foreign body (for additional details, see chapter on inflammation, FBR and repair - Babensee). Regardless of the size, nature, and overall biocompatibility of an implant, some degree of tissue disruption, necrosis, and cell damage is unavoidable, even with minimally invasive insertion. By itself, this will induce some inflammation and fibrosis at the tissue–implant interface. In general, synthetic biomaterials are not immunogenic, and are therefore not "rejected" by adaptive immune cells like a transplanted organ. However, they typically elicit a *foreign body reaction* (FBR), a special form of nonimmune inflammation involving the innate immune system. To the extent that a foreign body reaction is elicited, the fibrotic process will be augmented. The nature of the reaction is largely dependent on the chemical and physical characteristics of the implant. Tissue interactions can be modified by changing the chemistry of the surface (e.g., by adding specific chemical groupings to stimulate adhesion or bone formation in orthopedic implants, or inadvertently by adding some toxic component), inducing roughness, complexity, or porosity to enhance physical binding to the surrounding tissues, incorporating a surface-active agent to chemically bond the tissue, or using a bioresorbable component to allow slow replacement by tissue to simulate natural healing properties (Nour et al, 2019).

The most prominent cells in the FBR are macrophages, activated to phagocytose the material; however, degradation in many cases is likely to be difficult, if not impossible (e.g., a titanium implant). As already described, these activated macrophages (Chu et al, 2020) will elaborate cytokines that stimulate inflammation or fibrosis. The more *biocompatible* the implant, the more quiescent the ultimate response. However, in the absence of perfect biocompatibility, there will always be some degree of fibrosis. Moreover, the macrophage-driven

inflammation can cause local tissue injury; the ability of inflammatory cells to adhere to but not phagocytose particles larger than a critical size (*frustrated phagocytosis*) can lead to release of enzymes (exocytosis) to the extracellular environment. In bone, the cytokines elaborated by the macrophages can also induce bone resorption. Thus inflammatory cell products that are critical in killing microorganisms in typical inflammation can damage tissue adjacent to foreign bodies (e.g., osteolysis adjacent to an implant in bone).

Complications and Defective Wound Healing

In wound healing, normal cell growth and fibrosis may be altered by a variety of influences, frequently reducing the quality and adequacy of the reparative process:

- *Infection* is the single most important cause of delay in healing, by prolonging the inflammation phase of the process, and potentially increasing the local tissue injury.
- *Nutrition* has profound effects on wound healing; protein deficiency, for example, and particularly vitamin C deficiency, inhibit collagen synthesis and retard healing.
- *Glucocorticoids* have antiinflammatory effects (largely by reducing macrophage activation) and cause poor wound strength due to diminished fibrosis and/or remodeling.
- *Mechanical factors* such as increased local tension may cause wounds to pull apart (*dehisce*).
- *Poor perfusion* (e.g., due to atherosclerosis or obstructed venous drainage) also impairs healing.
- Finally, *foreign bodies* such as fragments of steel, glass, or even bone act as foci for chronic inflammation and impede healing.

Introduction

The extracellular matrix (ECM) serves as a microenvironmental niche providing both biophysical and biochemical signals in which cells reside and function within the body. Therefore, understanding the composition, structure, and functions of the native ECM is essential to engineering biomaterials for maintaining and/or directing cellular function for biomedical applications. This chapter summarizes compositions, properties, and functions of the native ECM, and how these inform the understanding and engineering of cell–biomaterial interactions. The following concepts are covered:

1. Definition, properties, and functions of the ECM
2. Cell–biomaterial interactions.

Extracellular Matrices

Extracellular matrices (ECMs) are heterogeneous mixtures of noncellular biological materials that, together with cells, constitute tissues and organs (Box 2.1.5.1). At a tissue-level, the ECM acts as scaffolding materials that provide structural and mechanical support. At a cellular-level, the ECM functions as a physical medium in which cells can adhere and function. Indeed, the ECM provides an array of biochemical and biophysical cues that regulate important cellular functions, including survival, proliferation, migration, self-renewal, and differentiation. Finally, the ECM also serves as a reservoir for growth factors and cytokines through sequestration; these signaling molecules are critical for modulating processes of tissue development, homeostasis, and regeneration (Fig. 2.1.5.1).

In many cases, the composition and structure of the ECM can permit highly specialized functions of a tissue. For example, in tendons, densely packed and aligned collagen fibers within the ECM grant high levels of tensile strength and elasticity (Benjamin et al., 2008). In the kidney, the glomerular basement membrane composed of a complex mixture of proteins, including type IV collagen, laminin, and proteoglycans, dictates selectively permeable filtration between the vasculature and the urinary space (Miner, 2012). Thus, variations in the ECM composition and structure can give rise to tissues with highly diverse forms and functions. Concurrently, tissue resident cells that interact with their ECM continuously process environmental cues to regulate tissue development, homeostasis, and regeneration.

The ECM is composed of cell-secreted proteins (Figs. 2.1.5.1 and 2.1.5.2A). The ECM is structurally dynamic and adaptive, as the cells constantly remodel (enzymatically and nonenzymatically) their surrounding microenvironment. Components of the ECM can be broadly classified into: (1) fibrillar, structural, and adhesive proteins (e.g., collagen, elastin, laminin, fibronectin, and vitronectin); (2) amorphous matrix macromolecules (e.g., proteoglycans, glycosaminoglycans, and hyaluronan); and (3) specialized soluble factors (e.g., growth factors, cytokines, and hormones). The ECM composition varies depending on the tissue type, developmental stage, age, and pathology. Details for these ECM components are discussed in the subsequent sections.

Properties of the Extracellular Matrix

The ECM provides a vast array of signaling cues for the cells to process and elicit downstream functions. Inherent ECM

properties define such signaling cues, which can be broadly categorized into biophysical and biochemical properties.

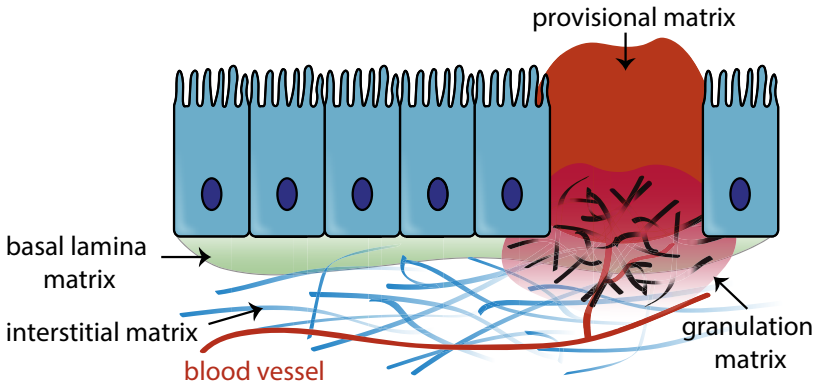
Biophysical properties of the ECM include stiffness, viscoelasticity, topography, and permeability (Fig. 2.1.5.2B). These properties dictate cellular functions in both direct and indirect manners. Mechanical properties of the ECM, such as stiffness and viscoelasticity, directly impact cellular phenotype and function through cell receptor-targeting ligands to which cells adhere. In response to the ECM mechanical properties, cells adapt their shape, cytoskeletal organization, and tension that result in changes to cellular function, such as migratory activity and gene expression. Structural properties of the ECM, such as topography, influence cellular shape, orientation, and alignment, which further contribute to determining tissue forms and function. The ECM instructs cells to regulate ECM composition and structure through an intricate feedback mechanism, a concept known as "dynamic reciprocity" (Bissell et al., 1982). Other biophysical properties, such as permeability, facilitate solute and nutrient transport. Thus, an assembly of biophysical properties of the ECM contributes to complex mechanisms governing tissue organogenesis, homeostasis, regeneration, and pathology in a cell- and tissue-specific manner.

Biochemical properties of the ECM include types of receptor-targeting ligands for cell adhesion, electrochemical potential, pH, protease sensitivity, and soluble signaling factors (Fig. 2.1.5.2B). Cells express a variety of receptors, including integrins, on their surface to bind to the ECM. The ECM proteins present targeted cell-binding sites that are specific to types of adhesion receptors (e.g., integrins) found on cell surface, which varies depending on the ECM composition (Fig. 2.1.5.2C). Engaging specific sets of adhesion receptors initiates critical cellular functions in a cell- and tissue-specific context, including cell survival, migration, proliferation, and stem cell self-renewal and differentiation. Interactions between receptors and the ECM also influence cellular anchorage to the ECM. Divalent cations, such as Ca^{2+} and Mg^{2+}, mediate the integrin–ligand binding event. Other ions present in the ECM, including Na^{+}, Cl^{-}, K^{+}, H^{+}, and OH^{-} are critical for maintaining physiological ionic concentration gradients, osmolarity, pH, and cellular membrane potential. Furthermore, certain ECM components (e.g., anionic hyaluronan and heparan sulfate proteoglycans) play important roles in sequestering specialized soluble factors (e.g., cationic growth factors) through charge interactions. Sequestration enables the ECM to protect growth factors from degradation, modulate availability in a spatiotemporal manner, and potentially enhance their activity. In some specialized tissues, such as articular cartilage, negatively charged proteoglycans interact with positively charged ions to achieve internal tissue pressurization through a Donnan osmotic effect (Mow et al., 1984; Roughley, 2006). This swelling effect gives articular cartilage not only the ability to withstand high compressive loads, but also provides a cellular microenvironment with high levels of hydrostatic and osmotic pressure to regulate

• BOX 2.1.5.1 Functions of the ECM

ECMs act as dynamic scaffolding materials that provide physical support and enable specialized functions of tissues. Furthermore, ECMs provide materials in which cells can adhere and function. The primary functions of ECMs include:

- Matrix for cell adhesion
- Regulation of cell morphology and orientation
- Regulation of cell proliferation
- Regulation of stem cell self-renewal and differentiation
- Sequestration and presentation of growth factors and cytokines.



Interstitial Matrix	Basal Lamina Matrix	Provisional Matrix	Granulation Matrix

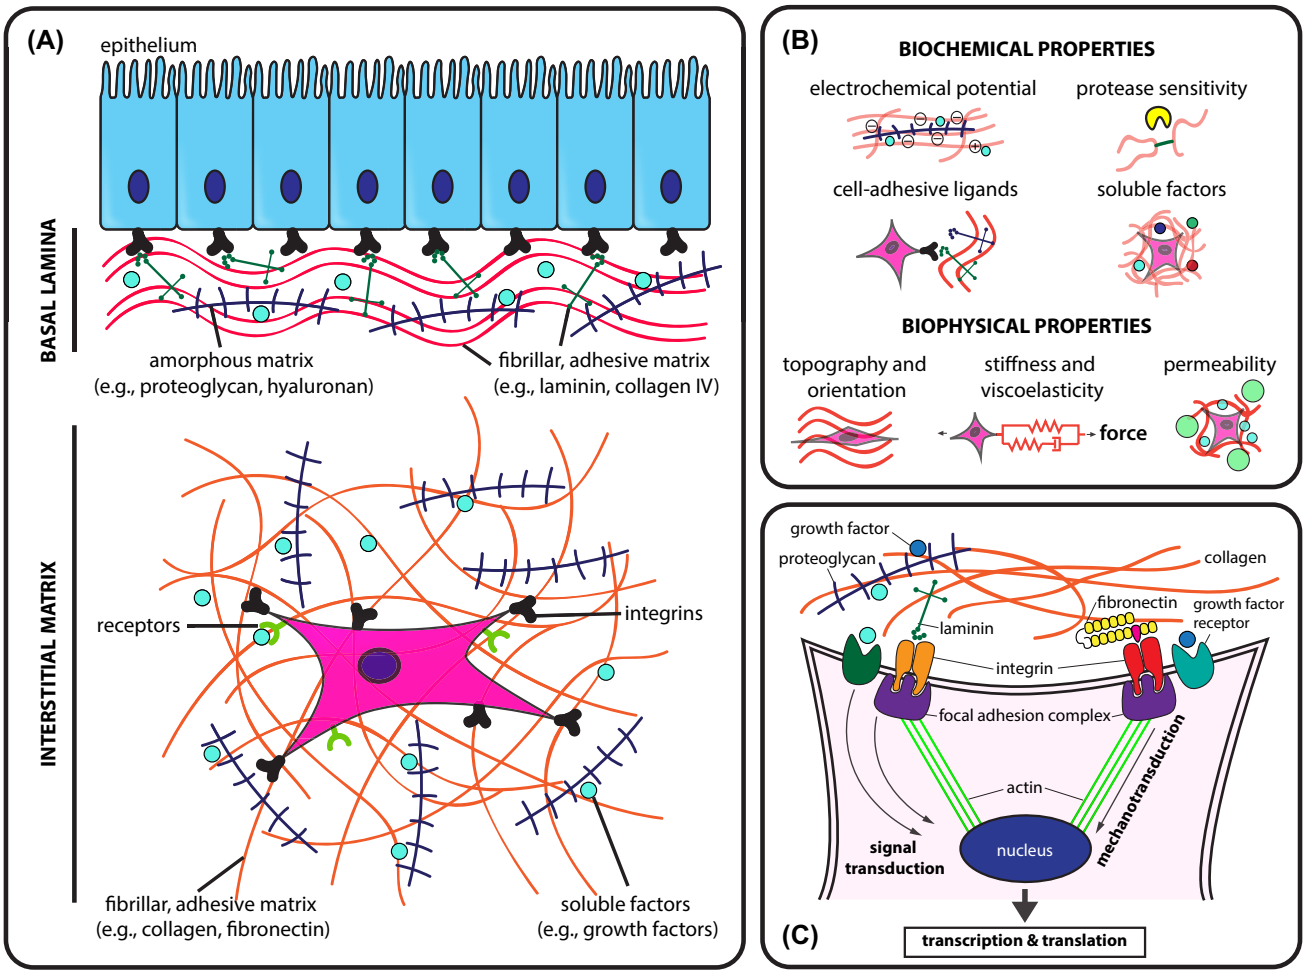
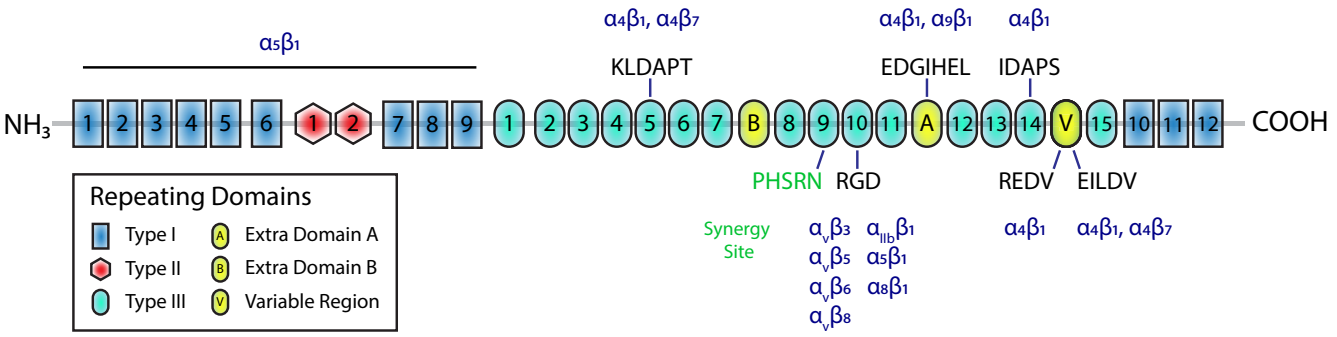
chondrocyte function. Finally, protease-sensitive domains found throughout various ECM proteins enable cells to readily degrade their surrounding matrix for remodeling and migration. Therefore, it is important to note that both biochemical and biophysical properties of the ECM collectively provide indispensable cell-instructive cues for regulating tissue development, homeostasis, and regeneration. ECM components that contribute to these properties are described below.

Collagens and Elastin

Collagen is a highly conserved family of proteins found throughout the body. In fact, collagen is one of the most common proteins in mammals, constituting approximately 25% of the whole-body protein composition. The primary function of collagen is to provide a structural framework for tissues and organs. In fibrous connective tissues, such as tendons, collagen plays an indispensable role in enabling tensile strength of a tissue. Collagen consists of a highly organized group of tropocollagens—a triple helical structure consisting of three polypeptide chains tightly coiled together. To date, there are over 25 different subtypes of collagens identified. Generally, these subtypes of collagens can be categorized into groups according to the structure they form—fibrillar and nonfibrillar. Collagen types I, II, III, and V are fibrillar collagens that are the most abundant in the body. Type I collagen is a ubiquitous component of hard and soft tissues, including skin, tendons, bone, and vasculature. Type II collagen is most commonly found in cartilaginous tissues, including articular cartilage and intervertebral disks. Type III collagen is a major component of soft tissues, including the liver and bone marrow. It is also normally present in conjunction with type I collagen. Type V collagen is found in dermal–epidermal junctions (e.g., hair) and placental tissues, and similarly to type III collagen, it is also commonly



• **Figure 2.1.5.2** The extracellular matrix (ECM). (A) Main components of the ECM. Prominent ECM components include collagens, fibronectin, laminins, proteoglycans, and growth factors. Basal lamina and interstitial matrix have different composition and structure. (B) Key properties of the ECM can be classified into biophysical and biochemical properties. These properties regulate cell behavior in both direct and indirect manners. (C) Cell–ECM interactions. Cells adhere to the ECM primarily through integrin–ECM interactions. Cells process various ECM cues through integrin and receptors. Integrins modulate activities of focal adhesion complexes and cytoskeleton, which further generate downstream signaling to alter transcription and translation.



• **Figure 2.1.5.3** Schematic of fibronectin depicting its structure, binding sites, and target integrins.

found in tissues containing type I collagen. Collagen type IV is a nonfibrillar collagen that is universally present in basement membranes, which form the basal lamina for epithelial and endothelial tissues throughout the body. Collagen, as one of the most abundant proteins that constitute the ECM, plays a critical role in giving tissues their mechanical and structural integrity. Consequently, it is one of the most important ECM components that prescribe the various biophysical properties of the ECM, such as stiffness, viscoelasticity, topography, and porosity. Furthermore, collagen also contains numerous integrin-binding domains that the cells can directly interact with. For example, integrins $\alpha_1\beta_1$ and $\alpha_2\beta_1$ are common collagen-targeting integrins that directly bind to sites within types I, II, and IV collagens (Gullberg et al., 1990; Staatz et al., 1991; Vandenberg et al., 1991). These $\alpha_1\beta_1$ an $\alpha_2\beta_1$ integrin-binding sites consist of the six-residue polypeptide sequence *GFOGER* arranged in a triple-helical conformation located in the α_1(I) chain of collagen I and IV (Knight et al., 2000; Reyes and García, 2003).

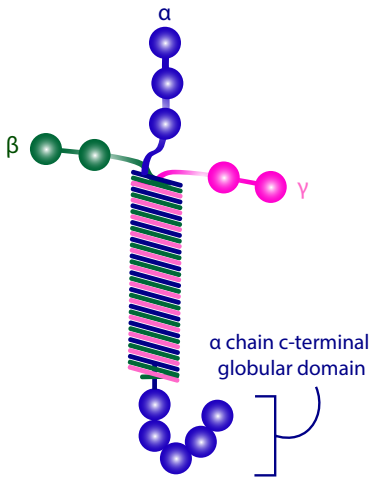
Elastic fibers, composed of elastin proteins, are primarily responsible for the highly elastic properties of a tissue, which allow tissues to return to their original or resting state after being deformed. Therefore, elastin plays a critical role in tissues that are mechanically dynamic, such as the arteries, lungs, skin, bladder, and tendons. Elastin further contributes to the complexity of ECM biophysical properties through direct regulation of the local elasticity at the cellular level. In addition, elastin possesses domains that target several integrins and other receptors. For example, the polypeptide sequences *GRKRK* and *VGVAPG* found in tropoelastin monomers bind $\alpha_v\beta_3$ and $\alpha_v\beta_5$ integrins, as well as a receptor known as the 67-kDa elastin-binding protein in a synergistic manner (Bax et al., 2009; Blood et al., 1988; Floquet et al., 2004; Lee et al., 2014; Patel et al., 2011).

Fibronectin

Fibronectin is a glycoprotein that contains numerous binding sites for integrins as well as other ECM proteins, such as collagen, fibrin, and proteoglycans. Two types of fibronectin exist: soluble plasma fibronectin and insoluble cellular fibronectin. Soluble fibronectin is a dimeric protein, where two polypeptide subunits are covalently joined by disulfide bonds at the C-terminal ends. Fibronectin is also synthesized and processed by cells to yield insoluble cellular fibronectin in the form of fibrils. The fibronectin molecule consists of three types of repeating domains: types I, II, and III (Fig. 2.1.5.3; Pankov and Yamada, 2002). These repeating domains present various binding sites for integrins and other ECM proteins as either exposed or cryptic forms (Fig. 2.1.5.3). Cryptic interaction sites, often found in type III domains, are normally inaccessible to binding due to their structure. However, these cryptic sites become accessible upon conformational change, such as cell-mediated mechanical unfolding of the protein, suggesting its dynamic nature. Here, it is important to highlight that fibronectin exists in different forms with differential adhesive properties due to alternative splicing that occurs prior to translation. Fibronectin harbors binding sites for more than 10 types of integrins, including $\alpha_5\beta_1$, $\alpha_4\beta_1$, $\alpha_5\beta_1$, and $\alpha_v\beta_3$, making it a ubiquitous and potent cell-adhesive protein found in the ECM (Pankov and Yamada, 2002). One of the most well-known binding sites, the *RGD* tripeptide sequence, is found in the type III domain of fibronectin. The *RGD* sequence alone recognizes a host of integrins, from $\alpha_5\beta_1$, $\alpha_8\beta_1$, $\alpha_v\beta_1$, $\alpha_v\beta_3$, $\alpha_v\beta_5$, $\alpha_v\beta_6$, $\alpha_v\beta_8$, to $\alpha_{IIb}\beta_3$ (Pankov and Yamada, 2002; Ruoslahti, 1996). Other integrin-binding sequences, such as *REDV*, *EILDV*, *IDAPS*, and *KLDAPT*, present within fibronectin bind integrins $\alpha_4\beta_1$ and $\alpha_4\beta_7$ (Pankov and Yamada, 2002). As a result, fibronectin is a vital ECM protein that regulates cellular functions in critical biological events, including embryogenesis, development, and wound healing.

Laminins

Laminins are a major constituent of the basement membrane. Laminins are large trimeric proteins consisting of α, β, and γ chains assembled in a coiled coil structure, which can give rise to at least distinct 15 isoforms (five variants of α, four variants of β, and three variants of γ; Fig. 2.1.5.4). As a major constituent of basement membranes, laminins play important roles in interacting with proteoglycans, glycoproteins, and collagens (e.g., syndecan, agrin, heparin, collagen IV, and collagen VII) and in turn strengthening the ECM structure. Through a series of systematic screening assays using proteolytic fragments and synthetic peptides, multiple cell-binding sites have been identified throughout



• **Figure 2.1.5.4** Schematic of laminins. Laminins are trimeric proteins consisting of α, β, and γ chains assembled in a coiled coil structure.

the trimeric chains. For example, in the laminin-111 isoform, 45, 14, and 12 active peptide sequences that modulate cell adhesion are present in α1, β1, and γ1 chains, respectively (Kikkawa et al., 2013). Of note, *YIGSR* from β1 chain (targets the 67-kDa laminin receptor) and *IKVAV* from α1 chain (targets $\alpha_3\beta_1$ and $\alpha_6\beta_1$ integrins) polypeptide sequences are implicated in various cellular and disease contexts, such as tumor adhesion, proliferation, and angiogenesis (Kikkawa et al., 2013).

Proteoglycans, Glycosaminoglycans, and Hyaluronic Acid

Glycosaminoglycans (GAGs) are highly polarized (charged) carbohydrates composed of repeating disaccharide units. GAGs are categorized into four groups based on their carbohydrate residues: hyaluronic acid, chondroitin/dermatan sulfate, heparan sulfate, and keratan sulfate. Highly sulfated GAG chains are coupled to core proteins to form proteoglycans that resemble a bottle brush. Hyaluronic acid is an exception, as it is the only type of GAG to lack sulfation, as well as lacking attachment to a core protein to form a proteoglycan. Diverse types of proteoglycans exist based on variation of the core protein and decorated GAGs. Small proteoglycans (<50 kDa) include decorin, biglycan, testican, fibromodulin, and lumican; large proteoglycans (>100 kDa) include versican, perlecan, aggrecan, neurocan, and brevican. Structurally, proteoglycans described as "filler" macromolecules that are amorphous. Despite the lack of defined structure, GAGs and proteoglycans impart important functions in the ECM. Proteoglycans attract and retain large volumes of water in the interstitial space through its polar nature. In certain tissues, such as the articular cartilage, GAGs and proteoglycans impart lubricating and shock-absorbing properties to the tissue (Mow et al., 1984; Roughley, 2006). Small proteoglycans participate in regulation of collagen fibril growth and organization (Chen and Birk, 2013; Kalamajski and Oldberg, 2010). Finally, cell membrane-bound proteoglycans, such as syndecans, also play an important role in binding collagen and fibronectin in the ECM as well as growth factors (Elfenbein and Simons, 2013).

Growth Factor Sequestering Proteins and Motifs

Soluble factors, such as growth factors, cytokines, and hormones, are potent modulators of cellular functions. Within the ECM, dynamic biochemical interactions between the ECM and growth factors intricately control the stability, availability, and bioactivity of growth factors. For example, heparan sulfate proteoglycans present in the ECM can bind soluble factors, such as fibroblast growth factor 2 (FGF-2), and regulate spatiotemporal presentation of the growth factor to the cells through sequestration (Ornitz, 2000; Raman et al., 2003). Alternatively, heparan sulfate proteoglycans present on outer cell membranes bind soluble growth factors to temporally increase local concentration to accentuate their effects (Bernfield et al., 1999). Fibronectin also contains domains (e.g., 12th to 14th type III repeats, III12–14) that promiscuously bind growth factors with high affinity, including the vascular endothelial growth factor (VEGF), platelet-derived growth factor (PDGF), and transforming growth factor-β (TGF- β; Martino and Hubbell, 2010). When this growth factor-binding domain is in proximity to an integrin-binding domain (e.g., presence of growth factor-binding III 12–14 and $\alpha_4\beta_1$ integrin-binding III 9–10 domains in the same polypeptide chain), a synergistic downstream response is produced through a cross-talk between the signals generated from the growth factor receptors and integrins (Martino et al., 2011). Similarly, multiple isoforms of laminin interact and bind growth factors through their α chain laminin-type G domains and accentuate the efficacy of growth factor-mediated responses (Ishihara et al., 2018). Thus, growth factor binding to the ECM sequesters growth factors from degradation, while increasing availability and bioactivity of growth factors in a spatiotemporal manner.

ECM Remodeling and Proteolysis

The ECM is structurally dynamic and adaptive, in which the cells continuously remodel through matrix degradation, synthesis, assembly, and modification. Regulation of ECM remodeling has direct implications on cell proliferation, migration, as well as release of sequestered growth factors, and it is essential for guiding important biological processes including morphogenesis, angiogenesis, development, and regeneration. In contrast, abnormal ECM remodeling is often associated with pathologic conditions. For instance, aberrant matrix deposition without adequate degradation causes fibrosis and matrix stiffening, which can further compromise normal cell function, tissue integrity, and aggravate disease progression (Bonnans et al., 2014). In fact, dysregulated ECM dynamics is a hallmark of cancer, where aberrant ECM promotes cellular mutation and metastasis (Lu et al., 2012).

Proteases mediate the breakdown of the ECM proteins. Three major families of proteases involved in degrading the ECM proteins are matrix metalloproteinases (MMPs), cathepsins, and a disintegrin and metalloproteinases with thrombospondin motifs (ADAMTS). There are over 20 members of MMPs that target a range of ECM proteins, including fibronectin, proteoglycans, collagen, and laminin (Nagase et al., 2006). Cathepsins are lysosomal proteases that are present in both intracellular and extracellular spaces and play critical roles in protein turnover. There are 11 types of cathepsins, which act as endopeptidases (types L, V, S, K, and F) or exopeptidases (types X, B, C, and H) to cleave peptide bonds at nonterminal and terminal ends of amino acid polypeptides, respectively. ADAMTS, consisting of 19 members, mostly target various types of proteoglycans. On the contrary, tissue inhibitors of metalloproteinases (TIMPs) regulate the enzymatic activity of MMPs through inhibition. Therefore, orchestrated activity of proteolytic enzymes, protease inhibitors, and protein synthesis and modifications dictate catabolic or anabolic outcomes of ECM remodeling.

Integrins and Adhesion Receptors

Cells interact with the ECM primarily through transmembrane adhesion receptors. A major class of such transmembrane proteins that mediate cell–ECM interactions are integrins. Integrins are heterodimers composed of two subunits of glycoproteins (α and β). In humans, there are at least 24 and 8 identified types of α and β subunits, respectively. Combinatory interactions of α and β subunits form diverse heterodimeric integrins, with each integrin type exhibiting differing ECM ligand-binding specificities. A list of human integrins and their respective target ECM ligands is summarized in Table 2.1.5.1 (Takada et al., 2007). Here, it is important to note that integrin–ECM ligand interactions (i.e., specificity and affinity) are dependent on extracellular divalent cations (Ca^{2+} and/or Mg^{2+}) as well as the conformational state of the extracellular portion of the integrins.

Two prominent functions of integrins are to provide anchoring forces to the ECM and to transduce signals from the ECM to the cell. During integrin-mediated adhesion, many adherent cell types form large cell adhesion complexes, known as focal adhesions, at the sites of integrin attachment. At focal adhesions, cytosolic proteins, such as vinculin, paxillin, tensin, and talin, cluster to form dynamic and multiprotein structures that provide a mechanical linkage between the ECM and cytoskeletal actin filaments. Cells process a variety of ECM-induced biophysical and/or biochemical signals through focal adhesion dynamics and signaling. Kinases, such as focal adhesion kinase (FAK) and Src kinases, regulate focal adhesion activity and its downstream functions. In many cases, growth factor receptors (e.g., epidermal growth factor receptor, EGFR) also localize to focal adhesions, and support integrin-mediated (e.g., $\alpha_2\beta_1$ and $\alpha_3\beta_1$) signaling through cross-talk signaling (Mainiero et al., 1996; Yu et al., 2000). Furthermore, emerging evidence implicates integrins in controlling cytoskeletal and nuclear structures in response to mechanical properties of the ECM. For example, mechanical signals (e.g., strain) may be transmitted from the ECM to the nucleus through integrin–actin–nuclear envelope connectivity and elicit alterations in the underlying chromatin structure to regulate gene expression, cellular phenotype, and function.

Integrin–ECM interactions are indispensable in governing critical biological functions in tissue- and cell-specific fashions. For instance, deletion of integrins (e.g., α_2, α_4, α_5, and β_1 integrins) or ECM proteins (e.g., fibronectin, laminin α_5) results in embryonic lethality, underscoring the critical importance of integrin–ECM interactions during early embryogenesis (De Arcangelis and Georges-Labouesse, 2000; George et al., 1993; Miner et al., 1998). In many cell types, including fibroblasts, epithelial, and endothelial cells, loss of integrin-mediated

TABLE 2.1.5.1 List of Human Integrins and Their Known ECM Targets (Takada et al., 2007)

Integrins	ECM Target
$\alpha_1\beta_1$	Laminin, collagen
$\alpha_2\beta_1$	Laminin, collagen, thrombospondin, tenascin
$\alpha_3\beta_1$	Laminin, thrombospondin
$\alpha_4\beta_1$	Thrombospondin, fibronectin, osteopontin
$\alpha_5\beta_1$	Fibronectin, osteopontin, fibrillin, thrombospondin
$\alpha_6\beta_1$	Laminin, thrombospondin
$\alpha_7\beta_1$	Laminin
$\alpha_8\beta_1$	Tenascin, fibronectin, osteopontin, vitronectin
$\alpha_9\beta_1$	Tenascin, osteopontin
$\alpha_{10}\beta_1$	Laminin, collagen
$\alpha_{11}\beta_1$	Collagen
$\alpha_v\beta_1$	Fibronectin, osteopontin
$\alpha_v\beta_3$	Fibrinogen, vitronectin, thrombospondin, fibrillin, tenascin, fibronectin, osteopontin
$\alpha_{IIb}\beta_3$	Fibrinogen, thrombospondin, fibronectin, vitronectin
$\alpha_6\beta_4$	Laminin
$\alpha_v\beta_5$	Osteopontin, vitronectin
$\alpha_v\beta_6$	Fibronectin, osteopontin
$\alpha_4\beta_7$	Fibronectin, osteopontin
$\alpha_D\beta_2$ (leukocytes)	Fibrinogen, fibronectin, vitronectin
$\alpha_M\beta_2$ (leukocytes)	Fibrinogen, heparin
$\alpha_X\beta_2$ (leukocytes)	Fibrinogen, heparin, collagen

adhesion results in anoikis (anchorage-dependent apoptosis; Frisch and Ruoslahti, 1997). In bone, fibronectin-specific $\alpha_5\beta_1$ and collagen-specific $\alpha_2\beta_1$ integrins are essential for osteoblastic differentiation of bone marrow-derived mesenchymal stromal cells (Mizuno et al., 2000; Moursi et al., 1997). In skeletal muscle, laminin-specific $\alpha_7\beta_1$ integrin is necessary for maintaining the quiescence and self-renewal capacity of muscle satellite cells (Blanco-Bose et al., 2001; Rozo et al., 2016). In the immune system, leukocytes express $\alpha_M\beta_2$ integrin to mediate macrophage interaction with fibronectin and fibrinogen (Flick et al., 2004; Yakubenko et al., 2002). These examples highlight the vital role of integrin–ECM interactions in governing biological functions.

In addition to integrins, other types of receptors regulate ECM adhesion in a cell type-dependent manner. For example, fibroblasts, smooth muscle cells, neutrophils, and several types of cancer cells express the 67-kDa elastin-laminin receptor that primarily interacts with elastin and laminin with high affinity. Discoidin domain receptors (DDR) are collagen receptors expressed by both epithelial cells (DDR-1) and cells of mesenchymal origin (DDR-2), which also function as receptor tyrosine kinases. Syndecans, single transmembrane proteins decorated with heparan sulfate and chondroitin sulfate chains, also facilitate cell adhesion to the ECM, including collagen I, III, V, and fibronectin in a cell type-dependent manner. In certain contexts, syndecans act as coreceptors with integrins and growth factor receptors to potentiate downstream responses. In blood, leukocytes express P-selectin glycoprotein ligand-1 that interacts with P-selectin expressed on the activated platelets and endothelium, which facilitate the recruitment of leukocytes to the inflamed tissue. Thus, cells express a wide array of adhesion receptors to mediate binding and interactions with their surrounding ECM.

Cell–Biomaterial Interactions

Because of the pivotal importance of ECM–cell interactions in modulating cellular functions, incorporation of ECM-mimicking biophysical and biochemical properties that guide context-dependent cellular function is a central consideration in engineering biomaterials. To promote interactions between cells and biomaterials, purified ECM molecules and engineered ECM-mimetic adhesive peptides that target specific integrins and/or other receptors can be incorporated into the material. Broadly, this can be achieved through (1) adsorption from solution, (2) biochemical functionalization, and (3) cell-mediated ECM deposition. Furthermore, other ECM-mimetic features, such as material degradability and geometry, can be engineered to direct more complex cellular function using biomaterials. The subsequent sections highlight key strategies for engineering ECM-mimetic biomaterials designed to guide cell–biomaterial interactions and to achieve targeted cell and tissue responses.

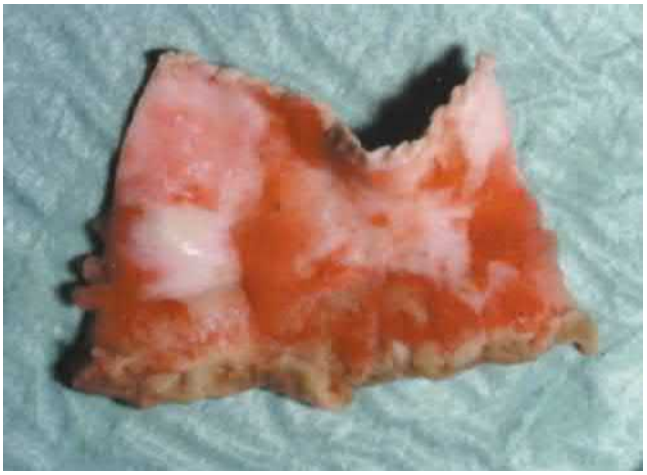
Cell Interactions With Adsorbed Proteins on Biomaterials

Biomaterials can be coated with proteins through a process known as adsorption, the noncovalent deposition of macromolecules from solution onto a surface. Protein adsorption is controlled by three major determinants: (1) relative protein concentrations in solution, (2) diffusion of proteins, and (3) protein affinity for a biomaterial substrate. Protein properties (e.g., size, charge, hydrophobicity, structural stability) and material surface properties (e.g., charge, topography, hydrophobicity) influence these factors, and thus are important considerations in protein adsorption processes. Indeed, interactions between protein and surface physicochemical properties define the composition, quantity, affinity, and conformation of adsorbed proteins (and other biomacromolecules), and ultimately impact the cells through engagement of integrins and other receptors with varying degrees of specificity. For instance, protein conformational changes that occur following adsorption may expose cryptic binding sites that increase cell adhesion, or mask cell-binding ligands that reduce cell adhesion (Vogel et al., 2001). The importance of surface chemistry on cell responses has been illustrated in basic studies using self-assembled monolayers as model surfaces. In adsorbing full-length fibronectin to a substrate, surface chemistry ($-CH_3$, $-OH$, $-COOH$, and $-NH_2$) has profound effects on its conformational presentation on integrin-binding domains to cells (Keselowsky et al., 2003). Fibronectin adsorbed onto $-OH$- and $-NH_2$-modified surfaces exhibits selective binding affinity for $\alpha_5\beta_1$ integrin, whereas fibronectin adsorbed onto a $-COOH$-modified surface exhibits high binding affinity for both $\alpha_5\beta_1$ and $\alpha_v\beta_3$ integrins (Keselowsky et al., 2003). Importantly, surface-directed modulation of fibronectin and its selective targeting of $\alpha_5\beta_1$ and $\alpha_v\beta_3$ integrins directly influences osteoblast adhesion, proliferation, and differentiation (Keselowsky et al., 2005). These studies highlight the importance of surface-dependent effects on ECM protein adsorption, bioactivity and integrin-binding specificity.

A major advantage of adsorbing a full-length ECM protein onto a surface is that it can support integrin-mediated cellular processes in a relatively simple manner with preservation of multiple bioactive sites. Physicochemical compatibility between the protein and substrate of interest is a predominant factor in controlling the presentation of these bioactive sites. However, the effects of specific integrins and growth factors are difficult to systematically investigate and control through adsorption of ECM proteins due to the presence of multiple integrin- and growth factor-binding sites. Additionally, adsorbed proteins can be out-competed or displaced by other macromolecules present in the biological environment. Furthermore, the possibility of transmitting a pathogen, eliciting a host immune response, and lot-to-lot variability of naturally derived matrices limit the use of such a methodology in the clinical setting (Box 2.1.5.2; Simon et al., 2003).

• BOX 2.1.5.2 Case Study—Safety Considerations in Manufacturing Naturally Derived Materials

Decellularized ECM scaffolds have been used in the clinical setting for over 10 years. A major advantage of decellularized ECM scaffolds is that they maintain bioactive sites and molecules. However, decellularized ECMs used in the clinic are typically derived from xenogeneic or allogeneic tissue sources, and therefore there is a possibility of transmitting pathogens and lot-to-lot variability. Furthermore, complete decellularization is difficult to achieve, and there is a significant risk of eliciting host immune responses. In 2001, xenogeneic collagen matrix-based decellularized porcine heart valves, Synergraft, were implanted in four pediatric patients (Simon et al., 2003). Unfortunately, three of the four patients died due to severe foreign body responses attributed to incomplete decellularization (Fig. 2.1.5.5). The fourth valve was prophylactically explanted from the patient 2 days after implantation (Fig. 2.1.5.5). Processing of naturally derived materials, thus, is an important safety consideration in clinical translation. These concerns also motivate the need for alternative *synthetic* approaches to regulate cell–biomaterial interactions in regenerative medicine, such as engineering receptor-targeting peptides, MMP-sensitive peptides, and synthetic peptide fibers that mimic the ECM structure.



• **Figure 2.1.5.5** An implant explanted 2-days post-implantation exhibits a severe inflammatory response and fibrotic sheath formation around the graft. Early failure of the tissue engineered porcine heart valve SYNERGRAFT® in pediatric patients. Eur. J. Cardiothorac. Surg. 23, 1002–1006. https://doi.org/10.1016/S1010-7940(03)00094-0.)

Engineered Receptor-Targeting Peptide Sequences for Cell Adhesion

A strategy to systematically modulate integrin-specific cell functions is to functionalize biomaterial surfaces with short synthetic ECM-mimetic adhesive peptides derived from appropriate ECM proteins. ECM proteins possess domains that exhibit affinity for specific integrins and receptors. Prior work with proteolytically degraded protein fragments and screening for their specific integrin and receptor binding affinity led to the identification of numerous receptor-targeting domains. These ECM-derived cell-binding motifs are typically comprised of a short sequence of amino acids and establish the minimal amino acid sequences necessary to bind one or more integrin receptors. Integrin-targeting peptide sequences can easily be synthesized with high reproducibility and covalently functionalized onto biomaterial surfaces to promote cell adhesion. Furthermore, functionalization of peptide sequences to synthetic substrates enables the generation of fully synthetic biomaterials, which offer numerous advantages over naturally derived matrices, including minimal lot-to-lot variability and reduced risk of pathogen transmission.

The fibronectin-derived cell-binding tripeptide sequence *RGD* (arginine-glycine-aspartic acid) was first discovered by Pierschbacher and Ruoslahti in 1984 (Pierschbacher and Ruoslahti, 1984). The *RGD* sequence enables ubiquitous interactions with multiple integrins (Ruoslahti, 1996, Table 2.1.5.2). Although the *RGD* sequence was originally derived from fibronectin, the RGD motif is also found in other ECM proteins, including vitronectin, osteopontin, thrombospondin, and fibrinogen. As a potent binder of integrins, biomaterial substrates with the *RGD* peptides grafted onto the surface are widely investigated for various biomedical applications. *RGD* peptides immobilized onto an inert substrate retain their bioactivity and support cell adhesion (Massia and Hubbell, 1990). Furthermore, hydrogels consisting of naturally derived, synthetic, or natural-synthetic composite materials have emerged as powerful tools to engineer artificial ECMs that mimic many key features of the native ECM (Hern and Hubbell, 1998; Lutolf and Hubbell, 2005; Tibbitt and Anseth, 2009). For example, synthetic hydrogels functionalized with *RGD* peptides support human pluripotent stem cell-derived intestinal stem cell expansion and differentiation, giving rise to organoids analogous to native tissue (Cruz-Acuña et al., 2017; Gjorevski et al., 2016). In skeletal muscle, synthetic hydrogels functionalized with *RGD* peptides support muscle stem (satellite) cell survival, proliferation, and differentiation, and enable a biomaterial-mediated cell delivery strategy for treating muscle trauma and pathology (Han et al., 2018). Collectively, these studies demonstrate that *RGD*-functionalized synthetic hydrogels exhibit equal or better performance in supporting cellular functions compared to naturally derived matrices, such as collagen and Matrigel, and establish *RGD*-tethered biomaterials as potential alternatives for naturally derived ECM scaffolds (Cruz-Acuña et al., 2017; Gjorevski et al., 2016; Han et al., 2018; Lutolf and Hubbell, 2005). Biomaterials functionalized with *RGD* sequences have been used to direct cell adhesion, migration, and differentiation in diverse applications, including bone, neural, endothelial, liver, and cancer cells (as reviewed in Hersel et al., 2003).

Ligand density and clustering profoundly influence cellular functions in a cell type-dependent manner. For example, adhesion strength, proliferation, and mineralization potential of osteoblasts on *RGD*-functionalized surfaces positively correlate with *RGD* peptide density (Harbers and Healy, 2005). Dorsal root ganglia cells exhibit a biphasic

TABLE 2.1.5.2 List of Peptide Sequences and Their Known Integrin and Receptor Targets

Peptide Sequence	Parent ECM	Target Integrins and Receptors
RGD	Fibronectin	$\alpha_v\beta_3$, $\alpha_v\beta_5$, $\alpha_v\beta_6$, $\alpha_v\beta_8$, $\alpha_{IIb}\beta_1$, $\alpha_5\beta_1$, $\alpha_8\beta_1$
EILDV	Fibronectin	$\alpha_4\beta_1$, $\alpha_4\beta_7$
REDV	Fibronectin	$\alpha_4\beta_1$
KLDAPT	Fibronectin	$\alpha_4\beta_1$, $\alpha_4\beta_7$
EDGIHEL	Fibronectin	$\alpha_4\beta_1$, $\alpha_9\beta_7$
IDAPS	Fibronectin	$\alpha_4\beta_1$
PHSRN	Fibronectin	Synergy sequence for $\alpha_5\beta_1$
GFOGER	Collagen	$\alpha_1\beta_1$, $\alpha_2\beta_1$
GRKRK	Elastin	67-kDa elastin receptor, $\alpha_v\beta_3$, $\alpha_v\beta_5$
VGVAPG	Elastin	67-kDa elastin receptor, galectin-3 receptor, $\alpha_v\beta_3$
YIGSR	Laminin β_1 chain	67-kDa laminin receptor
IKVAV	Laminin α_1 chain	$\alpha_3\beta_1$, $\alpha_6\beta_1$
KAFDITYVRLKF (C16)	Laminin γ_1 chain	Syndecans, β_1
RKRLQVQLSIRT (AG73)	Laminin α_1 globular domain	Syndecans
SYWYRIEASRTG (A2G10)	Laminin α_2 globular domain	$\alpha_6\beta_1$

neurite outgrowth response as a function of the *RGD* peptide density in both two- and three-dimensional matrices, where the maximal neurite outgrowth is achieved at intermediate ligand densities and the neurite outgrowth is inhibited at higher ligand densities (Schense and Hubbell, 2000). Furthermore, fibroblast motility is directly dependent on *RGD* peptide density, and nanoscale clustering of the *RGD* peptides supports cell motility at significantly reduced overall ligand density (Maheshwari et al., 2000). These studies show that ligand density and clustering directly control the degree of integrin clustering, which ultimately influences cell adhesion, locomotion, and other cell-specific phenotypic changes through integrin-mediated signaling pathways.

Another factor that regulates integrin specificity of the biomimetic peptide sequence is the molecular structure that the peptide sequences form, i.e., secondary and tertiary protein structures. As noted above, the linear *RGD* tripeptide sequence ubiquitously interacts with multitude of integrins. However, presentation of the tripeptide *RGD* in cyclic penta- and hexapeptide conformations further modulates its integrin specificity and affinity (Gurrath et al., 1992). For example, presentation of the *RGD* motif in cyclic forms, such as cyclo(*RGDFV*), significantly increases its binding specificity for $\alpha_v\beta_3$ integrin (Haubner et al., 1996). In the case of osteogenic cells, functionalization of the cyclic RGD on poly(methyl methacrylate) and poly(ethylene glycol)-poly(D,L-lactic acid) substrates promotes osteoblast adhesion, proliferation, and bone formation through selective engagement of $\alpha_v\beta_3$ and $\alpha_v\beta_5$ integrins (Kantlehner et al., 2000; Lieb et al., 2005). *GFOGER* is a hexapeptide sequence derived from the α_1(I) chain of collagen I and IV, where its mimicry of collagen's tertiary triple helical structure is critical for the recognition of $\alpha_1\beta_1$ and $\alpha_2\beta_1$ integrins (Knight et al., 2000; Reyes and García, 2003, 2004; Table 2.1.5.2). Indeed, the linear arrangement of the *GFOGER* sequence does not support effective binding of $\alpha_2\beta_1$ integrin in multiple cell types (Knight et al., 2000), highlighting the importance of the structure of integrin-targeting peptide sequences. In bone tissue engineering, *GFOGER*-functionalized hydrogels promote superior osteogenic differentiation and bone formation of human mesenchymal stromal cells compared to *RGD*-functionalized hydrogels both in vitro and in vivo (Shekaran et al., 2014). This further emphasizes the importance of targeting specific integrins in a context-dependent manner.

Other ECM-derived, integrin-targeting peptide sequences have been identified. Within fibronectin, other peptide sequences, such as *EILDV*, *REDV*, and *PHSRN*, are available. *EILDV* targets $\alpha_4\beta_1$ and $\alpha_4\beta_7$ integrins and plays a role in antimetastatic activity of tumors (Kaneda et al., 1997; Ukawala et al., 2011; Yamamoto et al., 1994, Table 2.1.5.2). *REDV* recognizes the $\alpha_4\beta_1$ integrin (Massia and Hubbell, 1992, Table 2.1.5.2). Fibronectin-derived PHSRN sequence acts as a synergistic motif with *RGD* in promoting $\alpha_5\beta_1$ binding to fibronectin and other $\alpha_5\beta_1$-targeting peptide sequences when presented appropriately (Aota et al., 1994; Pankov and Yamada, 2002, Table 2.1.5.2). The synergistic binding affinity for $\alpha_5\beta_1$ integrin binding is further improved through a recombinant fibronectin fragment derived from type III repeats ($FNIII_{7\text{-}10}$; contains both *PHSRN* and *RGD* sequences) that recapitulates the native structure present in fibronectin, where cells exhibit superior adhesion strength and proliferation on a substrate functionalized with $FNIII_{7\text{-}10}$ than on a substrate functionalized with the *RGD-PHSRN* linear peptide (Petrie et al., 2006). Furthermore, $FNIII_{7\text{-}10}$-coated titanium improves implant integration and stability in vivo, highlighting the importance of protein tertiary structure in further modulating integrin specificity of peptide sequences arranged in a linear form (Petrie et al., 2008). Elastin-derived peptides *GRKRK* (Bax et al., 2009; Lee et al., 2014) and *VGVAPG* (Blanchevoye et al., 2013; Blood et al., 1988; Floquet et al., 2004; Patel et al., 2011, Table 2.1.5.2) target $\alpha_v\beta_3$ and $\alpha_v\beta_5$ integrins, as

well as the 67-kDa elastin-binding protein in a synergistic manner. Finally, hundreds of adhesive peptide sequences are present within different isoforms of the laminin α, β, and γ chains (Hozumi et al., 2012, 2010; Katagiri et al., 2014, 2012; Kikkawa et al., 2013; Urushibata et al., 2010, 2009). Of note, *YIGSR* (β_1 chain-derived, targets 67 kDa receptor, Table 2.1.5.2) and *IKVAV* (α_1 chain-derived, targets $\alpha_3\beta_1$ and $\alpha_6\beta_1$ integrins, Table 2.1.5.2) sequences interact with different cell types, including cancer and mesenchymal stromal cells. Other laminin-derived peptide sequences and their respective targets are summarized in Table 2.1.5.2.

Engineered MMP-Sensitive Peptide Sequences for ECM Remodeling and Proteolysis

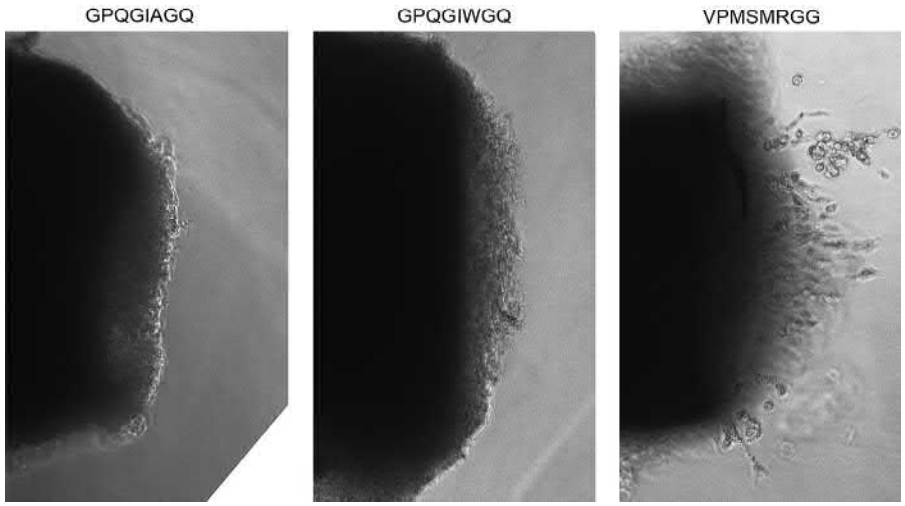
ECM remodeling is an important process that influences cellular activity (e.g., proliferation, migration) and tissue function (e.g., angiogenesis, regeneration) in native tissues. In designing biomaterials for regenerative medicine, material degradability is thus a major consideration in achieving the desired therapeutic outcomes. For example, when delivering stem cells using a hydrogel, the cells may need to degrade and remodel their surrounding matrix to survive, proliferate, migrate, and differentiate. It may also be necessary to engineer a biomaterial to degrade at a specific rate so that no material remains at the completion of therapy. To recapitulate cell-degradable properties, numerous proteolytically sensitive matrix metalloproteinase (MMP) and cathepsin substrate sequences have been identified and incorporated into biomaterials. For instance, these peptide sequences can be used to cross-link polymeric macromers to form a hydrogel, where the resulting hydrogel is endowed with a protease-sensitive property in which the cells can locally degrade as necessary. Incorporation of protease-sensitivity increases cell migration and proliferation within the material and provides a favorable condition for promoting an enhanced tissue-regenerative response in vivo (Lee et al., 2008, 2005; Lutolf et al., 2003, 2003b, 2003a; Phelps et al., 2010; West and Hubbell, 1999).

Early studies conducted to identify MMP-specific substrate sites using synthetic peptide sequences focused on protease-cleavable sites found in the α-chains of collagens (Dixit et al., 1979; Fields et al., 1987; Gross et al., 1974; Highberger et al., 1982; Miller et al., 1976; Nagai et al., 1976). It is now known that the peptide sequence *GPQG/IAGQ* (glycine-proline-glutamine-glycine-isoleucine-alanine-glycine-glutamine; / indicates the cleavage site) found in the α-chains of collagens is MMP-active, and that a single amino acid substitution from A to W significantly increases its proteolytic susceptibility (Nagase and Fields, 1996). Indeed, synthesizing hydrogels with peptide sequences with a single amino acid substitution as polymer cross-linkers results in hydrogels that exhibit varying rates of degradation (Lutolf et al., 2003a). When used as a scaffold for bone healing, bone morphogenic protein-2 (BMP-2)-loaded hydrogels that are more susceptible to proteolytic degradation support superior cellular invasion and bone formation in vivo degradation (Lutolf et al., 2003a). Similarly, superior vascularization is achieved when vascular endothelial growth factor (VEGF) is delivered using protease-sensitive hydrogels as opposed to nondegradable hydrogels, demonstrating that the protease-sensitivity is an essential property for promoting vascular invasion into the material (Phelps et al., 2010).

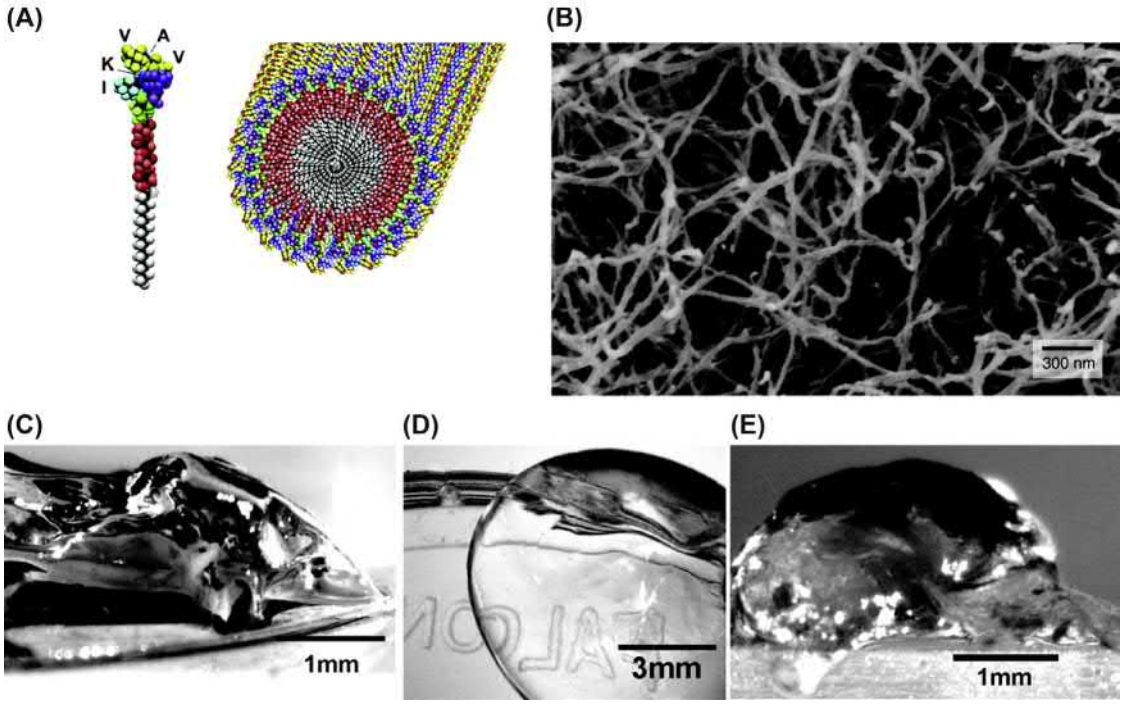
In addition to the collagen α-chains-derived *GPQG/IAGQ* or *GPQG/IWGQ* sequences, many ECM-derived protease substrate sequences that exhibit specific affinity for different MMP types have been identified (Nagase and Fields, 1996; Patterson and Hubbell, 2010). Incorporation of protease-sensitive peptide sequences that exhibit differential sensitivity and specificity enables more precise tuning of hydrogel degradability. For example, the *VPMS/MRGG* sequence exhibits increased sensitivity for MMP-1, 2, 3, 7, and 9 compared to the collagen α-chains-derived *GPQG/IAGQ* or *GPQG/IWGQ* sequences, and results in hydrogels that degrade more rapidly (Patterson and Hubbell, 2010). By tuning the hydrogel degradability, cellular functions, such as cell migration into the hydrogel, can be guided (Fig. 2.1.5.6, Patterson and Hubbell, 2010). *IPES/LRAG* sequence, compared to the *VPMS/MRGG* sequence, exhibits reduced sensitivity for MMP-1, 3, and 9, but similar sensitivity for MMP-2 and 7, while its sensitivity for all MMP-1, 2, 3, 7, and 9 is higher than the collagen α-chains-derived *GPQG/IAGQ* or *GPQG/IWGQ* sequences (Patterson and Hubbell, 2010). As a result, hydrogels cross-linked with the *IPES/LRAG* sequence exhibit an intermediary degradation response, where they degrade at a higher rate than the *GPQG/IAGQ* or *GPQG/IWGQ* sequences but at a slower rate than the *VPMS/MRGG* sequence in response to MMP-1 and MMP-2 treatment (Patterson and Hubbell, 2010). Consequentially, cell spreading, proliferation, and migration of myofibroblasts encapsulated in these hydrogels can be controlled in a degradation rate-dependent manner (Patterson and Hubbell, 2010).

Engineered Peptide Fibers That Mimic the ECM Structure

The native ECM is composed of heterogeneous protein mixtures that are often fibrillar in form (e.g., collagens, elastin, fibronectin). The fibrillar structure plays an important role in regulating local mechanical properties, providing topographical cues for cellular alignment, and enhancing integrin-binding affinity (e.g., *GFOGER* peptide). To generate scaffolds that mimic the native ECM structure, self-assembled peptide amphiphiles (PAs) have been explored for synthesizing materials with fibrillar properties (Gore et al., 2001; Lin et al., 2012; Silva et al., 2004, Fig. 2.1.5.7). PAs are peptides conjugated with hydrophobic moieties, such as lipid tails (Berndt et al., 1995). Due to their amphiphilic properties, imparted by a hydrophobic tail and beta-sheet



• **Figure 2.1.5.6** Cell invasion into hydrogels can be guided by tuning the hydrogel degradability. Phase contrast micrographs of chick aortic rings encapsulated in the hydrogels after 48 h. Slow (GPQG/IAGQ), reference (GPQG/IWGQ), fast (VPMS/MRGG) degrading hydrogels, respectively. (Adapted from Patterson, J., Hubbell, J.A., 2010. Enhanced proteolytic degradation of molecularly engineered PEG hydrogels in response to MMP-1 and MMP-2. Biomaterials 31, 7836–7845. https://doi.org/10.1016/j.biomaterials.2010.06.061.)



• **Figure 2.1.5.7** (A) Schematic of IKVAV-presenting peptide amphiphile. (B) Scanning electron micrograph of nanofibrous network. (C–E) Photographs of the gels formed by adding IKVAV-presenting peptide amphiphiles in biological solutions (Silva et al., 2004).

forming amino acids, PAs self-assemble into aggregates of diverse structures in water. When physicochemical properties (e.g., charge, branching, tail length) are appropriately modulated, PAs self-assemble into a hydrogel with nanofibrous structure (Gore et al., 2001; Lin et al., 2012; Silva et al., 2004; Sleep et al., 2017). For instance, assembly of PA fibers that recapitulate the triple helical structure of a collagen fibril can be guided through controlling amphiphile tail lengths (Gore et al., 2001). Encapsulation of neural progenitor cells in a hydrogel consisting of laminin-derived *IKVAV*-presenting nanofibrous network promotes selective and more rapid differentiation into neurons compared to laminin and soluble *IKVAV* peptides (Silva et al., 2004). Furthermore, myogenic precursor cells encapsulated in a PA hydrogel survive, proliferate, and differentiate into aligned myotubes (Sleep et al., 2017), suggesting that engineered

PAs can serve as a powerful system to introduce complex structural features in ECM-mimicking synthetic biomaterials for guiding cellular patterning and function. In addition to PAs, protein-based hydrogels consisting solely of artificially proteins, such as engineered elastin-like proteins, are also emerging as a strategy to generate bioscaffolds with precise control of structure and function (Sun et al., 2014; Wang et al., 2018) and present a tunable system for studying cell–matrix interactions.

Summary

The ECM is composed of a heterogeneous mixture of proteins and other macromolecules forming tissues and organs. The ECM provides both biophysical and biochemical signals to the resident cells, where the cell–ECM interactions are indispensable for many biological processes, including development, homeostasis, and regeneration. Therefore, recapitulating key aspects of the ECM is a critical consideration in engineering biomaterials. Notably, minimal peptide sequences that target specific integrins and other receptors enable systematic investigation of integrin-specific cell functions using biomaterials. Furthermore, peptide sequences that are sensitive to various types of proteases, as well as engineered peptide amphiphiles that self-assemble to form a nanofibrous network, increase the intricacy in mimicking structural dynamics of the native ECM, and enable engineering synthetic biomaterials for guiding cellular function and improving regenerative outcome in a context-dependent manner.

Chapter Exercises

- Describe key functions and properties of the extracellular matrix.
- How do cells interact with their surrounding extracellular matrix?
- What are some of the properties and factors that need to be considered when engineering a cell-instructive biomaterial?
- Describe a strategy to design a biomaterial that exhibits increased sequestration of growth factors, such as FGF2 and PDGF. Justify your proposed strategy.
- What are some of the advantages and disadvantages of using naturally derived matrices for biomedical applications? What are some of the advantages and disadvantages of synthetic matrices?

2.1.6

Effects of Mechanical Forces on Cells and Tissues

Introduction

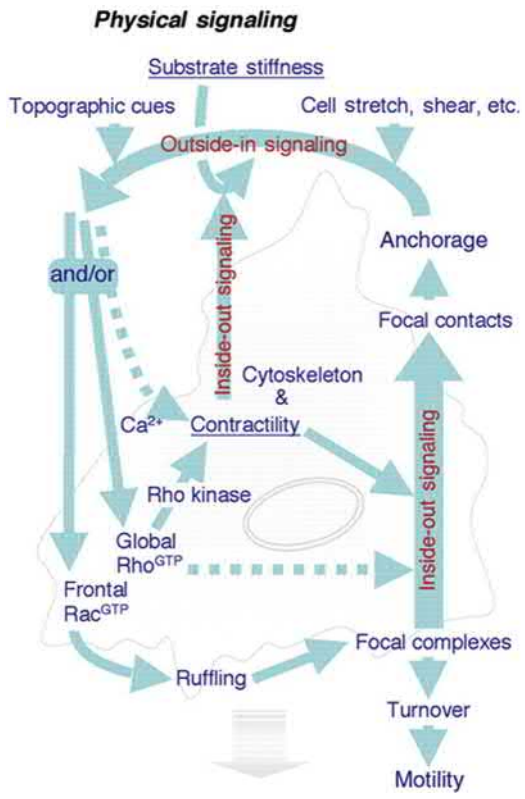
Mechanical forces are present throughout the body as a consequence of the normal motion and the physiological functioning of organs. These forces are key regulators of the body's interaction with biomaterials and it is essential to account for these mechanical factors in the design of biomaterials. The mechanical issues of biomaterial design can be divided into issues relating to the mechanical properties of biomaterials and issues of the mechanical forces experienced by the materials, cells, and tissue–material interfaces. This chapter reviews the basics of our understanding of how cells and tissues respond to mechanical forces and mechanical cues in their microenvironment. We first discuss the general aspects of how cells can sense their mechanical environment and then continue with a review of experimental techniques used to study mechanobiology and engineer-tailored mechanical environments in biomaterials. Finally, we examine the mechanical aspects of the vascular system and the bones, two organ systems that are highly regulated by mechanical forces.

Molecular Mechanisms of Cellular Mechanotransduction

In work published in 1892, Julius Wolff described the structural remodeling of bone in response to mechanical forces (Wolff, 1892). The concept that mechanical forces could alter tissue remodeling was one of the first realizations of mechanosensing in biological systems and later became known as Wolff's law. For several decades, it has also been known that forces from blood pressure and flow can induce remodeling in the vascular system. In fact, specific regions of the arterial system become prone to the formation of atherosclerosis based on the presence of low/oscillating shear stress (Koskinas et al., 2009). More recently, studies have found that the mechanical environment can alter the differentiation of stem cells and alter the behavior of cancer cells (Engler et al., 2006; Matthew et al., 2005). Fundamental to these processes is the mechanisms through which cells sense and respond to mechanical forces. Cellular mechanosensing can be roughly divided into three areas: (1) focal adhesion and mechanosensing at the extracellular matrix (ECM)/biomaterial interface, (2) cytoskeletal mechanotransduction, and (3) nuclear mechanotransduction.

Focal Adhesion and Mechanosensing at the ECM–Biomaterial Interface

Perhaps the most obvious place to search for mechanically sensitive molecules is at the location of attachment of the cell to its surrounding environment. Focal adhesions are complexes of proteins found at the cell membrane that provide physical attachment to the cell's extracellular environment. The dynamic regulation of focal adhesions plays a key role in cell migration, cytoskeletal remodeling, and cell survival (Parsons et al., 2010). Focal adhesions are integrin-containing, multiprotein architectures that form a mechanical link between the cell's cytoskeleton and the local microenvironment (Harburger and Calderwood,



• **Figure 2.1.6.1** Cellular motion is mediated by inside-out/outside-in integrin signaling. Integrins can be activated to bind ligands ("inside-out" signaling) or ligand binding via integrins can mediate cellular responses ("outside-in" signaling) (Discher et al., 2005).

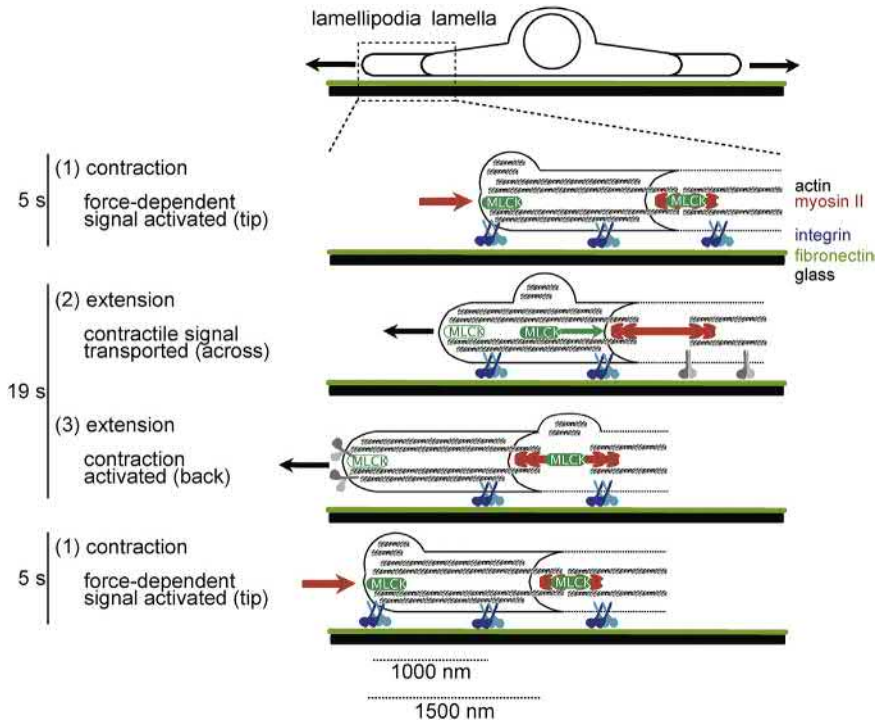
2009; Hynes, 2002). Integrins are heterodimeric cell surface receptors that bind to the ECM and other receptors (Hynes, 1992). The two integrin subunits that form the integrin (e.g., αvβ3) determine the types of ECM or other molecules to which the integrin binds (Plow et al., 2000). Integrins function bidirectionally. Integrins can be activated to bind ligands ("inside-out" signaling) or ligand binding can mediate cellular responses ("outside-in" signaling) (Fig. 2.1.6.1) (Shen et al., 2012; Geiger et al., 2001). The importance of integrin signaling on cell survival and proliferation has made it of interest in designing biomaterials that need to interact directly with cells. A common strategy to enhance cellular adhesion to biomaterials and hydrogels is to conjugate RGD-containing peptides (Ruoslahti and Pierschbacher, 1987; Burdick and Anseth, 2002), allowing cells to attach and survive on the materials. The RGD sequence mimics adhesion motifs in many extracellular matrix proteins that bind to and activate integrins.

The canonical model of cell adhesion is that integrin activation leads to the rapid recruitment of focal adhesion-associated proteins including vinculin, talin, and paxillin. Talin can link directly to the actin cytoskeleton, allowing mechanical force to be applied to the linkage and slowing retrograde flow of actin subunits. Vinculin can also control the formation of focal adhesion through interactions with talin and other proteins (Humphries et al., 2007), and directly senses mechanical tension across the focal adhesions (Grashoff et al., 2010). These nascent adhesion complexes lead to activation of focal adhesion kinase and subsequent recruitment of other scaffolding and signaling proteins as the focal adhesion matures. The focal adhesions can also alter cytoskeletal remodeling through multiple mechanisms. For example, integrin regulation of Src and focal adhesion kinase (FAK) activity can in turn regulate members of the Rho family of GTPases, such as Rac1 or RhoA, leading to reorganization of the actin cytoskeleton.

As cells move through their local microenvironment, they are continually sensing the local stiffness and adhesion of the surrounding matrix. During migration there is continual formation of new focal adhesions at the front of the lamellipodia. In one potential mechanism, cells can sense the stiffness of the material through cycles of contraction mediated by myosin II molecular motors (Fig. 2.1.6.2) (Giannone et al., 2004). Essentially, the cell pulls back on the adhesions during migration/cytoskeletal remodeling and based on mechanically sensitive signaling can assess the stiffness of the matrix. Mechanical tension applied by the cell to the underlying ECM can also lead to activation of transforming growth factor-beta (TGF-β), a growth factor involved in regulating fibrosis, proliferation, and many other processes (Shi et al., 2011). The cell synthesizes TGF-β1 as an inactive propeptide (latent TGF-β) that can deposit in the ECM. Latent TGF-β can be activated by a number of factors including the application of mechanical force by cells through αv integrins. In myofibroblasts, substrate stiffness can regulate the TGF-β pathway (Arora et al., 1999). On soft substrates, cell-generated tension on the TGF-β latent complex results in deformation of the matrix and the latent complex remains inactive, keeping TGF-β sequestered in the complex and preventing its release. On stiffer substrates, cell-generated tension deforms the TGF-β latent complex, releasing TGF-β where it can be activated (Wells and Discher, 2008). This bioactive TGF-β binds its receptor and activates Smad-family transcription factors. Mechanically regulated TGF-β signaling has been shown to mediate the communication between endothelial cells and vascular smooth muscle cells in the artery (Baker et al., 2008), cancer (Wei et al., 2015), and many other physiological processes (Horiguchi et al., 2012). While not reviewed extensively here, mechanical forces and cytoskeletal tension can also be sensed through cell–cell junctions and cell–cell adhesion molecules, including members of the cadherin family of proteins (Charras and Yap, 2018).

Cytoskeletal Mechanotransduction

Activation of focal adhesion complexes leads to the polymerization and organization of actin filaments and nonmuscle myosin II into stress fibers (Tojkander et al., 2012; Vicente-Manzanares et al., 2009). These actomyosin stress fibers form the major contractile structure in

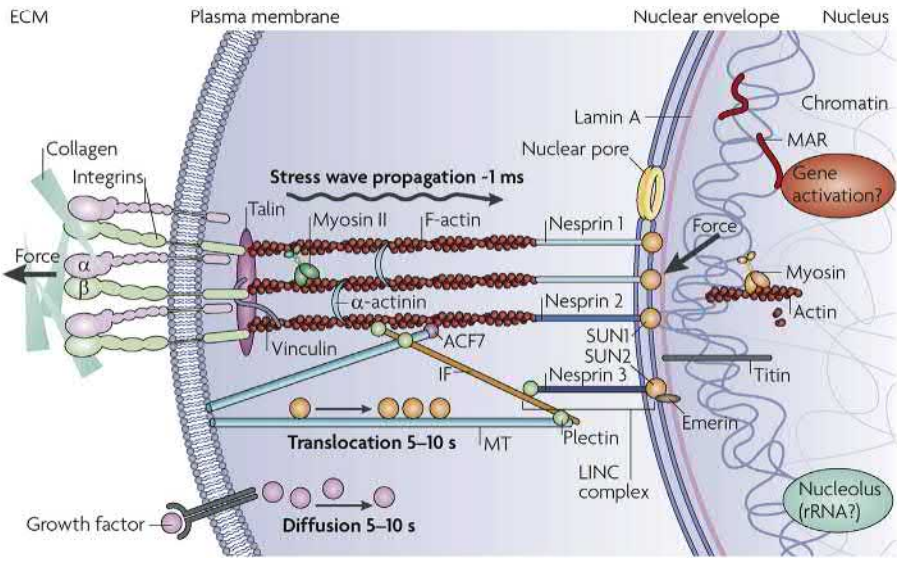


• **Figure 2.1.6.2** The cycle of contraction of myosin II molecular motors. (1) Lamellipodial contraction generates force that activates force-dependent MLCK signals (green ellipses) at the lamellipodial tip. This results in the formation of transient integrin/paxillin adhesion sites at the tip (blue). (2) The cell then extends after contraction. A wave of material (actin, α-actinin, MLCK) containing the contractile signal is transported rearward by actin flow. (3) When the contractile signal reaches the back of the lamellipodium, it stimulates the contractile machinery (myosin II, red) (Giannone et al., 2004).

most cells, powering cellular migration and the protrusion of lamellipodia and filopodia. Rho and Rac proteins are involved in the creation of focal adhesions (Buchsbaum, 2007). Respectively, Rho is inhibited through Src activation of RhoGAP and Rac is activated through Vav signaling and other pathways (reviewed extensively elsewhere) (Sit and Manser, 2011; Hall, 1998). Combined, these proteins coordinate the formation of actomyosin stress fibers (Nobes and Hall, 1995) and transmit the required force to bring epithelial cells together into continuous tissues (Vasioukhin et al., 2000; Nusrat et al., 1995; Yonemura et al., 1995; Ridley and Hall, 1992). Proteins such as talin and vinculin mediate the link between focal adhesions and actomyosin complexes and play a key role in how cells sense tension and mature their adhesions (Parsons et al., 2010; Grashoff et al., 2010). Internally, talin and vinculin act as a molecular clutch (Mitchison and Kirschner, 1988; Case and Waterman, 2015). When these proteins are subjected to high tension (integrin binding on stiff substrates), the proteins are activated, converting the contractile force of the actomyosin stress bundles into movement. When these proteins are subjected to low tensions, they do not activate and as a result the cells may retract their adhesions. It has also been suggested that the actin filament itself functions as a tension sensor (Hayakawa et al., 2011). Tension on actin filaments prevents the fibers from being severed and disassembled by members of the cofilin family of actin-binding proteins.

Nuclear Mechanotransduction

The nucleus can also directly participate in mechanosensing in cells. The nucleus contains the majority of the cell's genetic material that is separated from the cytoplasm by the nuclear envelope. The nuclear envelope is composed of two lipid bilayers separated by the perinuclear space. Nuclear pore complexes allow the regulated transfer of proteins into the nucleus. The nuclear lamina lines the inside of the nuclear envelope, providing mechanical support for the nucleus, anchoring nuclear pore complexes, and interacting with chromatin (Wang et al., 2009). Forces applied at focal adhesions can be transmitted to the nucleus either through signal molecules or direct mechanical force transmission (Wang et al., 2009). Nuclear envelope spectrin repeat proteins (nesprins) are found on the outside of the nuclear envelope and can link actin filaments and microtubules to the nucleus (Haque et al., 2006; Zhang et al., 2001). Lamins are found on the inner side of the nuclear envelope and are a major structural protein in the nuclear lamina. Nesprins link to the proteins SUN-1 or SUN-2 through a highly conserved KASH domain, and SUN1/2 binds to lamins to across the nuclear envelop. Thus, mechanical forces applied from the cytoskeleton can transmit directly to the chromatin (Fig. 2.1.6.3) (Sosa et al., 2012). These structures are collectively known as "linker of nucleoskeleton and cytoskeleton" (LINC) complexes, and disruption of LINC complexes prevents mechanically induced activation of genes. This, in turn, can lead to adverse effects on migration, membrane polarization,



• **Figure 2.1.6.3** Proteins involved in mechanotransduction from the ECM to the nucleus. A local force applied to integrins through the extracellular matrix (ECM) is concentrated at focal adhesions. This stress wave then propagates through stress fiber complexes, connected to the focal adhesions by molecular clutch proteins. Stress fibers then interact with the nuclear envelope through LINC proteins. At this interface, the force transferred from the cell surface can interact with chromatin structures (Wang et al., 2009).

and cellular structural development (Lombardi et al., 2011). The direct transmission of force from the extracellular environment in the form of tension or compression can affect chromatin opening and recombination, nuclear transport, and nuclear matrix distortion (Dahl et al., 2008; Wang et al., 2009). The absence of lamins, a key mediator of chromatin structures, has been shown to impair the cellular response to mechanical stress (Houben et al., 2007). Nuclei exposed to shear stress upregulate and redistribute lamins to change their nuclear shape (Philip and Dahl, 2008) and cells that do not contain lamin structures do not respond to shear stress. Lamins have also been shown to scale with tissue stiffness (Swift et al., 2013), where stiffer tissues contain more lamin proteins than softer tissues. Nuclear envelope distortion has also been shown to stimulate calcium entry through ion channels and alter gene transcription (Itano et al., 2003). Finally, stress and strain on nuclear scaffolds have also been shown to influence chromatin organization (Stein et al., 2007). One regulator of mechanically mediated signaling is the transcriptional regulators YAP and TAZ (YAP/TAZ), which are key molecules in the Hippo signaling pathway (Dupont, 2016; Dupont et al., 2011; Fischer et al., 2016). When cells are subjected to mechanical conditions with high tension, YAP/TAZ is localized to the nucleus where it affects a variety of cellular processes including proliferation. When cells experience low intracellular tension, YAP/TAZ is sequestered in the cytoplasm by proteins such as 14-3-3ε or degraded. The nuclear deformation caused by tension on LINC proteins helps to promote YAP/TAZ nuclear entry and subsequent transcription (Totaro et al., 2018; Elosegui-Artola et al., 2017). Combined, these results indicate that mechanical forces acting on the nucleus may alter the cellular process through multiple mechanisms which remains an area of active research.

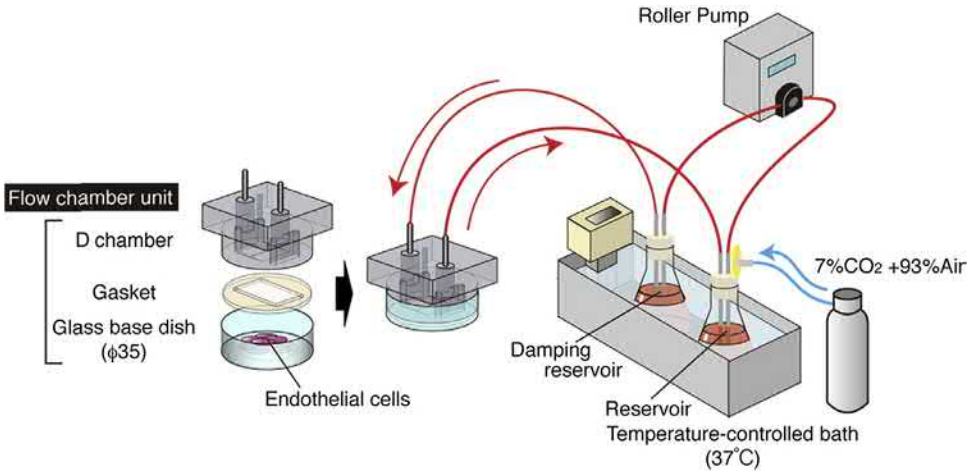
Techniques for Studying Mechanical Interactions of Cells

Shear Stress

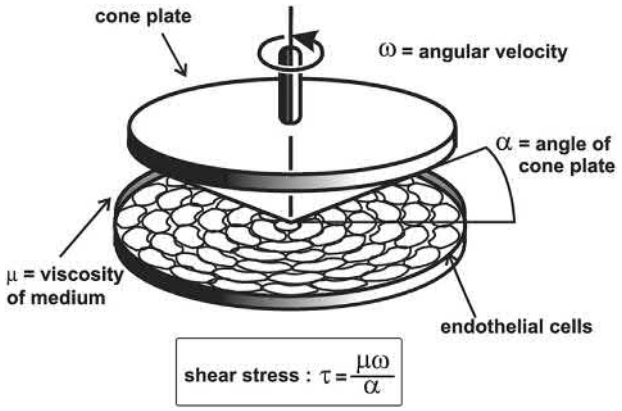
Two in vitro systems have been developed to characterize the response of endothelial cells to a variety of shear stresses: the parallel plate flow chamber (Fig. 2.1.6.4) and the cone and plate system (Fig. 2.1.6.5). In the parallel plate model, two glass slides are used to form a flow chamber with a thin gasket in between to provide accurate spacing (Frangos et al., 1988). This creates a very small gap width through which tissue culture medium can be circulated. The geometric dimensions are known, allowing for the calculation of the fluid shear stress from the flow rate. For a Newtonian fluid flowing through a parallel plate flow chamber with a rectangular cross section, under steady laminar flow yields a shear stress as follows:

$$\tau_w = \frac{6\mu Q}{bh^2}$$

in which τ_w = wall shear stress, μ = viscosity, Q = flow rate, b = channel width, and h = channel height. By varying the chamber geometry, the flow rate, or the viscosity, the entire physiological range of wall shear stresses can be investigated. The flow rate is varied using a syringe pump or gravity-driven system to provide the desired wall shear stress across the cells. The cone-and-plate system consists of a tissue culture dish as the plate, and a fixed-angle cone mounted to a motor that imparts an angular velocity. For small cone angles, the shear rate (and therefore the shear stress) is essentially constant throughout the flow field. Since the dimensions of this system are also characterized,



• **Figure 2.1.6.4** In vitro parallel plate systems for studying the effects of shear stress on cells. In the parallel plate system cells are grown on glass slides and mounted onto a parallel plate chamber. The gasket provides a known gap height. Fluid flows in the inlet, across the deck, and out the exit slot. Some systems may include a damping reservoir to mitigate the oscillatory effects of the roller pump (Yoshino et al., 2013).



• **Figure 2.1.6.5** Cone and plate systems for studying the effects of shear stress on cells. In the cone and plate system cells are grown on a circular dish, which forms a viscometer at the bottom. A small fixed angle cone is rotated at a constant angular velocity providing a constant shear stress across the cells. The degree of shear stress depends upon the viscosity of the medium, the angular velocity of the cone plate, and the angle of the cone (Morawietz et al., 2008).

the fluid shear stress can be calculated for a given angular velocity.

A common way to analyze the effects of shear stress in vitro is with a cone and plate apparatus. In these systems, cells are cultured on a substrate while being subjected to shear stress from a rotating cone. An advantage of this type of system is to be able to create complex shear stress waveforms that are found in the body (Blackman et al., 2002). For example, waveforms that model arterial shear stress have been used to evaluate the response in endothelial cells, and may give more accurate insight into how cells react in physiological conditions (Spencer and Baker, 2016b). Shear stress has been shown to change endothelial cell shape and affect cytoskeletal changes through Rac1 activation (Malek and Izumo, 1996; Tzima et al., 2002). It has also been shown to selectively upregulate specific adhesion proteins associated with focal adhesion sites (Nagel et al., 1994; Girard and Nerem, 1995).

Recently, a high-throughput system with 96 cone-tipped shafts was designed to allow drug screening and adhesion assay under flow in a 96-well format (Spencer et al., 2016; Spencer and Baker, 2016a). In order to analyze adhesion kinetics to biomaterials, methods such as the spinning disc assay have been employed (Reyes and Garcia, 2003; Garcia et al., 1997). In these assays, cells are cultured on biomaterials and subjected to high shear forces in a physiological solution. The resulting detachment patterns give an insight into the adhesive properties of the materials. Microfluidic devices have also been used to analyze the effects of shear stress in vitro (Lu et al., 2004; Polacheck et al., 2013). These apparatuses range from the commercially available microfluidic chambers to custom human-on-a-chip apparatuses that mimic relevant tissue structures. Lung-on-a-chip and intestine-on-a-chip devices provide a more accurate in vitro model of the mechanical forces that act on the cells. Organotypic microfluidic devices for blood vessels have also been employed (Polacheck et al., 2017). These systems use 3D gels that mimic the mechanical properties of blood vessels, to create more accurate representations of the organ system. As with the cone and plate systems, microfluidic devices have been created with higher throughput configurations (Voyvodic et al., 2012). In this device, Voyvodic et al. employed a pulse dampener to remove the pulsatility of the flow coming from the peristaltic pump. In this manner, they could then compare the effects of steady flow and pulsatile flow in the same apparatus.

Mechanical Stretch

Numerous devices have been devised to impart mechanical strain to cells and substrates (Brown, 2000). In general, cells are cultured on flexible membranes and these membranes are subjected to mechanical strains through deformation. Simple stretch machines employ one-directional

stress to their substrates. More complex biaxial and triaxial stretch devices have also been devised for both cell (Neidlinger-Wilke et al., 1994; Sellaro et al., 2007; Schurmann et al., 2016) and tissue applications (May-Newman and Yin, 1995). These multiaxial devices attempt to account for mechanical behavior that tissues experience in vivo (Sacks and Sun, 2003), by applying mechanical stretch in two and three dimensions. Substrate distension machines are also a popular method to impart mechanical strain to cells. Platen (Hasegawa et al., 1985), prong (Vandenburgh, 1988), vacuum (Banes et al., 1985), and fluid swelling (Winston et al., 1989) modalities have been employed to study mechanical strain. A review paper by Brown in 2000 provides a good starting point for those interested in designing and developing mechanical stretch devices. As with shear stress devices, the development of physiological waveforms has led to greater insights into the responses of cells to their mechanical environments (Orr et al., 2006). Mechanical stretch systems are commercially available, and high-throughput apparatuses have also been developed (Lee et al., 2013). In one such system, Lee et al. created a device that could apply mechanical stretch to six, six-well plates at the same time via a moveable platen. The linear motor that drives the motion of the plate can be programmed to apply arbitrary stretch waveforms, from simple sinusoidal waves to more complex biphasic waves.

Substrate Stiffness

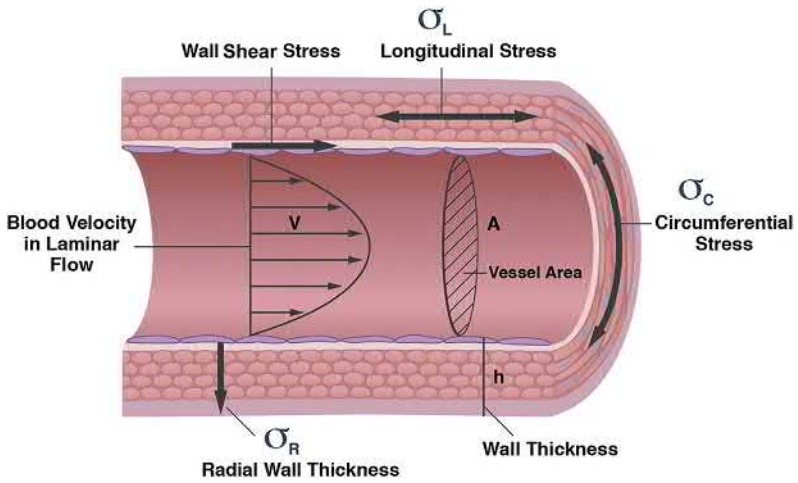
Substrate stiffness plays a key role in regulating normal cell growth and apoptosis (Wang et al., 2000). Furthermore, the movement of cells is also guided by the rigidity of their extracellular environments (Lo et al., 2000). For example, a soft substrate is easier for cells to deform, which reduces the stress at the focal adhesions in the cell. Conversely, on a stiffer substrate, the actin cytoskeleton may increase the force to equilibrate through passive deformation and through changes in myosin motor activity (Chen, 2008). During the process of balancing the external–internal forces, cytoskeletal structure changes could be triggered and following downstream regulations could happen (Torsoni et al., 2005; Xiao-Han et al., 2007; Liu et al., 2007). It has been demonstrated that stiffness modulates mechanotransduction pathways by directing FAs and myosin-based contractility. FAs are found to be smaller in cells cultured on soft substrates and focal adhesion kinase (FAK) phosphorylation is decreased (Paszek and Weaver, 2004). RhoA activity was also shown to be decreased on soft substrates (Engler et al., 2006). Collagen-coated polyacrylamide sheets with a transition in rigidity from soft to stiff were developed to elucidate cell preference for matrix compliance. More recently, photoactivatable gels that change their stiffness with exposure to light have been used to understand the effects of substrate stiffness (Isenberg et al., 2009; Rowlands et al., 2008). In addition, gels with reversible photoactivatable groups or biomolecule hybridization can be used to change polymer chain conformation, altering the substrate stiffness (Rosales and Anseth, 2016). In these systems, researchers can selectively direct the stiffness state of the substrate allowing the in vitro matrix to mimic responses and changes experienced in vivo.

Micro- and Nanopatterning

Micropatterning and more recently nanopatterning have emerged as powerful techniques to direct cell growth and morphology by altering the cell's local mechanical environment (Chen et al., 1998; Arnold et al., 2004; Kim et al., 2012). Ultraviolet photolithography techniques are often employed to create islands of ECM with photopolymerizable polymers. PDMS stamping is another popular technique to deposit proteins on a substrate surface (Christman et al., 2006). Common topographies include grooves, aligned fibers, pillars, and pits. Gradients of these topographies also have been used to ascertain the effects of feature distance. These arrays also help inform haptotactic behavior in cells. Haptotaxis occurs in response to the concentration of ligands on an adhesive surface (Engler et al., 2004). At the most basic level, micro- and nanopatterning direct cell integrin function (Arnold et al., 2004). These changes lead to effects on cell motility (Yim et al., 2005) and cell spreading (Cavalcanti-Adam et al., 2007). The in vivo extracellular milieu is a textured matrix of micro- and nanostructured pores, fibers, and protrusions. As a result, topographic cues also appear to be important in mechanical-mediating pathways. A number of studies have revealed the properties of cell alignment and elongation with micro- and nanogrooved substrates via the guidance of microtubules, actin microfilaments, and the interplay between lamellipodium and ECM ligands (Wojciak-Stothard et al., 1995; Walboomers et al., 2000; Oakley and Brunette, 1993). More than the morphological changes, surface patterning has also been shown to mediate FA formation, cytoskeletal organization, cell migration (Dalton et al., 2001), gene expression (Lee et al., 2009), differentiation (Cai et al., 2012), and other cell processes. In the past decade, new biomaterials have been synthesized and fabricated into various shapes, compliances, and surface topographies. The effects of 3D nanotopographies have also been explored (Horwitz and Alan, 2010). These materials are excellent candidates to mimic in vivo mechanical environments and efficient tools for deeper understanding of mechanotransduction.

Mechanical Forces in the Vascular System

Large blood vessels are comprised of three major cell types: endothelial cells, vascular smooth muscle cells, and fibroblasts. A single cell thick layer of endothelial cells forms the endothelium that lines the lumen of blood vessels. The endothelium provides barrier function, and controls thrombosis and hemostasis by maintaining an active thromboresistant



• **Figure 2.1.6.6** Schematic representation of the hemodynamic forces acting on the artery wall. Cross-section through the artery, in which all layers are constantly subjected to tensile stress (cyclic strain) which arises from normal forces generated by the pulsatility of blood flow. Longitudinal section through the artery. Fluid flow profile (illustrated by the parabola) imparts tangential forces (shear stress) to the blood vessel wall. Endothelial cells lining the blood vessel wall respond first to this force (Whitlock and Hundley, 2015).

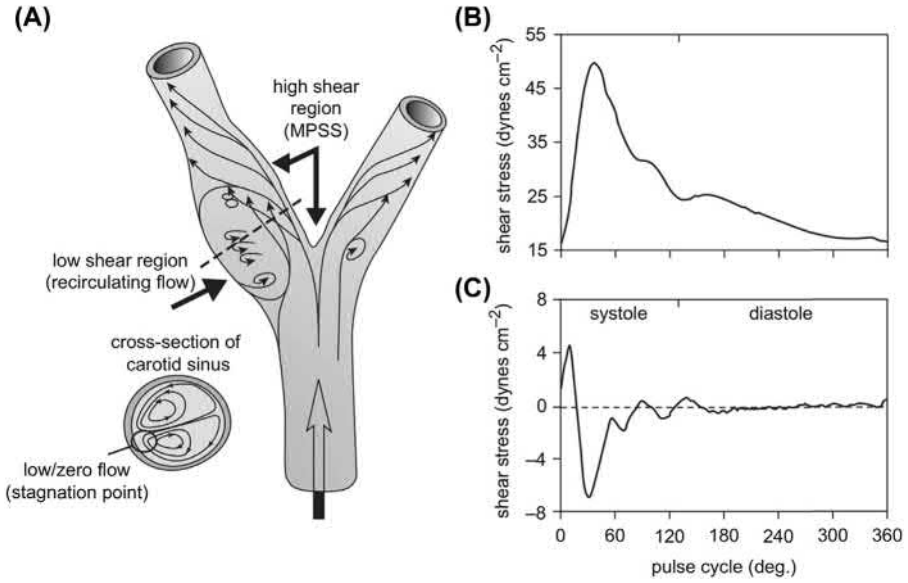
surface. Large arteries also include a middle layer, the media, which consists of smooth muscle cells with secreted extracellular matrix. The outermost layer, the adventitia, consists primarily of fibroblasts and extracellular matrix, and contains blood vessels and nerves supplying the artery itself. Vascular smooth muscle cells (vSMCs) in the medial layer contract, relax, proliferate, synthesize matrix, and migrate in response to shear stress, cyclic strain, and paracrine factors from endothelial cells. Vessels denuded of the endothelium expose the vSMCs to blood flow, resulting in the binding of platelets and thrombosis (Wagner and Frenette, 2008). Extensive studies that apply shear stress or cyclic strain to endothelial cells in vitro confirm that these cells actively participate in vascular physiology.

Mechanical forces resulting from blood flow directly affect cellular functions and morphology in the cardiovascular system (Davies, 2009). Over the cardiac cycle, blood vessels experience wall shear stress and circumferential strain (Fig. 2.1.6.6). These forces are essential for the homeostasis of vessels and altering these forces can lead to vessel remodeling to normalize these forces (Gibbons and Dzau, 1994). A key component of this is Murray's law that states the following,

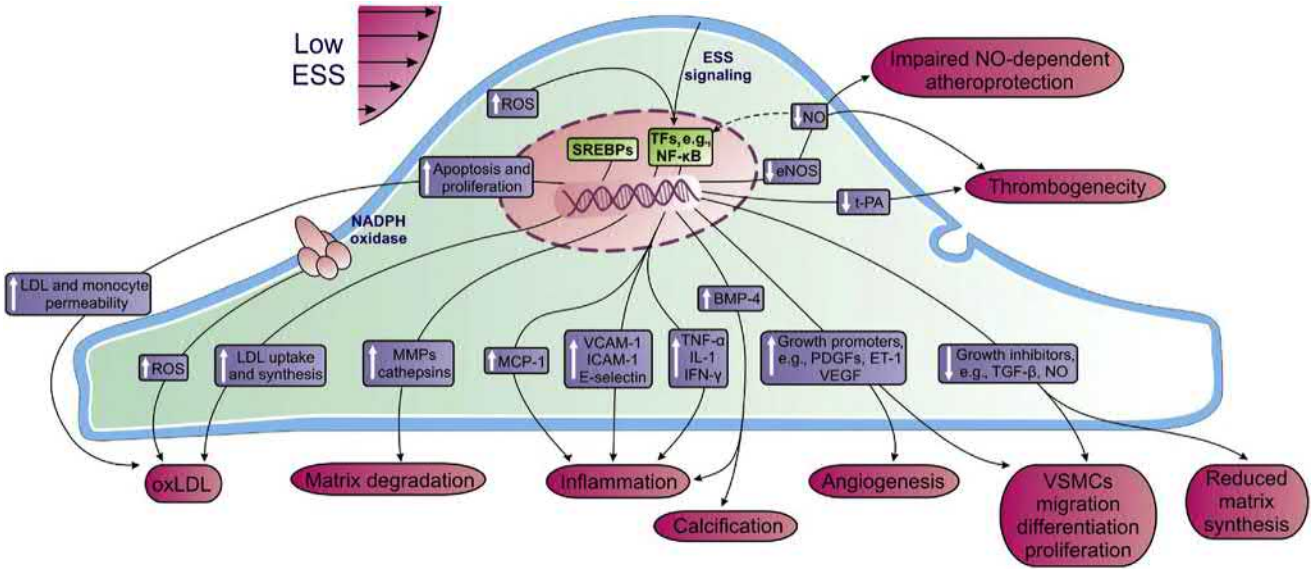
$$r_p^3 = r_1^3 + r_2^3$$

where, r_p is the parent vessel, and r_1 and r_2 are the daughter vessels (Williams et al., 2008). In this relationship, the cost of transport and maintenance is minimized. Disruption or distortion of hemodynamic forces can prime areas of the vasculature for the formation of atherosclerotic plaques (Glagov et al., 1988). Regions within vasculature that have low time-averaged shear stress, flow reversal, or spatial/temporal gradients in shear stress have increased probability for formation of vascular disease (Glagov et al., 1988; Davies, 2008). One reason for the profound effect of flow on vascular disease is the exquisite sensitivity of endothelial cells to flow. Atheroprone flow induces a proinflammatory state in the endothelial cells, feeding the cycle of chronic inflammation that drives the development of atherosclerotic plaques. Virchow's triad delineates the factors important to the formation of thrombosis and includes vessel wall injury, hypercoagulability, and flow disturbance (stasis) (Watson et al., 2009). Consequently, alterations in flow can also alter the risk of formation of clotting in blood. Overall, disturbances in mechanical forces and flow due to implantation of medical devices in the vascular system can create new pathophysiological processes, including the proliferation of vSMCs, immune cell activation, and thrombosis.

Endothelial cells have been studied extensively for their ability to respond to changes in shear stress. Endothelial cells exposed to long-term (24 h or greater) steady shear stress at arterial levels (10–25 dyn/cm^2), as well as pulsatile, nonreversing shear stress (Fig. 2.1.6.7A and B), have been shown to possess a more antiinflammatory and antiproliferative phenotype than when exposed to pulsatile, reversing conditions or low shear stress or to static culture (Fig. 2.1.6.7C) (McCormick et al., 2001; Dai et al., 2004; Chien, 2008; Yee et al., 2008). Acute responses to arterial shear stress include release of signaling molecules such as nitric oxide and prostacyclin, phosphorylation of membrane proteins, and activation of GTPases and tyrosine kinases (Frangos et al., 1985; White and Frangos, 2007). Released signaling molecules, such as prostacyclin and nitric oxide, can in turn act on smooth muscle cells to mediate vasorelaxation. The response of endothelial cells to arterial level shear stresses of 24 h or longer includes alignment of the actin cytoskeleton, movement of the microtubule organizing center toward the direction of flow, and cell elongation and alignment in the direction of flow (Eskin and McIntire, 1988; Orr et al., 2006).

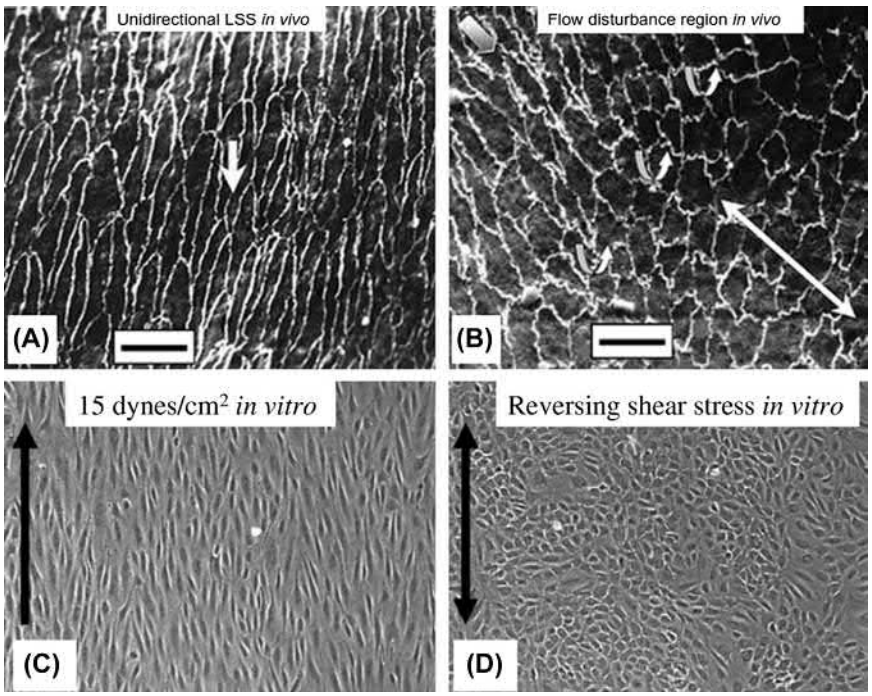


• **Figure 2.1.6.7** Representation of flow features at the carotid bifurcation. (A) Change in wall shear stress throughout the course of the cardiac cycle at two locations within the carotid bifurcation, low shear (including recirculating flow) and high shear regions (MPSS, mean positive shear stress). (B) Waveform of shear stress during one cardiac cycle (1 s) measured at the high shear stress region; (C) waveform of shear stress at the low shear stress region, showing reversing (recirculating) flow (White and Frangos, 2007).



• **Figure 2.1.6.8** Overview of molecular mechanisms in arteries under high and low shear stress conditions. (Chatzizisis, Y.S., Coskun, A.U., Elazer, M.J, Edelman, R., Feldman, C.L., Stone, P.H., June 2007. Role of endothelial shear stress in the natural history of coronary atherosclerosis and vascular remodeling. J. Am. Coll. Cardiol. 49 (25), 2379–2393.)

Endothelial cells respond differently to reversing or oscillatory shear stress as compared to nonreversing shear stress. Steady or nonreversing shear stress transiently induces proinflammatory and proliferative pathways, which are subsequently downregulated by long-term exposure to shear stress. However, oscillatory or reversing shear stress results in sustained activation of these pathways, leading to the hypothesis that under steady shear stress cells adapt and downregulate these pathways, whereas under disturbed flow the continued changes in flow magnitude and direction lead to sustained activation (Dai et al., 2004; Orr et al., 2006; Chien, 2008). Fig. 2.1.6.8 shows a summary of the changes induced by reversing shear stress in comparison with nonreversing shear stress. The increases in cell proliferation, lipid metabolism, and inflammation observed in endothelial cells exposed to reversing shear stress in vitro suggest that in vivo disturbed hemodynamics may prime local sites for atherosclerosis.



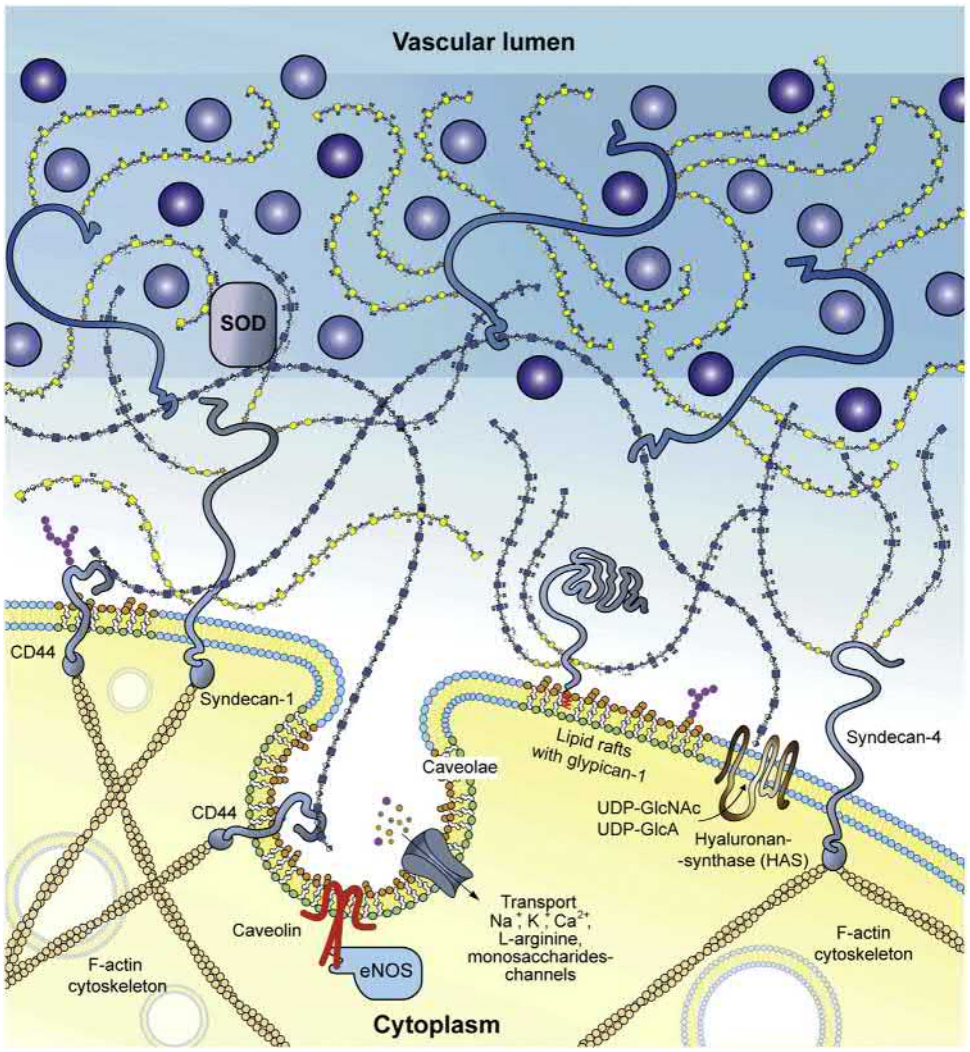
• **Figure 2.1.6.9** Arterial endothelial cell alignment in vivo (porcine) and in vitro (human). (A) Endothelial cell alignment in undisturbed unidirectional laminar flow in the descending thoracic aorta (LSS, laminar shear stress), and (B) absence of transition from alignment in disturbed flow adjacent to a branch of the aorta. In (B), a region of cell alignment changes abruptly to polygonal cell morphology beyond a line of flow separation (curved arrows) that marks the boundary of a disturbed flow region in which oscillating, multidirectional flow typically occurs (double-headed arrow). Scale bar in each panel = 15 μm. (C) Endothelial cell alignment under in vitro steady shear stress (15 dyn/cm^2), and (D) reversing shear stress (modeled after the wall shear stress at the carotid sinus) is similar to in vivo alignment (Davies, 2009).

Consistent with biochemical differences, cells do not elongate or align in the direction of flow at sites of atherosclerosis (Fig. 2.1.6.9).

There is evidence that endothelial cells respond to shear stress within seconds. Rapid changes occur through the activation of ion channels, G-proteins, and stimulation of protein kinases (Davies et al., 2003; White and Frangos, 2007). Shear stress may act directly on the cell membrane to deform the cell surface and activate unknown sensor proteins. However, recent evidence has suggested that shear stress forces are transmitted by the cytoskeleton to intracellular locations where signaling can occur, such as intercellular junctions, focal adhesions, the nuclear membrane, and lipid-rich regions of the cell membrane known as caveolae (Stamatas and McIntire, 2001; Davies et al., 2003; Boyd et al., 2003). In addition to remodeling of the cytoskeleton in response to shear stress there is also evidence of focal adhesion remodeling and activation of proteins at these adhesion sites (Davies et al., 2003), supporting the hypothesis that the majority of shear stress sensing is directly coupled to the cytoskeleton.

More recently, the glycocalyx has reemerged as an important mechanosensor of shear stress in endothelial cells. The glycocalyx is an extracellular membrane-bound layer of glycoproteins and plasma proteins that has been shown to extend up to 500 μm from the endothelial cell membrane (Fig. 2.1.6.10). In vivo, this structure is large enough to prevent cells and even large plasma proteins from reaching the surface of the cell. Removal of key glycocalyx molecules results in a reduced response to shear stress (reduction in nitric oxide production, absence of cell elongation in response to flow, and loss of shear stress-induced suppression of cell proliferation), suggesting that the glycocalyx is an important mechanosensor of fluid shear stress in endothelial cells (Tarbell and Pahakis, 2006). A reduction in the glycocalyx has also been observed in a number of disease states, including hypertension, inflammation, ischemia and reperfusion, hyperglycemia, and at known sites of atherosclerosis (internal carotid sinus). Furthermore, reduced glycocalyx expression has been correlated with increased leukocyte adhesion, suggesting that the glycocalyx may provide protection against atherogenesis (VanTeeffelen et al., 2007). Recently, it has been suggested that in vitro endothelial cells do not form a hemodynamically relevant glycocalyx, highlighting the need for a better understanding of the formation and regulation of this potentially important mechano-sensitive extracellular structure (Potter and Damiano, 2008).

Animal models have further validated data generated from in vitro systems. Suo et al. used computational fluid dynamics to model the wall shear stress in the mouse aortic arch (Suo et al., 2007). Although the mouse vasculature



• **Figure 2.1.6.10** A schematic of the endothelial glycocalyx (V Maksimenko, 2017).

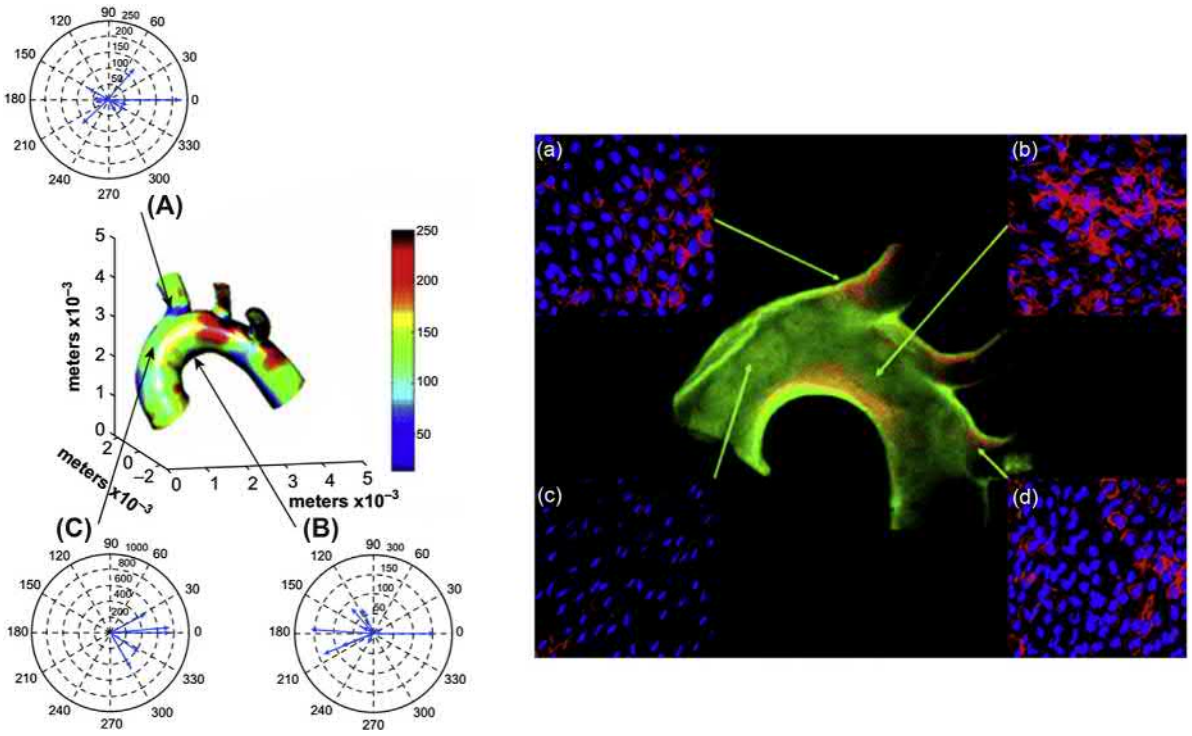
has higher overall shear stresses than the human vasculature, inflammatory markers, such as intracellular adhesion molecule-1 (ICAM-1) and vascular cell adhesion molecule-1 (VCAM-1), were upregulated at sites with low time-averaged shear stress and changes in shear stress direction (Fig. 2.1.6.11) (Suo et al., 2007). Microarray analysis of disturbed flow and undisturbed flow regions in the porcine aorta showed increased inflammatory cytokines and receptors in regions of disturbed flow (Passerini et al., 2004). These in vivo studies suggest that shear stress at sites of atherosclerosis may prime the endothelium toward an inflammatory state, which then may be exacerbated by additional risk factors (e.g., cholesterol, smoking, exercise).

Effect of Shear Stress on Blood Vessels

The flow of blood over the endothelium generates viscous drag forces in the direction of flow. The resulting tangential force exerted per unit area of vessel surface at the blood–endothelium surface defines shear stress. Mathematically, the product between the viscosity (μ) and the velocity gradient at the wall, also known as the wall shear rate ($\dot{\gamma}$), equates to wall shear stress (τ_w):

$$\tau_w = \mu\dot{\gamma}$$

With ventricular contraction, momentum propagates as waves down the aorta, but diminishes in amplitude on the arterial side of the circulation, with distance from the



• **Figure 2.1.6.11** Regional differences in wall shear stress in the mouse aortic arch correlates with regional differences in VCAM-1 expression. (Left) The computed, time-varying wall shear stress vectors are depicted at areas (A), (B), and (C) in one mouse aorta. The color coding indicates the mean wall shear stress distribution (defined as the wall shear stress magnitude averaged over the cardiac cycle). The vector diagrams indicate the time-varying changes in the direction and magnitude of wall shear stress throughout the cardiac cycle. There is a greater variation in the direction of the instantaneous wall shear stress vectors in areas (a) and (b), as can be seen in the polar plots of wall shear stress. Note that the relatively low mean wall shear stress zone at the inner curvature of the aortic arch (b) has instantaneous magnitudes of wall shear stress up to approximately 150 dyn/cm^2, whereas values exceeding 600 dyn/cm^2 were found along the lateral wall of the ascending aorta (c). (Right) High expression of VCAM-1 protein correlates with areas of the aortic arch with low and time-varying shear stresses (a, b, and d), whereas VCAM-1 expression in the ascending aorta (c) is lower, consistent with unidirectional flow (Suo et al., 2007).

heart. Pulsatility is generated by the pumping action of the heart and gives rise to pulsatile shear stress and cyclic strain. Typical mean arterial values of shear stress range from 6 to 40 dyn/cm^2, but can vary from close to 0 to well over 100 dyn/cm^2 elsewhere in the vasculature (Goldsmith and Turitto, 1986; Dobrin et al., 1989). While pulsing down the arterial tree, blood flow normally remains laminar throughout the vascular system with the exception of the ascending aorta, which can have turbulent regions. In regions of complexity, such as regions of arterial branching or tortuosity, there can be disturbed laminar flow with flow reversal and regions of recirculation (Fig. 2.1.6.7).

Effect of Cyclic Strain on Blood Vessels

Along with momentum, pressure propagates as waves down the arterial tree, leading to a periodic circumferential tensile stress in the vessel lumen (Fig. 2.1.6.6). In vivo, blood pressure measures the variation in force against the blood vessel wall as the blood is ejected from the heart during each heartbeat (each cardiac cycle). In measuring blood pressure in humans, the brachial artery is occluded by a pressure cuff (attached to a sphygmomanometer), while the sound of the blood flow is measured downstream with a stethoscope. The pressure cuff is slowly loosened, allowing the pressure to decrease and the blood to flow downstream. The pressure at which the blood flow begins is the systolic pressure. As the pressure continues to decrease, the value at which the sound disappears is the diastolic pressure. Since the arterial wall is compliant, this periodic pressure difference gives rise to a cyclic wall strain. Since arteries and some synthetic substrates on which cells are cultured are elastic, cyclic strain can be measured as the percentage change in diameter between the systolic and diastolic pressures. In normal circulation, the internal diameter and, thus, circumference of large mammalian arteries, increases cyclically between 2% and 18% over the cardiac cycle at a frequency of approximately 1 Hz (60 cycles/min) (Dobrin, 1978). The arterial cyclic strain can increase by 15% in hypertension (Gupta and Grande-Allen, 2006). Typical systole/diastole values in large human arteries range from 90/60 mmHg to 120/80 mmHg.

To study cyclic strain effects in vitro, cells must be cultured on a deformable substrate, usually silicone rubber or segmented polyurethane coated with extracellular matrix proteins, then subjected to cyclic deformation at a rate similar to the heart rate (1 Hz). Most frequently, custom-built

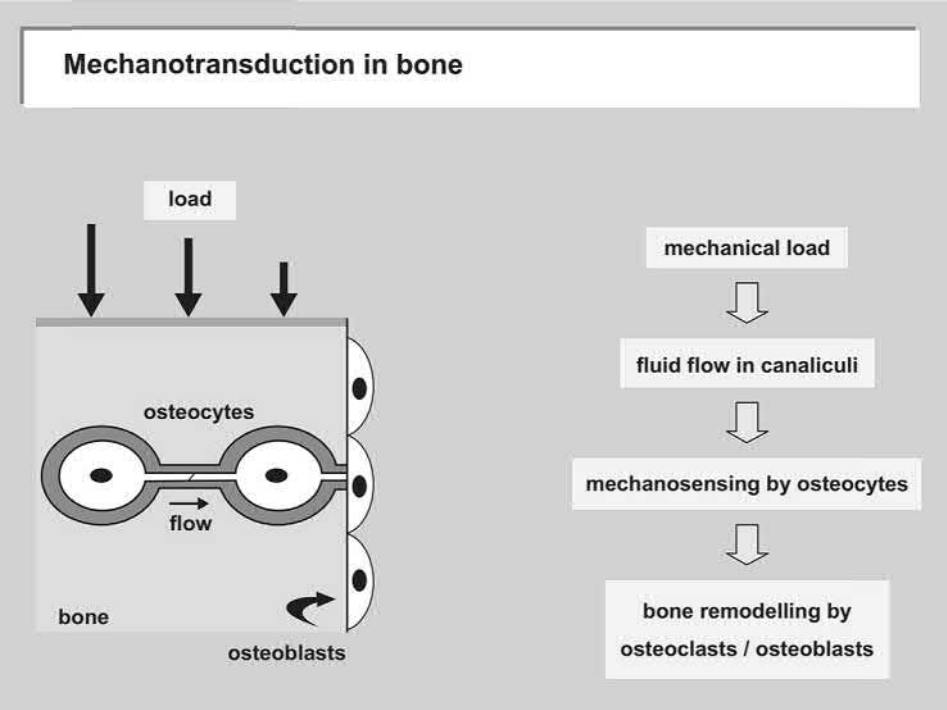
uniaxial strain devices are driven mechanically by an eccentric cam, which imposes a nearly uniform strain along the substrate at a frequency simulating the heart rate (1 Hz) (Frye et al., 2005; Yung et al., 2009). Custom-built biaxial strain units have also been used (Kim et al., 1999). The mechanical forces generated in in vitro studies on uniaxial cyclic strain optimally include a "motion control" condition. "Motion control" controls for the reversing shear stress (less than 0.5 dyne/cm^2) from fluid motion accompanying the cyclic strain of the membrane. Some endothelial cells are more responsive to motion control than to cyclic strain (Sung et al., 2007). Cultured cells have been exposed to cyclic strain in commercially available Flexercell Strain Units (Flexcell International, Corp.), which can deform in uniaxial or biaxial modes (Matheson et al., 2007). These units are driven by vacuum pressure beneath six-well plates with flexible elastomeric bottoms, on which cells are cultured, thus deforming substrate and cells (Haseneen et al., 2003). It should be noted that not only do the mechanical forces that impinge on a population of cultured cells alter their function, but also the substrate on which the cells are cultured may affect cell response. Cyclic strain has been shown to alter the phenotype of cultured smooth muscle cells on polymeric scaffolds (Kim et al., 1999), and to cause differentiation of embryonic stem cells into smooth muscle cells (Shimizu et al., 2008).

Although the effects of shear stress and cyclic strain are most frequently studied independently of each other, recent work has suggested that the synchronization of the two forces when applied simultaneously can affect gene expression and morphology (Owatverot et al., 2005). The stress phase angle has been defined as the temporal phase angle between cyclic strain and wall shear stress (Dancu et al., 2004). The stress phase angle has been shown to be most negative at sites prone to atherosclerosis when compared to other regions of the vasculature and can be made even more negative with hypertension (Dancu et al., 2004). Cells exposed to identical wall shear stress and cyclic strain, but at a stress phase angle of –180 degrees instead of 0 degrees, had reduced endothelial nitric oxide production and increased endothelin-1 production (Dancu et al., 2004), suggesting that asynchronous wall shear stress and cyclic strain could lead to endothelial cell dysfunction.

Bone and Cartilage

Bone is made up of three types of cells: osteocytes, osteoblasts, and osteoclasts. These cells maintain bone function, build new bone, and degrade bone, respectively. Furthermore, they reside in a matrix of collagen and hydroxyapatite, a complex tetracalcium phosphate, which is produced by osteoblasts. The osteocytes are mechanosensors, which release prostaglandins in response to mechanical forces, principally shear stress (Jiang et al., 2007). They transmit signals to other bone cells and the matrix through thin channels in the matrix to influence bone remodeling. Bone is a tissue that is constantly undergoing remodeling in response to mechanical loading, forming new bone parallel to the loading direction, and losing density in unstressed regions. Bone loss from a sedentary lifestyle, limb paralysis, or microgravity during space flight has provided conclusive in vivo evidence for the positive effects of physiological loading of skeletal tissues (Orr et al., 2006). Mechanical loading generates fluid shear stress, hydrostatic compression, and stretch on bone cells. The dense bone matrix resists compressive forces, limiting the transfer of force to the cells (Orr et al., 2006). Physiological strains are only 0.04%–0.3%; however, in vitro it has been shown that strains must be 1%–10% to induce cellular responses (Orr et al., 2006). Unmineralized matrix around osteocytes is more permeable than mineralized bone, creating lacuno-canalicular porosities for interstitial fluid flow. As a result, compressive forces generate pressure gradients that drive interstitial fluid flow in the matrix; these shear stresses have been estimated to be 8–30 dyn/cm^2, similar to arterial wall shear stress (Orr et al., 2006). Interstitial fluid flow due to mechanical loading is thought to be the primary mechanism for action of mechanical forces on bone (Fig. 2.1.6.12) (Klein-Nulend et al., 2005). Although in vitro both osteoclasts and osteoblasts have been shown to respond to shear stress, the geometry of the lacuno-canalicular porosity suggests that interstitial fluid flow is preferentially sensed by the osteoclasts (Orr et al., 2006). Osteocytes respond to mechanical stimuli by secreting factors that can then, in turn, modulate both osteoblasts and osteoclasts (Klein-Nulend et al., 2005). Recent models, however, have suggested that the interstitial fluid flow applies drag forces to the pericellular matrix of the osteocyte that are 20 times larger than the fluid shear forces applied directly to the cell surface (Han et al., 2004). The fluid flow through the pericellular matrix induces strain on the actin filaments of the cytoskeleton, which results in strain amplification at the cellular level an order of magnitude greater than tissue-level strains. These recent models question the hypothesis that the regulatory mechanical force on osteocytes is fluid shear stress, and instead suggest that shear-induced strain may be the principal mechanotransducing force (Orr et al., 2006; Han et al., 2004).

Exercise-stimulated bone remodeling may be the response of osteoblasts to interstitial fluid flow (Reich et al., 1990; Hillsley and Frangos, 1994). Furthermore, temporal gradients in interstitial fluid flow, imposed by pulsatile shear stress (designed to simulate mechanical loading) stimulate osteoblast proliferation in vitro (Jiang et al., 2002), whereas steady shear stress does not stimulate osteoblast signal transduction or proliferation. Exposure of mouse osteocytes and mixed-population human bone cells to pulsating shear stress in vitro increased prostaglandin and nitric oxide release, similar to the effects of shear stress on vascular endothelial cells, suggesting that there may be some similar mechanisms for sensing fluid flow (Klein-Nulend et al., 2005). Strain rate has been shown to be more important than strain amplitude in inducing bone formation in response to loading, supporting the hypothesis that bone formation is stimulated by dynamic rather than static loads (Klein-Nulend et al., 2005).



• **Figure 2.1.6.12** Model for the transduction of mechanical strain to osteocytes in bone. (Left) The osteocyte-lining cell network of bone tissue under stress (large arrows). Loading results in flow of interstitial fluid in the canalicular nonmineralized matrix (horizontal arrow) (Klein-Nulend et al., 2005).

Cartilage, located on the articulating surfaces of joints, provides low friction for freely moving joints. In the growing embryo, cartilage is the precursor to bone. Cartilage cells (chondrocytes) secrete a matrix of collagen fibers embedded in mucopolysaccharide (e.g., chondroitin sulfate). Although cartilage is relatively avascular compared with bone, cartilage responds to mechanical loading similarly to bone. Increased load leads to increased matrix production, resulting in stronger tissue. Cartilage must withstand tensile and shear forces in addition to compression (Kim et al., 1994). Most of the work on cartilage loading focuses on compression and hydrostatic pressure. Cyclic compression of explants (0.1 Hz, 2%–3% compression) stimulated matrix synthesis by chondrocytes (Shieh and Athanasiou, 2003).

Summary

Nearly all mammalian cells and tissues are subject to mechanical forces. We began by highlighting the molecular mechanisms behind mechanotransduction, as well as the major protein architecture responsible for sensing and transducing mechanical forces. We have highlighted the cardiovascular and skeletal systems adapted specifically to mechanical forces, to variations in blood flow and pressure, and to loadbearing, respectively. In vitro models have been employed to study how isolated endothelial and smooth muscle cells from arteries and veins respond to conditions of controlled shear stress and cyclic strain. Gene expression is sensitively regulated by alterations in shear stress and cyclic strain, which translates to functional changes in the cells. The elucidation of roles of different bone cell types has been clarified using in vitro models. We are just beginning to understand interstitial fluid flow in the lymphatic system, and the influence mechanical forces may have on cell migration and tumor growth.

In order to properly design biomaterials that successfully simulate native tissues, understanding the mechanical environment in which the biomaterial is implanted is important. Cells exposed to disturbed mechanical environments (e.g., reversing flow in blood vessels, compliance mismatch of blood vessel grafts, lack of weight bearing on bone) typically have reduced function, and may promote the development of a pathological condition. In designing a biomaterial, we must attempt to recreate the mechanical environment that is to receive the implant for maximum success and long-term viability.

2.2.1 Introduction to Biological Responses to Materials

SHELLY E. SAKIYAMA-ELBERT

Department of Biomedical Engineering, The University of Texas at Austin, Austin, TX, United States

Systemic and tissue-level responses to biomaterials and medical devices are largely driven by biomaterial–tissue interactions in the local environment where they are implanted. Particularly for devices that are not retrieved and are meant to be "permanently" implanted, their ability to function and alleviate the condition for which they were implanted is dependent on minimizing or quickly resolving undesirable interactions with host tissue. Key concepts and systems that mediate these host responses are described in the following chapters.

The first chapter focuses on inflammation, wound healing, and foreign body response to implanted materials. Inflammation is one of the most critical responses, which is required for healing but needs to be balanced and resolved over time to avoid chronic issues. The second chapter focuses on immune responses to materials, both innate and adaptive, including the key types of cells involved in each type of response. It also highlights key regulatory elements of immune responses, and how those can be potentially modulated with materials. The third chapter focuses on complement and how this key component of the innate immune response can play an important role in the response to biomaterial implants. It provides detail on the different activation pathways, signaling and key interaction with the coagulation cascade, as well as highlighting applications where complications often arise due to complement activation. The fourth chapter focuses on systemic and immune-mediated toxicity of materials, which can be a source of failure for medical devices, particularly "permanent" implants. Key areas of discussion include metals, hypersensitivity and immunotoxicity, as well as localization of the response.

The fifth chapter focuses on coagulation and blood–material interactions. This is a critical topic for materials that are involved in vascular applications. Most if not all materials that are implanted surgically will come into contact with blood during implantation, so these issues are broadly important. Modification of material surfaces to alter the interactions with blood proteins and platelets have been a major focus of biomaterials research over the years. The sixth chapter focuses on the potential that implanted materials could cause or promote tumor growth. This chapter focuses on the pathobiology of tumor formation near biomaterials and also highlights concerns specific to the transplantation of stem cells with biomaterials. The final chapter in this section focuses on biofilms and device-related infections. Infections are a major source of failure for long-term biomaterial implants, and thus approaches that prevent bacterial adhesion and biofilm formation could reduce complications in many types of implants.

2.2.2

Inflammation, Wound Healing, the Foreign-Body Response, and Alternative Tissue Responses

JULIA E. BABENSEE

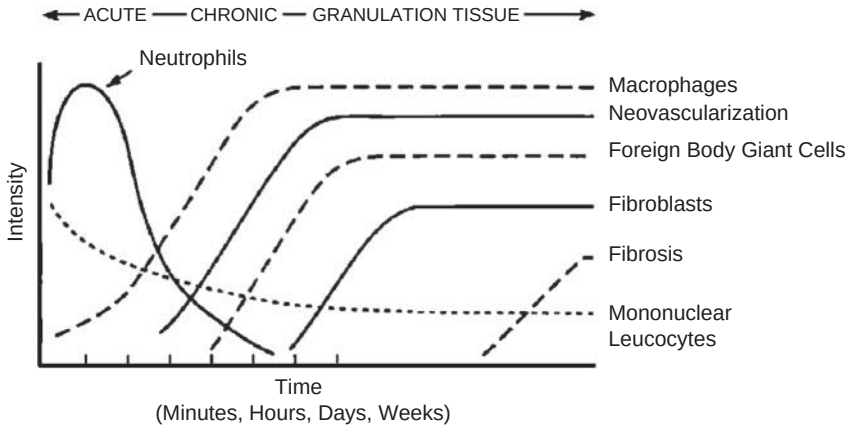
Biocompatibility and Implantation

The surgical implantation of a biomaterial or introduction of an injectable biomaterial via a minimally invasive process, introduces the biomaterial into a physiological environment. The site or type of tissue into which the material is implanted will determine the chief biological processes which will predominate in the host response. For example, anastomosis of a vascular graft to replace a diseased vessel puts a material in contact with flowing blood, so clearly blood compatibility will be a key factor in determining the success of the biomaterial. However, the tissue response on the adventitial side will involve soft-tissue healing. The accepted definition of biocompatibility, proposed by D.F. Williams, is "the ability of a material to perform with an appropriate host response in a specific application" (Williams, 1999). From this definition, biocompatibility defines a particular host response that allows for the biomaterial to perform its intended function in a specific application context. The anatomical site into which the biomaterial is implanted and how the body will respond to that material macroscopically will also play a role in determining the host response.

The temporal sequence of events following implantation of a biomaterial is illustrated in Fig. 2.2.2.1. The properties of the biomaterials influence the host response, and hence the biocompatibility of materials. Material properties include biomaterial size, shape, roughness, topography, surface chemistry, and stiffness. Biomaterial properties may be responsible for variations in intensity and duration of the inflammatory and wound-healing process phases. Furthermore, the intensity and/or duration of the inflammatory reaction may characterize the biocompatibility of the biomaterial. The host response is proportional to the implant surface area that the body needs to respond to. Degradation of biomaterials, either intended for the function or an unintended consequence of the environment, may produce degradation products or particulates which may stimulate inflammatory cells or have toxic effects to affect the biocompatibility of the material used in the device.

The host response to the biomaterial will determine the success or failure of a biomedical device. Examples of beneficial aspects of the tissue reaction to a biomaterial include a vascularized tissue reaction, a thin fibrous capsule, and integration of the material with the surrounding tissue to result in a seamless continuity within the tissue. Examples of deleterious consequences of an adverse tissue reaction include thick fibrous and avascular capsule, scar formation, and chronic inflammatory response.

As noted by the definition of biocompatibility, the aspects of the tissue reaction would need to be considered with respect to the intended application and how the tissue reaction hinders or supports the function of the device. For example, for biosensors that detect an analyte in the blood, the analyte needs to diffuse out of the blood vessel, through the tissue to the sensor. Thus, an avascular fibrous capsule would act as a diffusion barrier and could also be comprised of cells that consume the analyte, making the analyte reading by the biosensor inaccurate (Klueh et al., 2007). A vascularized tissue reaction would bring blood vessels closer to the biosensor–tissue interface to facilitate more accurate readings of blood levels of the analyte (Kenneth Ward et al., 2004). A similar case can be made for the necessity of close vascular structures and adequate functional vascularization of the tissue surrounding or incorporated into tissue-engineered constructs or regenerated tissue (Richardson et al., 2001). Scar-free healing, observed in embryonic/fetal wounds (Ferguson and O'Kane, 2004), is often a desirable host response and the unique features that facilitate this are often aimed to be recapitulated for this desirable host response. Scar-free healing



• **Figure 2.2.2.1** The temporal variation in the acute inflammatory response, chronic inflammatory response, granulation tissue development, and foreign-body reaction to implanted biomaterials. The intensity and time variables are dependent upon the extent of injury created in the implantation and the size, shape, topography, and chemical and physical properties of the biomaterial.

is distinct from adult wound healing, the former having a predominance of TGF-β3 and hyaluronic acid (Ferguson and O'Kane, 2004).

Sequence of the Host Response Following Implantation of Medical Devices

The implantation of a biomedical device, if it involves surgical incision, will initiate a wound healing response. Wound healing involves hemostasis, inflammation, proliferation, and remodeling. Each phase is mediated by distinct cellular and molecular participants in an intensely directed response to the implant (Anderson, 2008). Cytokines initiate and orchestrate the manifold cellular activities which underscore inflammation and healing. Immediately upon insertion of a biomaterial, the cutting of blood vessels will initiate blood coagulation, involving platelet activation and deposition of a provisional fibrin matrix. Thus, the biomaterial will interact with these blood-derived coagulation factors and blood compatibility of the material will contribute to these initial host responses. During this early phase, plasma proteins will adsorb to the biomaterial, blood coagulation and complement activation would occur as directed by the biomaterial properties as well as the homeostatic response to the insertional injury. The adsorbed proteins will mediate all cellular responses with the material.

The second phase is the inflammatory phase in which phagocytic cells, first neutrophils followed by macrophages, migrate to the injury site in response to released chemotactic factors to clear the injury/implant site of cellular and tissue debris and any pathogens. The implanted biomaterial can activate tissue macrophages to release chemokines (Rodriguez et al., 2009) and components of the complement activation pathway in response to the biomaterial, releases chemotactic anaphylatoxins for chemotaxis of inflammatory cells to the tissue implant site (Nilsson et al., 2007). Fibrin degradation fragments, produced upon plasmin degradation of the early fibrin clot, are chemoattractants for leukocytes. Pathogen-derived fragments such as fMLP (*N*-formylmethionyl-leucyl-phenylalanine) from bacteria are chemoattractants for leukocytes if there is any bacterial infection of the implant site. These cells release growth factors and cytokines to attract the next wave of reparative cells and affect the functions that they will perform. For example, macrophages release vascular endothelial cell growth factor (VEGF), which is a chemotactic and proliferative factor for endothelial cells, promoting new blood vessel formation in the injury site. Transforming growth factor released by platelets and neutrophils stimulates fibroblast migration to the injury site to restore normal tissue and deposit extracellular matrix (ECM).

Finally, there is a remodeling phase of the nascent tissue under the influence of enzymes such as matrix metalloproteinases (MMPs) or tissue inhibitor of metalloproteinase (TIMP). Wound healing is often presented as cutaneous wound healing and the proliferative phase focuses on reepithelization and keratinocyte proliferation to remake the skin barrier (Sun et al., 2014). The fibroblast proliferation and collagen formation are analogous to scar tissue formation. Remodeling can also be considered from the point of view of tissue or scar contraction. As with all of the biological processes considered in determining the host response to a biomaterial, careful control of the amount of inflammation or the extent of fibrous tissue formation is needed since excessive levels of these processes can lead to too much inflammation and deleterious consequences such as tissue damage or biomaterial damage. Excess fibroblast proliferation with associated collagen deposition can lead to excessive scar tissue or fibrous encapsulation. However, as wound healing is initiated, the first stage is inflammation, and one must go through the inflammatory stage, but a short-lived inflammatory stage is ideal to encourage the subsequence reparative phase of wound healing. Resolution of the proinflammatory phase to the prohealing phase is necessary for successful wound healing (Eming et al., 2007).

Wound Healing

Wound healing is a response to injury to return the system to homeostasis. Wound healing, whether initiated by trauma, microbes, or foreign materials, proceeds via an overlapping

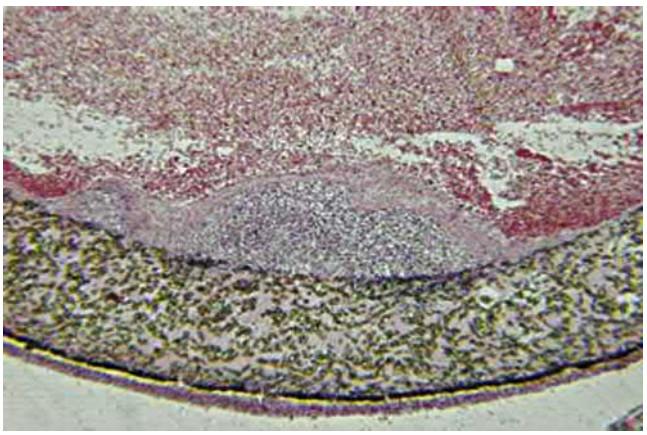
pattern of events including coagulation, inflammation, epithelialization, formation of granulation tissue, tissue formation, and matrix/tissue remodeling (Sun et al., 2014). Complex interplay between plasma protein-derived components, multiple cytokines/growth factors, cells, and extracellular matrix is central to the initiation, progression, and resolution of wounds.

During the homeostatic response to blood vessel cutting, coagulation occurs with a fibrin clot formation where platelets release biomolecules such as platelet-derived growth factor (PDGF) and transforming growth factor-β (TGF-β) to call in the inflammatory cells (Sun et al., 2014). Fibrinopeptides released upon plasminogen degradation of the clot are also chemoattractants. The first type of inflammatory cells to the injury site is the neutrophil, which also responds to chemokines released early in inflammation such as CX3CL1 and CCLs. Complement activation fragments such as C5a and C3a are chemoattractant for neutrophils.

Inflammation is an early necessary phase of the wound-healing response (Eming et al., 2007). Wounds do not heal without the initial inflammatory phase to bring in leukocytes which will clear the injury site of debris and pathogen during the proinflammatory phase. The inflammatory phase is characterized by the expression of proinflammatory cytokines such as tumor necrosis factor-α, interleukin-1 (IL-1), IL-6, and growth factors such as TGF-β and PDGF, and is directed to a large extent by macrophages (Eming et al., 2007). As fewer proinflammatory mediators are released and proregenerative mediators are generated, the wound healing will enter into a regenerative phase with the goal of restitution of the tissue structure and restoring of normal tissue function (Eming et al., 2007). Growth factors released by macrophages, endothelial cells, keratinocytes, and fibroblasts provide autocrine and paracrine signaling for reparative cell recruitment and proliferation for angiogenesis, tissue regeneration, or scar tissue formation. Factors released at the wound site that drive the process of inflammatory resolution include antiinflammatory cytokines such as IL-10, TGF-β isoforms, IL-1 receptor antagonist (IL-1Ra), and other mechanisms to reduce inflammation such as reconstitution of vascular permeability, receptor and transcription factor downregulation (e.g., NF-κB), proteolysis of chemokines, and lymphatic drainage (Eming et al., 2007). The healed wound site can undergo subsequent remodeling under the influence of growth factors such as TGF-β, PDGF, and fibroblast growth factor-2 (FGF-2), and MMPs and TIMPs (Sun et al., 2014).

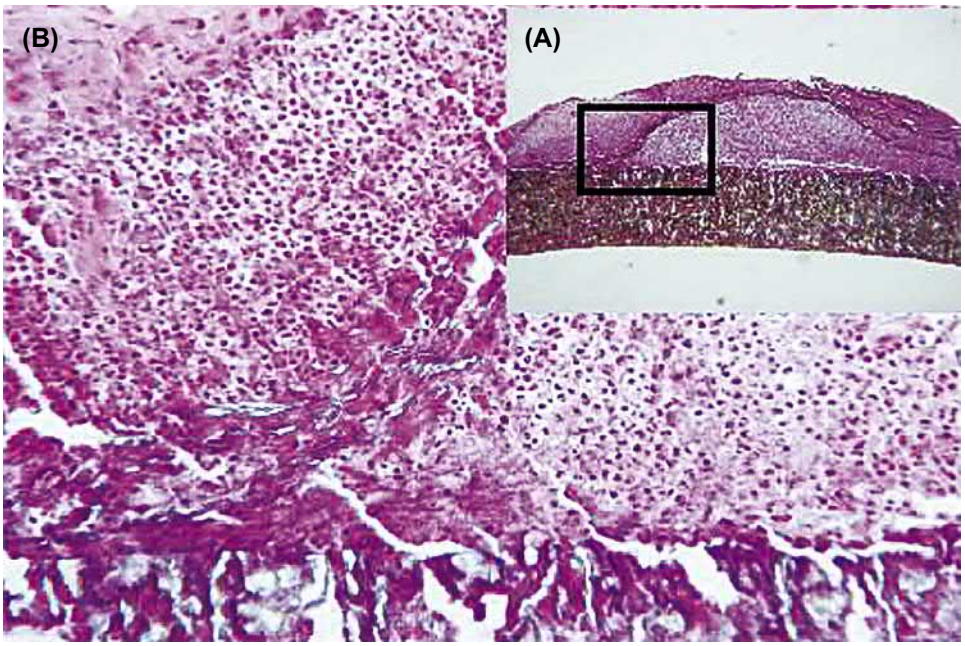
Host Response to Implanted Biomaterials

The implantation or introduction of a biomaterial into living tissue will initiate an inflammatory response to the material (Anderson, 2008). This occurs within the wound-healing context of any injury caused by the implantation of the biomaterial. However, there are distinct aspects and stages of the inflammatory response to a biomaterial which should be discussed. The inflammatory response is fundamentally a protective response, the ultimate goal being to rid the organisms of both the initial cause of cell injury (e.g., microbes, toxins) and the consequences of such inflammation. The inflammatory response is closely intertwined with the process of repair. Inflammation serves to destroy, dilute, or wall off the injurious agent, but it, in turn, sets into motion a series of events that, as far as possible, heal and reconstitute the damaged tissue (Anderson, 2008). The first phase of the inflammatory response to the implantation of a biomaterial is the response to injury, the cutting of blood vessels during insertion of the biomaterial, which initiates the coagulation cascade and platelet activation and degranulation resulting in clot formation and deposition of a provisional fibrin matrix. The platelets release biomolecules which are chemoattractant for leukocytes such as PDGF and TGF-β. The fibrin matrix provides a provisional matrix for leukocytes and other cells to use to migrate in the wound site, as the normal matrix may be damaged or destroyed. Fibrin degradation products are also chemotactic for leukocytes, aiding in their recruitment to participate in healing. The key cellular players of the inflammatory response and their morphological features for their identification in micrographs are discussed in Chapter 2.2.3 by B.G. Keselowsky.



• **Figure 2.2.2.2** Acute inflammation, secondary to infection, of an ePTFE (expanded poly tetrafluoroethylene) vascular graft. A focal zone of polymorphonuclear leukocytes is present at the lumenal surface of the vascular graft, surrounded by a fibrin cap, on the blood-contacting surface of the ePTFE vascular graft. Hematoxylin and eosin stain. Original magnification 4×.

The early phase of the inflammatory response is the acute inflammatory response (Anderson, 2008). This phase can last minutes to several days, as determined by the extent and persistence of an acute inflammatory stimulus such as bacteria or microparticles. Local hemodynamic changes, increased vascular permeability resulting in "leaky vessels" that allows the passage of a protein-rich exudate to the extravascular space, include a process known as exudation. With exudation, plasma proteins contact subendothelial tissue factor to initiate the extrinsic pathway of blood coagulation with fibrin deposition. Local neutrophil accumulation is the hallmark of acute inflammation (Fig. 2.2.2.2). Acute inflammation is a very stereotypical reaction. These leukocytes that circulate in flowing blood within the vasculature, sample the endothelium, until they encounter an inflamed activated endothelium that expresses cell surface molecules such as E-selectin and other unique glycoproteins, that capture flowing leukocytes and mediate their rolling as the L-selectin that they express,



• **Figure 2.2.2.3** Chronic inflammation, secondary to infection, of an ePTFE arteriovenous shunt for renal dialysis. (A) Low-magnification view of a focal zone of chronic inflammation. (B) High-magnification view of the outer surface with the presence of monocytes and lymphocytes at an area where the outer PTFE wrap had peeled away from the vascular graft. typically on projecting microvilli, interacts with its counterligand on the inflamed endothelium (Ley et al., 2007). As this leukocyte is rolling and interacting with the inflamed endothelium, it is activated by cytokines such as interleukin-8 (IL-8) that is released by the endothelial cells. Once activated, the integrin receptor that they express will change its conformation to an activated form such that it can bind to its counterreceptor intracellular adhesion molecule (ICAM-1) on endothelial cells to mediate firm adhesion of the leukocyte. Leukocytes (neutrophils, monocytes) roll, firmly adhere to, and transmigrate through the endothelium and provisional fibrin clot and ECM to chemotactic stimulus. Integrins are the receptors used to bind to ECM motifs for migration through the tissue. Proteolytic degradation of the ECM by MMPs facilitates leukocyte movement through the tissue.

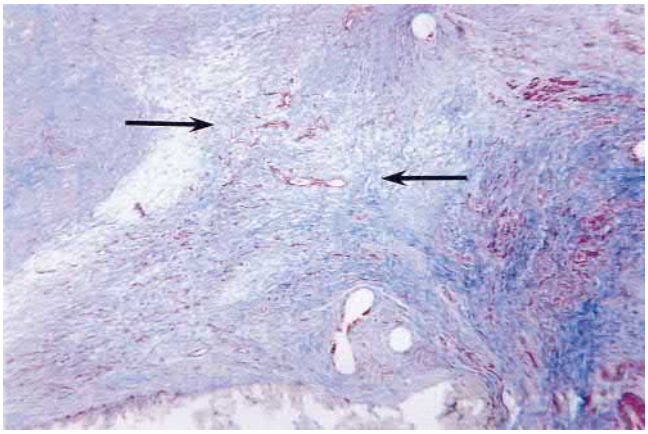
Once at the site of inflammation, leukocytes will clear the site of any cellular debris, bacteria, or foreign material by receptor-mediated phagocytosis and release toxic products (e.g., reactive oxygen species, lysosomal enzymes) to kill or destroy the foreign matter. Neutrophils also release growth factor mediators of tissue regeneration and recruitment of the second wave of inflammatory cells, the monocytes that differentiate in the tissue to macrophages. Neutrophils and macrophages interact with foreign surfaces through receptor-mediated binding to implant surface-adsorbed proteins to result in cell attachment and activation, which includes secretion of cytokines, release of reactive oxygen intermediates, and proteolytic enzymes, the latter two aiming to degrade the foreign material upon phagocytosis of the implant. Tissue-resident macrophages can also participate in directing the inflammatory response to an implant, sensing the foreign material or its biologically derived signals, to the call for recruitment of circulating leukocytes. Tissue-resident macrophages can also proliferate in situ to add to the force of inflammatory cells reacting to the foreign entity (Ensan et al., 2016).

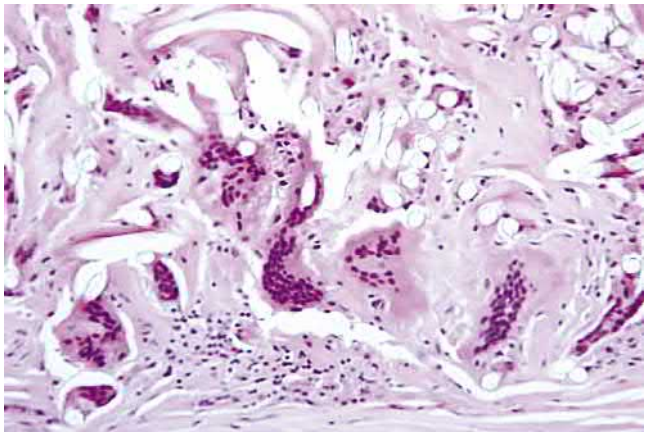
The next phase of the inflammatory response is chronic inflammation (Anderson, 2008). Persistence of an inflammatory stimulus leads to chronic inflammation, as do repeated bouts of acute inflammation, persistence of intracellular microorganisms, prolonged exposure to nondegradable substances, immune reactions, and micromotion of implants. The cellular profile is characterized by the presence of monocytes/macrophages and particularly lymphocytes and plasma cells (Fig. 2.2.2.3). During this stage, there is proliferation of blood vessels and fibroblasts, the latter to increase the presence of connective tissue. However, the chronic destructive nature of this stage of the inflammatory response will lead to tissue destruction that can then only be repaired by scarring. The chronic inflammatory response can also lead to biomaterial destruction, such as stress cracking of surfaces, particularly those associated with foreign body giant cells. This stage of the inflammatory response should resolve within a week or so, but with persistence of a stimulus it can last weeks to years. Thus, the reaction is much less stereotypical than acute inflammation.

Granulation tissue is the healing phase of inflammation and is initiated by the action of macrophages and their release of molecular factors (Anderson, 2008). This phase is characterized by the proliferation of fibroblasts, synthesis of collagen and proteoglycans, and angiogenesis (Fig. 2.2.2.4). Depending on the extent of injury, it can be seen as early as 3–5 days after injury.

This final stage of biomaterial inflammation, the foreign body reaction, is comprised of foreign body giant cells (FBGCs)/macrophages apposed to the biomaterial surface (Fig. 2.2.2.5),

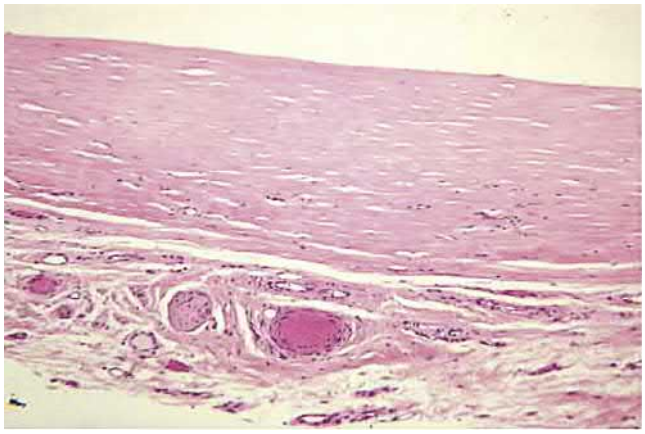


• **Figure 2.2.2.4** Granulation tissue in the anastomotic hyperplasia at the anastomosis of an ePTFE vascular graft. Capillary development (red slits) and fibroblast infiltration with collagen deposition (blue) from the artery form the granulation tissue (arrows). Masson's Trichrome stain. Original magnification 4×.



• **Figure 2.2.2.5** Foreign-body reaction with multinucleated foreign body giant cells and macrophages at the periadventitial (outer) surface of a Dacron vascular graft. Fibers from the Dacron vascular graft are identified as clear oval voids. Hematoxylin and eosin stain. Original magnification 20×.

surrounded by granulation tissue and/or fibrosis (Anderson, 2008). Blood vessels would be seen within the granulation tissue, but typically not in the fibrous capsule. Foreign body giant cells are formed by the fusion of multiple macrophages as they try to engulf a surface that is too large for them to phagocytose, so they undergo "frustrated phagocytosis" (Anderson, 2008). Foreign body cells are very large cells with abundant cytoplasm and as many as 10 nuclei of the macrophages are fused to form this cell. The presence of FBGCs at the surface of biomaterials, as with polyurethane pacemaker leads, is associated with stress cracking just beneath them on the biomaterial surface with subsequent device failure (Zhao et al., 1991). This suggests that these FBGCs have presumably formed to intensify their local inflammatory activity at the biomaterial site. Thus, in this sense they are viewed as bad as far as biomaterials are concerned (McNally and Anderson, 1995). However, other studies suggest that they may be a stable, quiescent, and thus less inflammatory cell than actively inflammatory macrophages (McNally and Anderson, 2002).



• **Figure 2.2.2.6** Fibrous capsule composed of dense, compacted collagen. This fibrous capsule had formed around a Mediport catheter reservoir. Loose connective tissue with small arteries, veins, anda nerve is identified below the acellular fibrous capsule.

Another type of final stage of biomaterial inflammation is fibrosis (Fig. 2.2.2.6). This response is characterized by a dense, aligned collagen produced by the interspersed fibroblasts. The response is characterized by mature fibroblasts and associated collagen that surround the material and wall it off from the rest of the native tissue. Fibroblasts can take on a myofibroblast phenotype to participate in the contraction of the fibrous capsule associated with the implant (Anderson, 2008). Other deleterious consequences of a foreign body reaction/fibrosis are its mass transfer barrier and consumption of nutrients for tissue-engineered cell/biomaterial constructs, encapsulated cells, or biosensors for an analyte in the blood. The foreign body reaction lasts for the lifetime of the device recipient, as long as the implant remains in the body (Anderson, 2008).

Tissue Remodeling and Biomaterial Integration—Alternative Tissue Responses

The wound-healing environment is becoming better understood by the scientific community, with a shift in the goal of biomaterial scientists to utilize this understanding to design biomaterials that integrate more naturally with the implant environment. Alternative host responses to the foreign body response and fibrosis were suggested in a J.M. Anderson review citing an angiogenic tissue response as a potential outcome (Anderson, 1993). One needs to understand the range of host responses that can be achieved in vivo and define new goals for a desirable tissue reaction. One also needs to consider the cell types and biological mediators of these alternative tissue reactions. Finally, one needs to understand the physiochemical and design features of biomaterials and devices that give rise to these alternative tissue responses.

A tissue response to implanted biomaterials that was deemed desirable is one that is well vascularized. This was first observed using a biomaterial system with a pillared biomaterial surface topology which allowed host cell infiltration into the membrane with close vascular structures (Picha and Drake, 1996). The work by J.H. Brauker at Baxter identified

the pore size of membranes as influencing inflammatory cell infiltration into pores with close vascular structures (Brauker et al., 1995). Baxter was interested in encapsulating cells with immunoisolation to facilitate cell transplantation without the need for immunosuppression as for allogeneic or xenogeneic cell transplantation. They recognized that not only did they need to keep immune cells and immune components from entry into the immunoisolation device, but they had another design criteria which was to have vascularization in the tissue surrounding these devices so that nutrients could be delivered to the encapsulated cells, and waste products removed, and also that the secreted product, which was the biologic drug target of the system, needed to be taken up by the bloodstream. They showed a pore size of about 5–8 μm as promoting vascularizing membranes (Brauker et al., 1995). They used a laminated membrane with an inner immunoisolating membrane and an outer vascularizing membrane.

Ratner followed up on these studies using membranes of a set pore size, prepared using a sphere templated porous hydrogel scaffold in which pores around 40 μm (Marshall et al., 2004) were optimal for close vascular structures or 60 μm for percutaneous porous biomaterial epithelial and dermal integration (Fukano et al., 2010). Concurrently, S.L. Badylak et al. were describing the unique tissue restorative capacity seen with a decellularized ECM, porcine small intestine submucosa (SIS) (Valentin et al., 2009). These authors showed constructive remodeling and tissue integration with noncross-linked decellularized matrices which were lost with cross-linking of ECM materials. See Chapter 1.3.6A by K.L. Christman for further discussion. Brown also demonstrated a tendency for reparative, wound-healing phenotype of M2 macrophages with these positive tissue reactions (Brown et al., 2012). Macrophage phenotype is thought to occur within a color wheel with three equidistant spoke locations of classical inflammatory (M1), regulatory macrophages, and wound-healing macrophage phenotypes (M2) (Mosser and Edwards, 2008). A caveat to the M1/M2 macrophage characterization/notation is the complex and dynamic in vivo environment of wound healing or tissue response to biomaterials wherein macrophages may shift their expression of phenotypic markers in response to the ever-changing microenvironmental signals, potentially expressing a range of M1/M2 markers (Brown et al., 2012). A solely biomaterial chemistry-based angiogenic response was observed with polyacrylate copolymers containing poly(methacrylic acid) (Butler and Sefton, 2007).

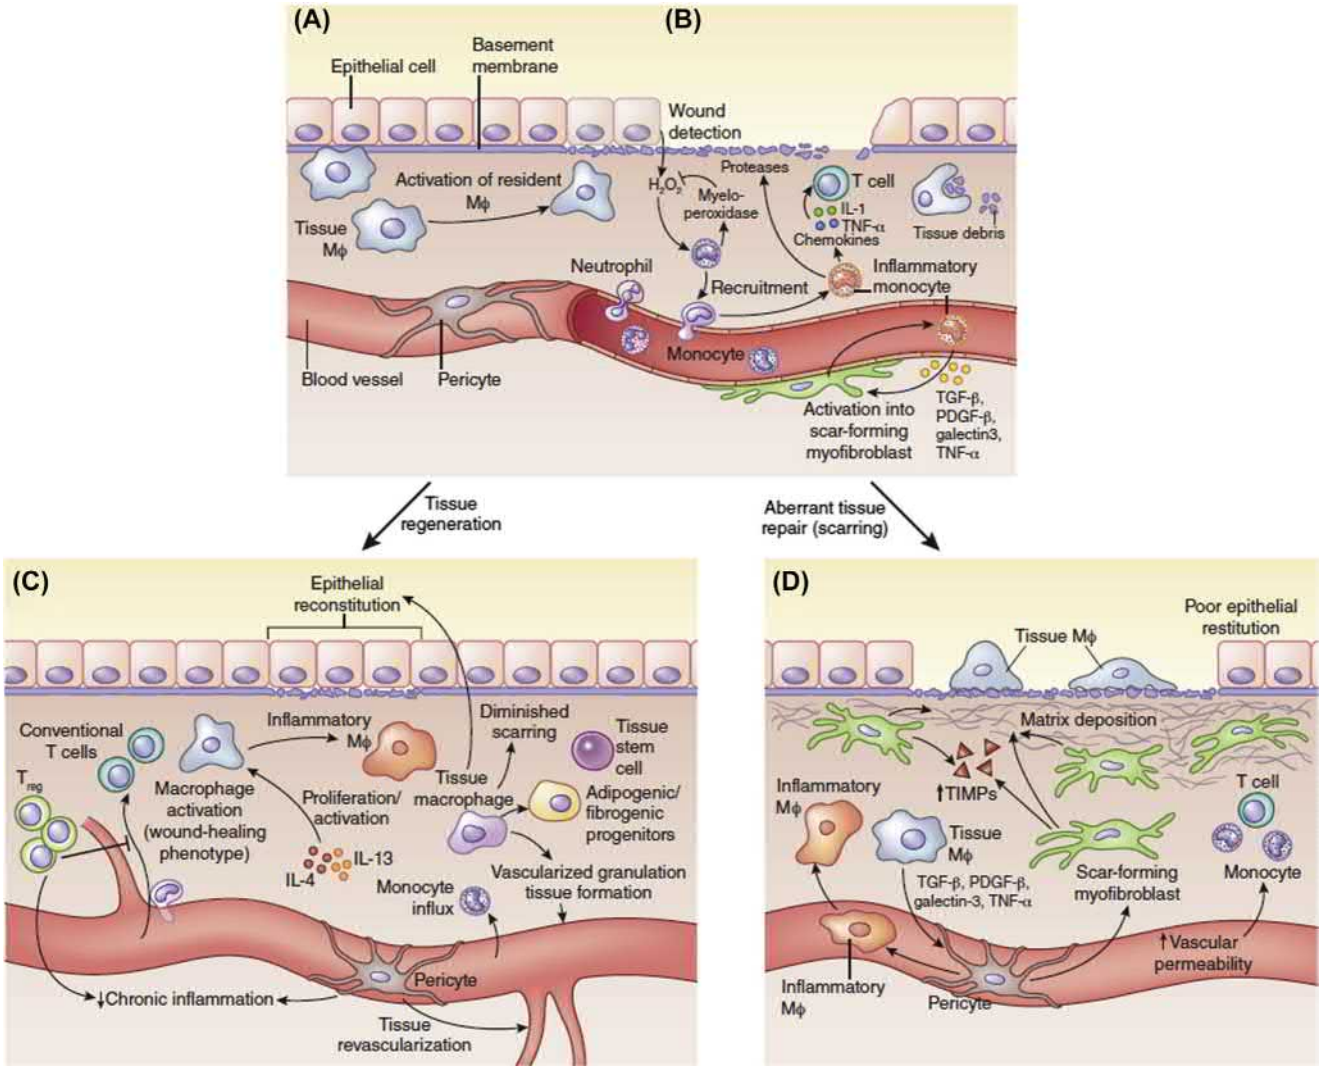
Alternatives to a fibrotic tissue response to a synthetic polymeric mesh of polypropylene used to treat hernias were demonstrated in two structural designs—one based on the pore size of the mesh and the other on the three-dimensional design of the device. Meshes with an in vivo effective pore size of <1 mm demonstrate a tissue reaction of granuloma and fibrosis around each fiber that merge and form bridging fibrosis around the mesh (Klinge et al., 2002). An alternative tissue response was observed for large pore size meshes >3 mm, wherein the mesh was integrated into a loose network of perifilamentary granulomas and fat tissue in the region between the widely placed fibers (Muhl et al., 2008). A cellular/molecular basis for this alternative tissue reaction is based on the multipotential nature of circulating fibrocytes in their ability to differentiate into myofibroblasts (the cells that form the fibrous capsule around biomaterials) (Schmidt et al., 2003) as well as adipocytes (fat cells) (Hong et al., 2005). Tang et al., demonstrated the induction of adipogenic (fat) tissue associated with biomaterial implants when inhibiting transforming growth factor or infusing an adipogenic differentiation cocktail at the implant site (Baker et al., 2014).

Another example of an alternative to a fibrotic tissue response was observed for a large-pore, polypropylene mesh, that was multilamellar "flower"-shaped positioned on the outside of the peritoneum with a flat sheet on the other side of the peritoneal wall (Amato et al., 2014). This device is not strictly fixed at the implant site, and the movement of the device is meant to adapt to the movement of the implant site, but the design holds it in place. The flower shape of the device has an inherent outward recoil, which as opposed to cone-shaped plugs, has a tendency to collapse. A beneficial aspect of the host response to this 3D dynamic responsive prosthesis was noted with neotissue formation, myogenesis, lack of fibrosis, newly formed elastic fibers, angiogenesis, and neurogenesis (Amato et al., 2014).

Cellular and Molecular Mediators of Constructive Remodeling and Tissue Restoration

The wound-healing environment and key cellular and molecular players that determine constructive remodeling/tissue restoration as opposed to a scarring/fibrotic response have been described in a new paradigm by Forbes and Rosenthal (2014). The regenerative capacity of stem cells delivered to a site of degenerative diseases is greatly influenced by the cellular and signaling components of the local microenvironment to which they are seeded. This microenvironment is the "soil" to the "stem cell seed." The inflammatory state of the implant site can affect the extent to which a stem cell therapy is successful. Endogenous healing of tissues such as liver and skeletal muscle are described in this chapter, including the conditions of key players in regeneration (Fig. 2.2.2.7). Situations that will lead to aberrant regeneration, scarring, and tissue death are clearly described.

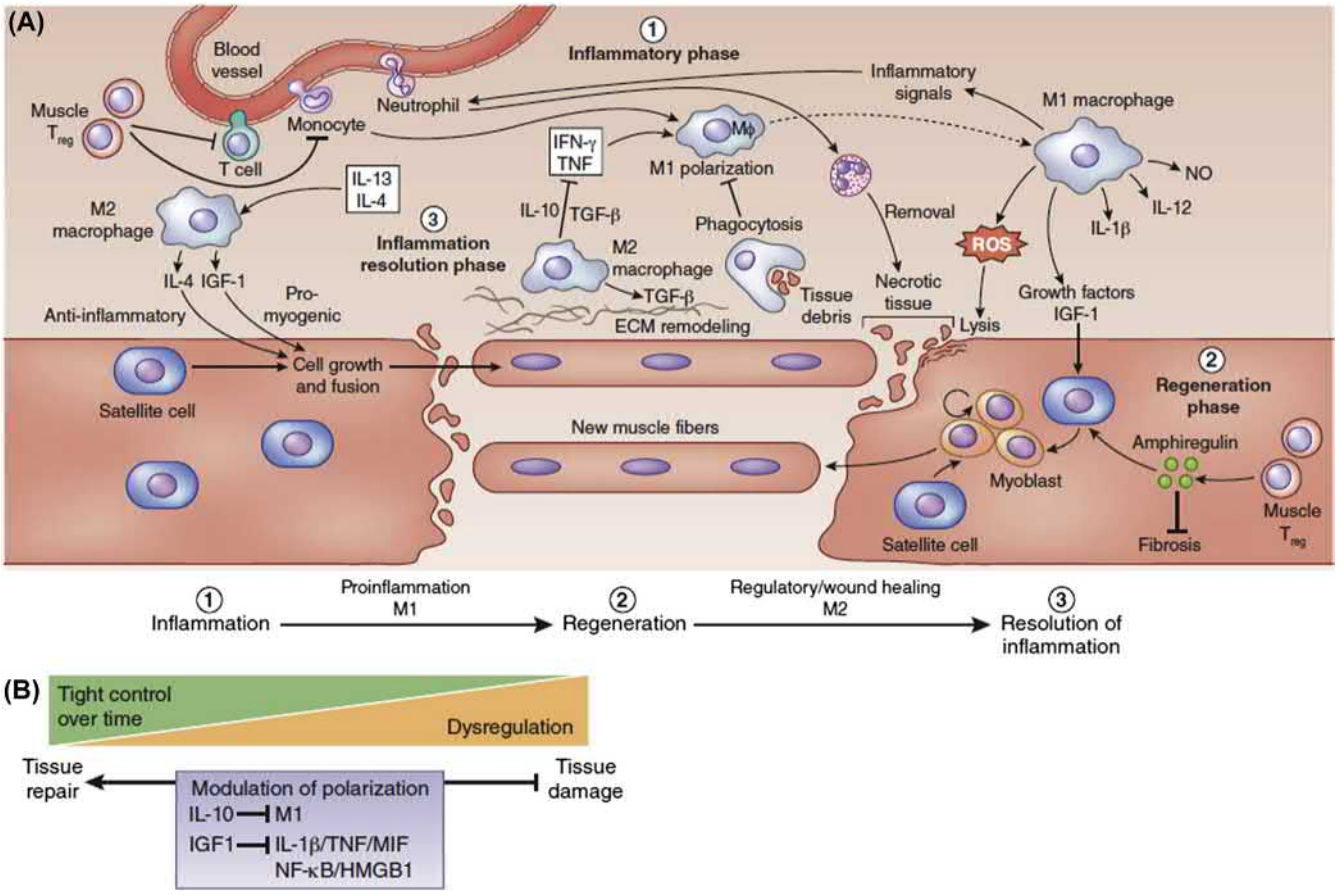
Macrophage phenotype is a central player in determining the wound-healing outcome. Proinflammatory M1 macrophages release signals such as platelet-derived growth factor-β (PDGF-β), transforming growth factor-β (TGF-β), tissue necrosis factor-α (TNF-α), and galectin-3. Endothelium-encircling pericytes are affected by these factors to induce scar-forming myofibroblasts. In tissue restoration, macrophages are influenced by antiinflammatory molecules such as IL-4 and IL-13 to result in a wound-healing type of macrophage M2. The environmental signals that determine tissue regeneration or adherent healing and scarring are described in Rosenthal for the liver, gut, skin, kidney, skeletal muscle, and heart. Regulatory T cells (T_{regs}) are present in a regenerating



• **Figure 2.2.2.7** General model of tissue repair. (A) In healthy tissue, there is little monocyte trafficking or neutrophil efflux into tissues, an intact basement membrane and no scar tissue. (B) Upon tissue damage, there is loss of epithelia, neutrophil influx, activation of resident macrophages (Mϕ) and recruitment of inflammatory monocytes. in addition to release of inflammatory factors and activation of pericytes into myofibroblasts. (C) During tissue regeneration. there is epithelial proliferation for reconstitution, macrophage activation into a wound-healing phenotype and matrix remodeling. In addition. T_{reg} cells are recruited to decrease chronic inflammation. (D) During aberrant tissue repair, excessive scarring occurs as a result of continued activation of inflammatory cells and impaired epithelial regeneration. TIMPs, tissue inhibitor of metalloproteinases: PDGF-β, platelet-derived growth factor-β.

tissue to provide signals to inhibit chronic inflammation and activation of conventional T cells. A positive remodeling tissue environment supports endogenous tissue stem cells, adipogenesis/fibrogenic progenitors, and endothelial progenitors to participate in new tissue formation and tissue restitution. Another principle of tissue repair as opposed to tissue dysregulation is that tight control over the inflammatory response is needed (Fig. 2.2.2.8). A dysregulated inflammatory response will lead to tissue damage and scarring. Macrophage polarization is central in determining such outcomes of wound healing with immunosuppressive molecules such as IL-10 and insulin growth factor-1 (IGF-1), inhibiting proinflammatory M1 phenotype processes such as IL-1β/TNF-α/macrophage infiltration factor (MIP), proinflammatory nuclear factor-kappa B (NF-κB)/high-molecular-weight group box 1 (HMGB1) pathways. As such, potential targets and mechanisms for enhancing a healing response to implanted biomaterials are suggested by such knowledge.

The central role of the immune system in adult tissue regeneration is also discussed in a relevant review by D.L. Mann et al., who present the immune cell profile in the resting, uninjured heart as including immune cells, primarily macrophages, sparse populations of dendritic cells, mast cells, and B cells and regulatory T cell subsets (Epelman et al., 2015). Neutrophils are recruited to the site upon injury or infection. Immune cells such as regulatory T cells, B cells, and dendritic cells support the role that adaptive immune cells can provide regulatory signals for tissue



• **Figure 2.2.2.8** Modulation of inflammation and cell replacement in muscle regeneration (A) Muscle injury disrupts capillaries and triggers inflammatory cascades, which result in neutrophil invasion for necrotic tissue removal and MI macrophage activation by IFN-γ and TFN. MI macrophages secrete proinflammatory factors and IGF-1 (1). Muscle regeneration depends on a precise balance between pro- and anti-inflammatory factors: wound repair initiates fibrosis and ECM remodeling replacing destroyed myofibers with connective tissue, but continued accumulation of fibrotic tissue compromises muscle function (2). Together with IL-4 and IL-13, IGF-1 promotes polarization of M2 macrophages, which control excess inflammation and promote regeneration through release of TGF-β (3). T_{reg} cells have also been recently shown to have a role in this process regenerative process by regulating macrophage activation and releasing amphiregulin for muscle repair, clearing the inflammation[33]. (B) Macrophage polarization is promoted by cytokines (IL-10) and growth factors (IGF-1). The temporal control over the polarization process is crucial: dysregulation leads to excessive inflammation and disease. ROS, reactive oxygen species. regeneration under the appropriate conditions. Along a similar argument, a recent study showed that the improved heart function upon intracardiac injection of cardiac stem cells to treat a heart ischemic injury was by inducing an acute sterile immune response, characterized by the temporal and regional induction of CCR2$^+$ and CX3CR1$^+$ macrophages, that led to functional regeneration of the heart without incorporation of delivered cardiac cells or production of new cardiomyocytes (Vagnozzi et al., 2020).

Biomaterials scientists, such as J.H. Elisseeff, have demonstrated adaptive immune cell participation in sterile inflammatory/tissue responses to biomaterials and tissue regeneration. Elisseeff demonstrated a clear role of adaptive immunity in driving the repair of a volumetric muscle loss murine model of traumatic injury using a tissue-derived decellularized ECM biomaterial (Sadtler et al., 2016). Specifically, a role for CD4$^+$ T cells and a Th2 helper phenotype were shown to be regulatory through its secretion of IL-4 that influenced macrophages to an M2-like phenotype and the increased presence with time of CD4$^+$FoxP3$^+$ Tregs. The culmination of such a response is dependent on the immune cell recruitment and activation based on interaction with the ECM biomaterial-derived signals and communication between the different cells present. Another study showed infiltration and polarization of several immune subtypes including macrophages, dendritic cells, neutrophils, monocytes, B cells, and T cells in response to implanted tissue-derived ECM scaffolds (Sadtler et al., 2017).

Strategies to Control Host Responses

A recent study by O. Veiseh et al. explored the role of the geometry, shape, and size of biomaterial implants on the

extent of the foreign body reaction and fibrosis around the implant (Veiseh et al., 2015). They found that implanted spheres of 1.5 mm or above in diameter across a wide range of material types, including hydrogels, ceramics, metals, and plastics, significantly abrogated the foreign body reaction and fibrosis when compared to smaller spheres. This interesting result appears to contradict prior dogma wherein the amount of surface area of an implant is directly correlated with the extent of foreign body reaction and fibrosis—as the implant recipient has a greater surface area to respond to so the implant has a greater host response. Macrophages were shown to be key to the extent of foreign body reaction/fibrosis, with attenuation of these responses when this cell population was depleted in a transgenic model. Furthermore, gene expression profiles for classically activated (proinflammatory, $M_{classic}$), alternative activation (prohealing, M_{wound}), and regulatory activation (M_{Reg}) were analyzed for 1.5 or 0.5 mm capsules, wherein it was demonstrated that a lack of regulatory macrophage cell accumulation on large-sized spheres correlates with the truncated fibrosis responses. Presumably the geometry or curvature of the biomaterial surface on a microscale to which the host cells respond affects the macrophage phenotype, accounting for the results seen in this study.

In another study by this group, a combinatorial library of alginate microcapsules was screened in an in vivo whole-animal imagining system using a fluorescent probe for cathepsin activity at implant sites as an indicator of inflammatory response (Vegas et al., 2016). Unique microcapsule hydrogel chemistries were identified that showed thin fibrous capsules upon subcutaneous implantation in rodents or for at least 6 months in nonhuman primates. The unique chemistry moieties identified were triazole derivatives. While the mode of action of this chemistry on the inflammatory response to implanted microcapsules was not known, a small molecule triazole scaffold is being investigated as an immunomodulatory agent through its effects on T cells, not macrophages (Kharb and Sharma, 2011; Lindstedt et al., 2009).

Another interesting piece of the story of host response to biomaterials cited the central role of a chemokine receptor, colony-stimulating factor-1 receptor (CSF1R), for the foreign body response to biomaterial implants in rodents and nonhuman primates (Doloff et al., 2017). It was demonstrated that macrophages are required and responsible for downstream B-cell recruitment via the B-cell chemoattractant CXCL13, and that following their arrival B cells enhance fibrotic deposition. Inhibition of the macrophage-associated cytokine receptor CSF1R eliminated host-immune-mediated recognition and propagation of foreign body rejection responses to a broad range of materials. The attenuation of the host responses was not, however, done at the expense of other macrophage functions such as skin incision wound healing, macrophage phagocytic activity, and reactive oxygen species production. The result suggests a potentially highly specific target for abrogating the fibrotic response to implanted biomaterials rather than generally suppressing the immune system to avoid a fibrotic response.

Immunotherapy technologies are beginning to be applied to the problem of fibrosis. For example, in a recent study, T cells were engineered using chimeric antigen receptors (CAR) T-cell technology to target pathogenic cardiac fibrosis (Aghajanian et al., 2019). The efficacy of redirected T-cell immunotherapy to specifically target pathological cardiac fibrosis in mice was demonstrated. It was found that cardiac fibroblasts expressing a xenogeneic antigen can be effectively targeted and ablated by adoptive transfer of antigen-specific $CD8^+$ T cells. An endogenous target of cardiac fibroblasts was identified using expression analysis of the gene signatures of cardiac fibroblasts obtained from healthy and diseased human hearts, namely, fibroblast activation protein. Adoptive transfer of T cells that express a chimeric antigen receptor against fibroblast activation protein resulted in a significant reduction in cardiac fibrosis and restoration of function after injury in mice, suggesting a promising approach for clinical testing. Immunotherapy approaches are expected to be able to modulate aspects of the host response to biomaterials and regeneration.

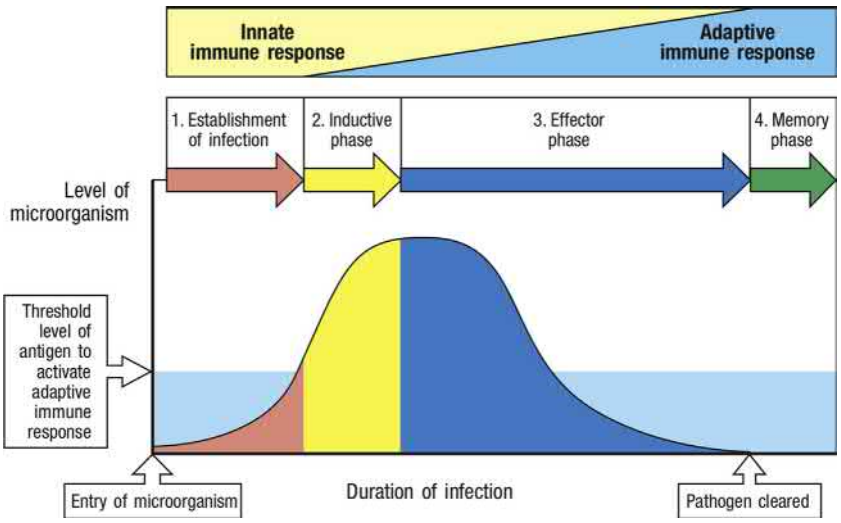
Overview

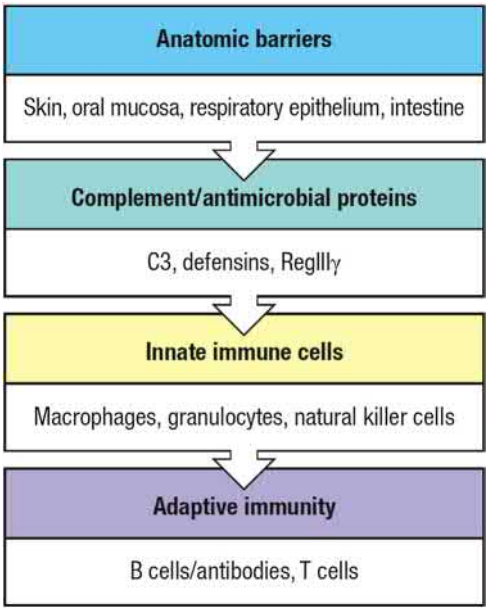
The intersection of immunology and biomaterials is a rich field for synergy. For example, early immunology work by Ilya Mechnikov in the late 1800s, remarkably relevant to modern biomaterials approaches to immune engineering, utilized readily available natural material as a tool to observe the process of phagocytosis. He inserted plant thorns composed primarily of the natural polymer cellulose (potentially along with microbial contaminants) into starfish larvae and observed an influx of interrogating cells. This line of inquiry and availability of materials-based tools subsequently uncovered the fundamental process of phagocytosis, the means by which immune cells engulf and degrade foreign material. Mechnikov's work earned him the Nobel Prize in Physiology or Medicine, shared with Paul Ehrlich in 1908. In keeping with the synergy between materials and immunology, the use of the material alum as a vaccine adjuvant began in the 1920s and has since been saving millions of lives annually. With these and many more such powerful examples in fundamental science and application as guideposts, a growing number of biomaterial scientists aim to continue this tradition, but often must first become acquainted with the basic principles of immunology.

The immune system is the defense mechanism of the body that is responsible for protecting against damaging foreign pathogens, maintaining components of self, and permitting benign commensal microbes (Matzinger, 1994; Ridge et al., 1996; Janeway, 1989). It is notable that aspects of immunology are integral in enormously diverse topics in biology and medicine spanning conception to death. These topics include reproduction, development, wound healing, infection, vaccination, cancer, immunotherapy, autoimmunity, transplantation, and diagnostics. More extensive discussion of the immune system can be found in a number of excellent basic immunology texts (Abbas and Pober, 2000; Travers et al., 2001). Emerging concepts are extending even further, as immunology is increasingly being understood as an integral component of the homeostatic health of many tissues, for example, through interactions with stem cells, localized metabolic regulation, and regulating the microbiome (Wood and Martin, 2017; Masopust D, 2019; Round and Palm, 2018; Immunity in the tissues, 2013; O'Neill et al., 2016).

Keeping in mind the intended biomaterials scientist readership, we discuss here the primary components and functions of classical immunology and how the immune system recognizes and eliminates or reacts to foreign bodies at an introductory level. Components of the immune system that differentiate between "self" and "nonself" along with mechanisms for elimination of the recognized threat are described. While the field of immunology is typically covered in multiple introductory and specialized courses, this overview chapter only introduces *innate* and *adaptive* immunity with the intent to provide a fundamental understanding of the body's response to the insertion of a foreign material. It is with these basic immunology concepts in mind that the reader can be better prepared to anticipate issues that arise at the biomaterials–tissue interface. This chapter therefore outlines the two main arms of the immune response, the interlinked innate and adaptive systems, with the innate immune response preceding, potentiating, and directing the adaptive response to the establishment of infection, followed by an induction phase, effector phase, and memory phase (Fig. 2.2.3.1). Each arm of immunology possesses multiple layers of defense with many interacting components (Fig. 2.2.3.2). Finally, areas of particular interest to biomaterials and biomaterials-centric applications are described. Note, the topic of the foreign body reaction to implanted synthetic materials is covered in detail in Chapter 2.2.2.



• **Figure 2.2.3.1** The innate and adaptive immune response act in concert to eliminate pathogens. (1) Pathogen establishes infection and induces the innate response upon detection. (2) As the antigen levels goes above a threshold, they trigger the adaptive immune response. (3) After 4–7 days, adaptive immune response components clear the infection. (4) After the infection is cleared, long-term memory in the form of antibodies and cells is established (Travers et al., 2001). (Figure 11.1 Janeway's Immunobiology ninth edition).



• **Figure 2.2.3.2** Protection against pathogens relies on several levels of defense. The first is the anatomic barrier provided by the body's epithelial surfaces. In the second, various chemical and enzymatic systems, including complement, act as an immediate antimicrobial barrier near these epithelia. If epithelia are breached, nearby various innate lymphoid cells can coordinate a rapid cell-mediated defense. If the pathogen overcomes these barriers, the slower-acting defenses of the adaptive immune system are brought to bear (Travers et al., 2001). (Figure 1.5 Janeway's Immunobiology ninth edition).

Innate Immunity

Innate immunity encompasses the first phase of responses to foreign pathogen or injury (Medzhitov, 2007). The primary response of innate immunity is to recruit effector cells to the site of invasion or injury, and recognize nonspecific or broadly specific foreign body markers. These responses then lead to effective removal of a foreign body or initiation of tissue remodeling and healing.

Innate immunity utilizes a range of biomolecules, including antimicrobial enzymes, antimicrobial peptides, complement systems, cytokines, and reactive oxygen and nitrogen species among others to neutralize the perceived "danger." Additionally, innate immunity also has a range of different types of specialized cells such as macrophages, dendritic cells (DCs), natural killer (NK) cells, and γδ T cells among others to neutralize the perceived "danger" (Travers et al., 2001). Notably, some cells of the innate immune system can recognize pathogen-associated molecular patterns (PAMPs) of different types of pathogens, setting in motion development of an immune response capable of eliminating the pathogen within minutes to hours (Iwasaki and Medzhitov, 2010; Janeway et al., 2002; Kumar et al., 2011). Only when the innate immune system fails to clear pathogens is the adaptive immunity (described later) activated, which then generates a "memory" response toward the pathogen. In the following sections we will discuss different components of the innate immune system, their function, and mechanisms.

First Barriers Against Danger

Epithelial layers of the body such as those in skin, gut, lungs, and oral cavity provide the first barrier against foreign bodies (Fig. 2.2.3.3). Epithelial cells are joined by tight junctions to provide mechanical tissue integrity. In addition to physically blocking pathogen entry, epithelia are also responsible for producing various chemicals and biomolecules that provide defense against pathogens. Specifically, these cells can produce lysozymes and phospholipases to dissolve the membrane of bacteria (Travers et al., 2001). If the pathogens survive this first barrier, the next line of defense, called the complement system, is activated (Travers et al., 2001).

	Skin	Gut	Lungs	Eyes/nose/oral cavity
Mechanical	Epithelial cells joined by tight junctions			
	Longitudinal flow of air or fluid	Longitudinal flow of air or fluid	Movement of mucus by cilia	Tears Nasal cilia
Chemical	Fatty acids	Low pH	Pulmonary surfactant	Enzymes in tears and saliva (lysozyme)
		Enzymes (pepsin)		
	β-defensins Lamellar bodies Cathelicidin	α-defensins (cryptdins) RegIII (lecticidins) Cathelicidin	α-defensins Cathelicidin	Histatins β-defensins
Microbiological	Normal microbiota			

• **Figure 2.2.3.3** Many barriers prevent pathogens from crossing epithelia and colonizing tissues. Surface epithelia provide mechanical, chemical, and microbiological barriers to infection (Travers et al., 2001). (Figure 2.5 Janeway's Immunobiology ninth edition).

Complement System

The complement system is a large, diverse set of soluble proteins produced primarily in the liver, which are utilized by the innate immune system to complement antibody responses to recognize and eliminate a foreign body. The complement system can recognize a pathogen's molecular patterns and become activated, which can result in direct killing of the pathogen, enhanced phagocytosis, and production of local inflammatory responses. Notably, various natural and synthetic biomaterials can also engage and activate the complement system, increasing biomaterial-associated inflammation (Hubbell et al., 2009). The complement system is described in detail in Chapter 2.2.4.

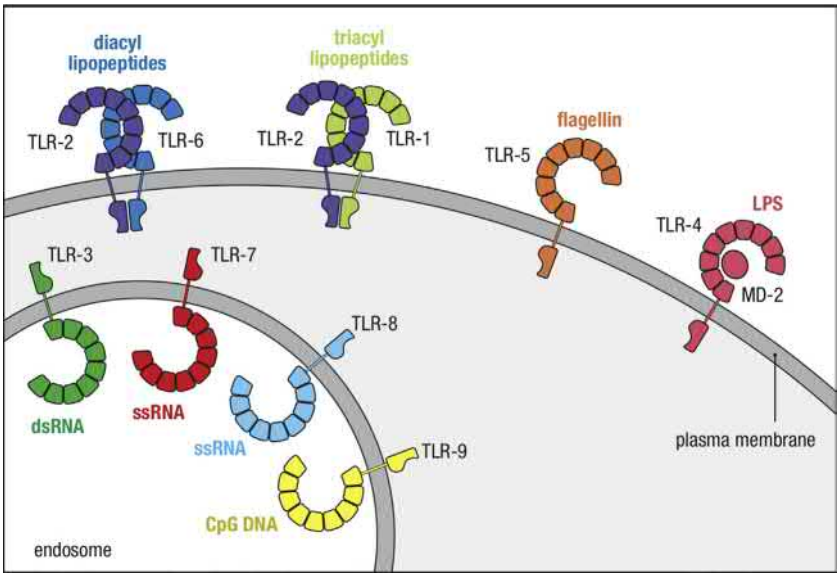
Pattern Recognition by the Innate Immune System

The innate immune system has evolved receptors that recognize specific patterns of foreign materials. This class of receptors is called pattern recognition receptors (PRRs) (Janeway et al., 2002). PRRs are divided into four main categories: (1) soluble complement receptors (discussed earlier), (2) membrane-bound phagocytic receptors, (3) membrane-bound signaling receptors, and (4) cytoplasmic signaling receptors.

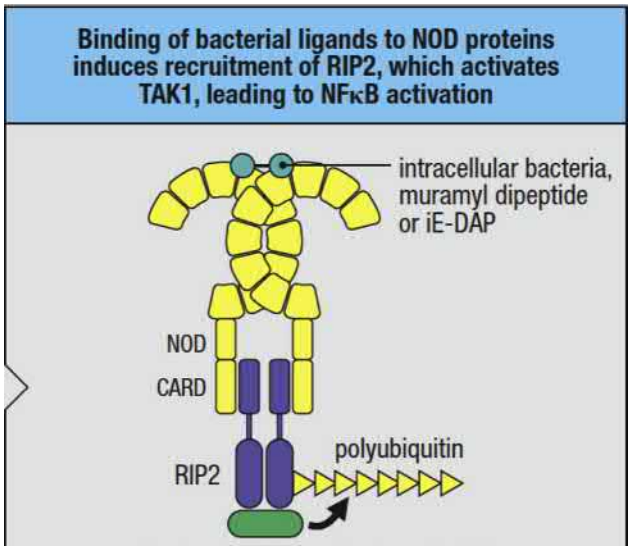
Membrane-bound phagocytic receptors, such as mannose receptor, Dectin-1, lipid receptor, and scavenger receptors among others are utilized by cells of the innate immune system to phagocytose foreign materials (discussed in the section "Antigen Processing and Presentation"). On the other hand, membrane-bound signaling receptors such as toll-like receptors (TLRs) (Kumar et al., 2011; Acharya et al., 2016) are utilized to signal the presence of pathogen and induce an immune response. TLRs are ancient pathogen-recognizing receptors that can recognize different molecules expressed by pathogens. Since these molecules are characteristic of the pathogens that are not found in host tissue, they are called PAMPs. There are several PAMPs such as lipopolysaccharide (expressed in the cell wall of Gram-negative bacteria), bacterial DNA, diacyl and triacyl lipopeptide, flagellin, and double- and single-stranded RNA, which are recognized by the innate immune system. To recognize these wide variety of molecules, TLRs (TLR1–TLR10 in humans; TLR1–TLR13 in mice) located either on the cell surface or in endosomal vesicles are utilized (Fig. 2.2.3.4). These TLRs are capable of activating MYD88 and TIR-domain-containing adapter-inducing interferon-β signaling pathways, which then lead to immune cell activation and functions such as phagocytosis and removal of pathogens.

Another group of receptors recognizing PAMPs in the cytosol of innate immune cells are called nucleotide-binding oligomerization domain (NOD)-like receptors (NLRs) (Inohara and Nuñez, 2001). Examples of NLRs include NOD-1 and NOD-2 (Fig. 2.2.3.5), which are responsible for detecting breakdown products of the peptidoglycans of bacteria. Another interesting subclass of NLRs is called NOD leucine-rich repeat and pyrin domain (NLRP). There are 14 different types of NLRPs expressed in humans, and although the activation of these is not clearly understood they can recognize extracellular ATP molecules.

A very important group of cytosolic RNA-detecting mechanisms of the innate immune system is called retinoic acid-inducible gene I (RIG-I)-like receptors (RLRs) (Takeuchi and Akira, 2008). RIG-I detect single-stranded RNA and induce the production of type I interferons. Similar to RIG-I, another RLR, MDA-5 (also called helicard) detects double-stranded RNA. Both RIG-I and MDA-5 are important receptors of intracellular viruses and for mounting an antiviral immune response (Fig. 2.2.3.6). Cytosolic DNA molecules such as cyclic-di-AMP, cyclic-di-GMP, etc. are detected by stimulator of interferon genes (STING) receptors (Archer et al., 2014). STING receptors are innate



• **Figure 2.2.3.4** The cellular locations of the mammalian toll-like receptors (TLRs). TLRs are transmembrane proteins whose extracellular region contains 18–25 copies of the leucine-rich repeat (LRR), but these cartoons depict only nine LRRs for simplicity. Some TLRs are located on the cell surface of dendritic cells, macrophages, and other cells, where they are able to detect extracellular pathogen molecules. TLRs are thought to act as dimers. Only those that form heterodimers are shown in dimeric form here; the rest act as homodimers. TLRs located intracellularly, in the walls of endosomes, can recognize microbial components, such as DNA, that are accessible only after the microbe has been broken down. The diacyl and triacyl lipopeptides recognized by the heterodimeric receptors TLR-6:TLR-2 and TLR-1:TLR-2, respectively, are derived from the lipoteichoic acid of Gram-positive bacterial cell walls and the lipoproteins of Gram-negative bacterial surfaces (Travers et al., 2001). (Figure 2.14 Janeway's Immunobiology ninth edition).



• **Figure 2.2.3.5** Intracellular nucleotide-binding oligomerization domain (NOD) proteins sense the presence of intracellular pathogens. NOD-like receptors reside in the cytoplasm, and are activated in the presence of various ligands (bacterial ligand shown here). NOD1 recognizes γ-glutamyl diaminopimelic acid (iE-DAP), a breakdown product of Gram-negative bacterial cell walls. The binding of these ligands to NOD1 or NOD2 induces aggregation, allowing caspase recruitment domain (CARD)-dependent recruitment of the serine–threonine kinase RIP2. RIP2 is then responsible for inducing nuclear factor kappa-light-chain-enhancer of activated B cells (NFkB) production, which then leads to activation of the immune cells (Travers et al., 2001). (Adapted from Figure 3.17 Janeway's Immunobiology ninth edition).

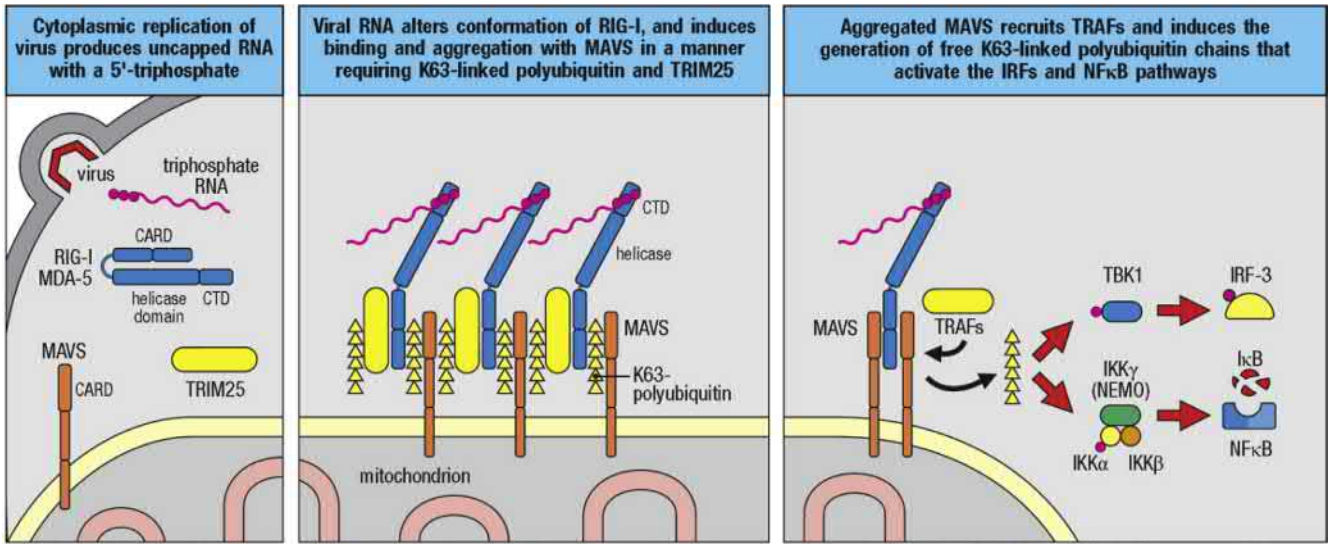
sensors of intracellular DNA fragments generated by viral or bacterial species (Fig. 2.2.3.7).

In sum, the innate immune system has multiple PRRs that can recognize a variety of different molecules from pathogens. Once these molecules are recognized, PRRs induce downstream signaling in innate immune cells for the production of cytokines, chemokines, and costimulatory molecules, which are essential for the function of adaptive immune responses. Furthermore, PRRs can also be activated by host molecules that can be generated from cellular infection, damage, stress, or transformation. Such host molecules have been termed damage-associated molecular patterns (DAMPs), and some of the molecules in this class can also be recognized by receptors involved in pathogen recognition, such as the TLRs. Upon recognition of DAMPs, innate immunity is activated leading to further immune responses.

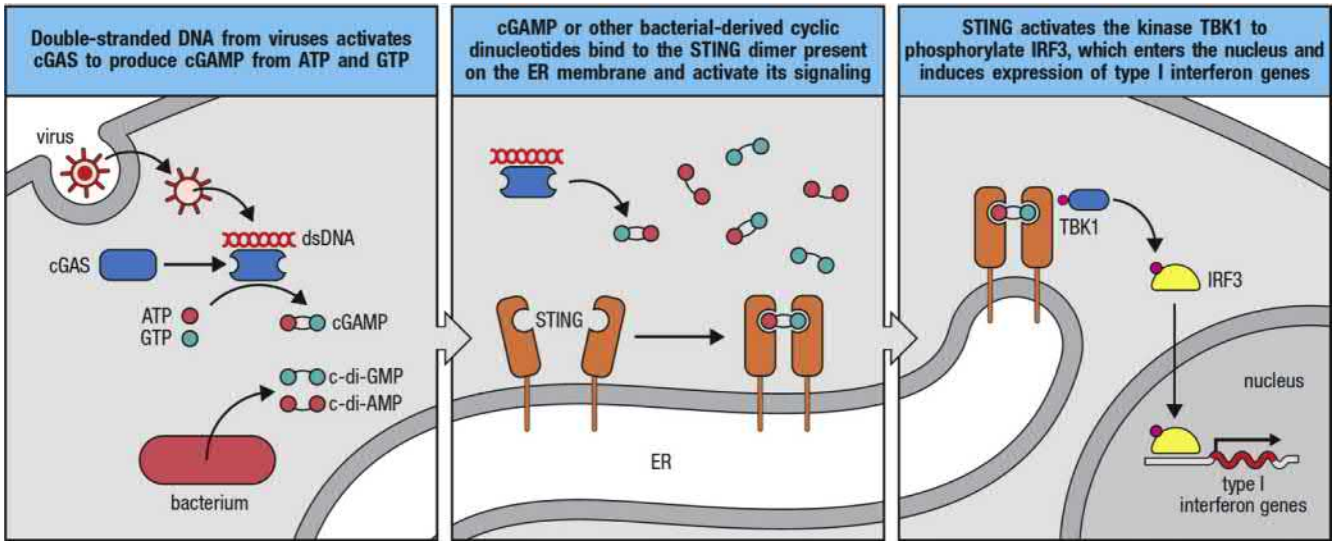
Cells of the Innate Immune System

To mount a robust immune response, the innate immune system utilizes several different types of immune cells such as innate lymphoid cells (ILCs, e.g., NK cells), mast cells, eosinophils, basophils, γδ T cells, neutrophils, monocytes, macrophages, and DCs (Fig. 2.2.3.8). The function of each of these innate cells is outlined next:

Monocytes: Monocytes are one of the largest constituents of total white blood cells in terms of abundance (Travers et al., 2001). Monocytes are derived from hematopoietic

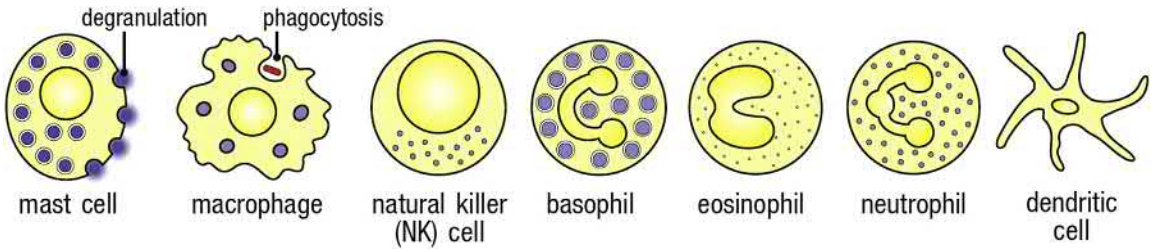


• **Figure 2.2.3.6** Retinoic acid-inducible gene I (RIG-I) and other RIG-I-like receptors are cytoplasmic sensors of viral RNA. Detection of uncapped 5'-triphosphate RNA by RIG-I, or viral dsRNA by MDA-5, changes the conformation of their caspase recruitment domain (CARD) domains to become free to interact with the aminoterminal CARD domain of the adaptor protein called mitochondrial antiviral signaling protein (MAVS), attached to the outer mitochondrial membrane. This interaction involves the generation of K63-linked polyubiquitin from the E3 ligases TRIM25 or Riplet. The K63 polyubiquitin is then able to upregulate interferon and nuclear factor kappa-light-chain-enhancer of activated B cells (NFkB) signaling leading to the activation of the immune cells (Travers et al., 2001). (Adapted from Figure 3.21 Janeway's Immunobiology ninth edition).



• **Figure 2.2.3.7** Stimulator of interferon gene (STING) recognizes cytosolic cyclic DNA (cDNA) and induces a type I interferon-mediated innate immune response against intracellular pathogens. *First panel*: cyclic GMP-AMP synthase (cGAS) resides in the cytoplasm and serves as a sensor of double-stranded DNA (dsDNA) from viruses. When cGAS binds dsDNA, its enzymatic activity is stimulated, leading to production of cyclic-GMP-AMP (cGAMP). Bacteria that infect cells produce second messengers such as cyclic dinucleotides, including cyclic diguanylate monophosphate (c-di-GMP) and cyclic diadenylate monophosphate (c-di-AMP). *Second panel*: cGAMP and other bacterial dinucleotides can bind and activate the STING dimer present on the endoplasmic reticulum (ER) membrane. *Third panel*: in this state, STING activates type I interferons through TBK1 and IRF3, although the details of this interaction are still unclear (Travers et al., 2001). (Adapted from Figure 3.22 Janeway's Immunobiology ninth edition).

stem cells, and although not terminally differentiated, play an important role in innate immunity. Monocytes typically circulate in the blood for 1–3 days, and in the presence of injury or infection are directed to enter peripheral tissue via extravasation through blood vessels as directed by endothelial cell upregulation of adhesion (e.g., selectin) and chemoattractant molecules. Monocytes utilize adhesion molecules (e.g. carbohydrate ligands), to bind to endothelium and exit the blood stream. Cytokines produced by tissue-resident innate immune cells induce rolling monocytes



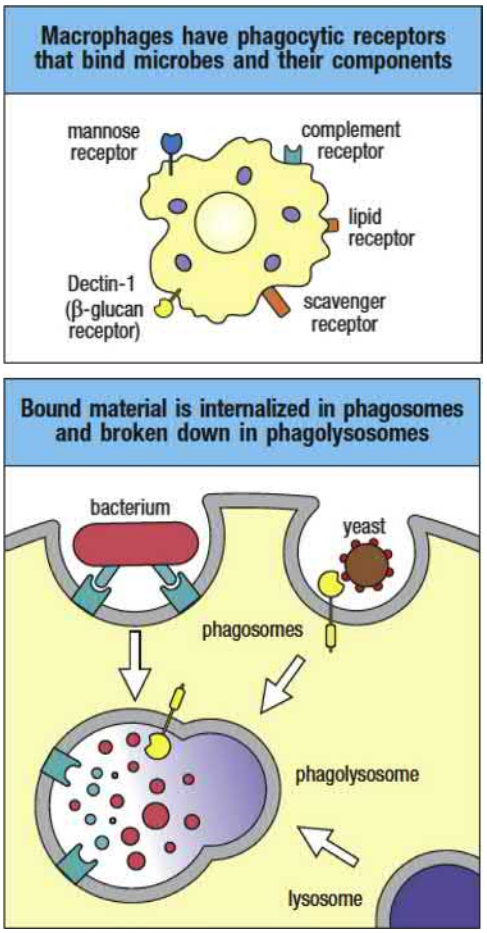
• **Figure 2.2.3.8** Cells of the innate immune system. Travers et al., 2001. (Adapted from the preface, "Icons used throughout the book", Janeway's Immunobiology ninth edition).

to activate integrin receptors that then tightly bind to the endothelial cells. A sequential step of cytoskeleton rearrangement then allows monocytes to extravasate between endothelial cells into tissues. Once in the tissue, monocytes terminally differentiate into DCs or macrophages.

Macrophages: Bone marrow-derived macrophages differentiate from monocytes and are a type of phagocytic cell (Travers et al., 2001). A major function of macrophages is to phagocytose cellular debris, pathogens, foreign particles, malignant cells, and other particulates, as illustrated in Fig. 2.2.3.9. Phagocytosis is initiated when specific receptors on the surface of the cell interact with the microbial-specific molecules present on the surface of the pathogen. The bound pathogen is first surrounded by the phagocyte plasma membrane and then internalized in a large membrane-enclosed endocytic vesicle known as a phagosome. The phagosome then fuses with another vesicle, the lysosome, to generate a phagolysosome, which has low pH (Abbas and Pober, 2000; Travers et al., 2001; Wood and Martin, 2017), digestive enzymes such as lysozyme and defensins, antimicrobial peptides, and increased levels of reactive oxygen species such as superoxide, as well as nitric oxide radicals. Once in the phagolysosome, ingested materials are degraded by their combined action, and pathogens are killed.

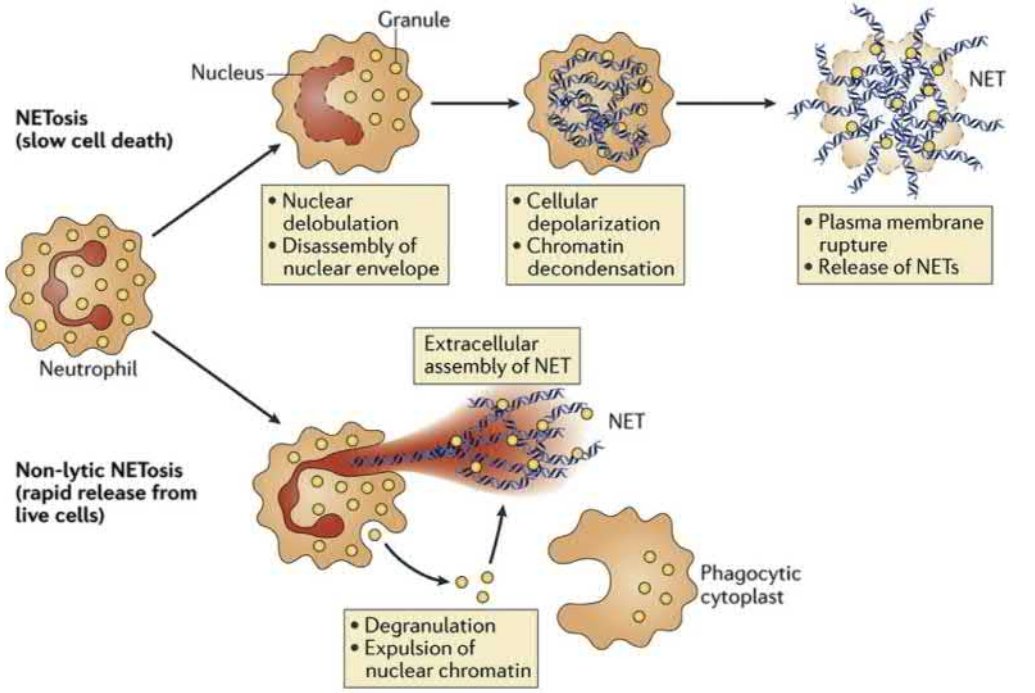
Interestingly, certain pathogens such as *Mycobacterium tuberculosis* have evolved with humans to survive within macrophages by preventing the fusion of phagosomes and lysosomes. Notably, in the presence of bulk materials (e.g., a biomaterial implant) or particulate too large to be phagocytosed by a single macrophage (greater than ~10 μm), many macrophages will fuse together to form multinuclear foreign body giant cells (FBGCs). These cells either attempt to engulf the entire material or try to degrade it by releasing reactive oxygen species.

Dendritic cells (DCs): There are functionally two main types of DCs: plasmacytoid DCs (pDCs) and conventional DCs (or most often simply DCs), arising from distinct progenitors in the marrow. A major function of pDCs is production of type I interferons. On the other hand, DCs form the bridge between innate and adaptive immunity. In addition to producing cytokines in response to signaling through PRRs, DCs are specialized for particularly efficient antigen uptake, processing, and presentation (discussed further in the section "Antigen Uptake, Processing, and Presentation") in a manner uniquely capable of initiating adaptive immune responses (Acharya et al., 2016; Acharya et al., 2009; Acharya et al., 2008; Acharya et al., 2011; Banchereau and Steinman, 1998; Palucka and Banchereau, 2012).



• **Figure 2.2.3.9** Macrophages express receptors that enable them to take up microbes by phagocytosis. Macrophages express receptors such as Dectin-1 (member of the C-type lectin family), complement receptor, lipid receptors, mannose receptors, and scavenge receptors for binding molecules on pathogen surfaces. The receptor-bound material is phagocytosed into intracellular phagosomes, which fuse with lysosomes to form an acidified phagolysosome in which the ingested material is broken down by lysosomal hydrolases (Travers et al., 2001). (Adapted from Figure 3.2 Janeway's Immunobiology ninth edition).

DCs act as sentinels in the periphery and form an important part of gut-associated lymphatic tissue and epithelium lymphatic tissue. Specifically, DCs line the mucosal layers of the nose, intestine, lungs, stomach, and skin. In these and other peripheral tissues, DCs continuously sample the environment for the presence of foreign materials. DCs express an array of TLRs and other types of PRRs to recognize pathogens. Once foreign materials are recognized, DCs release an array of cytokines and chemokines, and then traffic toward secondary



• **Figure 2.2.3.10** Neutrophil extracellular traps (NETs) protect against infection. Neutrophils undergo a slow cell death pathway termed NETosis that begins with nuclear delobulation and the disassembly of the nuclear envelope and continues with loss of cellular polarization, chromatin decondensation, and plasma membrane rupture. Moreover, neutrophils can also undergo a nonlytic form of NETosis. In this case, cell death is accompanied by secretion of nuclear chromatin and granule proteins through degranulation (Liongue et al., 2011). (Figure 1, Nat Rev Immunol. 2018 Feb;18(2):134–147. https://doi.org/10.1038/nri.2017.105).

lymphoid organs to initiate an adaptive immune response, aspects of which are discussed further in the sections "Antigen Processing and Presentation" and "Adaptive Immunity."

Neutrophils: Neutrophils, also called polymorphonuclear neutrophils (PMNs), are the most abundant cells of the immune system in the bloodstream and are the hallmark of acute inflammation due to infection or injury (Travers et al., 2001). Neutrophils extravasate through the endothelium to reach the site of injury or infection in response to cytokines and chemokines. Once in injured or infected tissue, neutrophils perform the functions of phagocytosis of infectious agents, degranulation, release of soluble antimicrobials, and generation of neutrophil extracellular traps. Specifically, neutrophils are capable of phagocytosing foreign particles that are opsonized or coated with antibodies. Once phagocytosed, the foreign particles are exposed to reactive oxygen species in phagosomes, leading to their killing and elimination. Neutrophils are also capable of releasing granules that contain a powerful arsenal of molecules that can neutralize pathogens. For example, these granules contain myeloperoxidase that generates reactive oxygen species, defensins, proteases, elastase, collagenase, histaminase, and alkaline phosphatase among others. Interestingly, neutrophils also generate neutrophil extracellular traps (NETs) that are composed of chromatin (Fig. 2.2.3.10). These NETs are capable of trapping pathogens such as bacteria, thereby restricting them to the site of infection. Notably, formation of NETs has also been demonstrated to occur in response to exposure to synthetic biomaterials (Sperling et al., 2017; Jhunjhunwala & et al., 2015).

Mast cells: Mast cells are large innate immune cells of the hemocytoblast lineage with granules filled with several inflammatory molecules (Travers et al., 2001). These cells become activated when multimeric antigen binds immunoglobulin E (IgE) antibody expressed on its surface. Multimeric antigens can come from parasites such as protozoa or helminths. Once activated, mast cells release granule contents, leading to chemoattraction of several adaptive immune cell types. Unfortunately, these inflammatory mediators (e.g., histamine and cytokines) are also involved in several immune disorders, including allergy, anaphylaxis, and autoimmunity.

Eosinophils: Eosinophils are derived from bone marrow from hemocytoblasts and like mast cells are filled with granules containing cytotoxic granule cationic proteins such as major basic protein, eosinophil cationic protein, and eosinophil peroxidase, which produce reactive oxygen species (Travers et al., 2001). After activation via recognition of antibody-coated parasites, eosinophils undergo cytolysis (cell death), releasing the granules. While inefficient phagocytes, eosinophils still play an important role in the killing of multicellular parasites too large to be phagocytosed.

Basophils: Similar to mast cells and eosinophils, basophils are a member of the phagocytes derived in the marrow from hemocytoblasts (Travers et al., 2001). Basophils are the rarest type of innate immune cells, and constitute less than 1% of the circulating leukocytes. Similar to mast cells, basophils

TABLE 2.2.3.1 Some of the Cytokines of the Innate Immune System and Their Targets

Cytokine	Principal Cell Sources	Principal Cellular Targets and Biologic Effect
TNF	Macrophage	Endothelial cell activation; neutrophil activation, apoptosis in different cells
IL-1	Macrophage, endothelial cells, epithelial cells	Endothelial cell activation
IL-12	Macrophage, dendritic cells	NK cell and T cell activation, increased cytolytic activity
Type 1 interferons	Macrophages, dendritic cells, fibroblasts	Antiviral activity in all cell types, increased MHC-I expression, activation of NK cells

IL, Interleukin; *MHC*, major histocompatibility complex; *NK*, natural killer; *TNF*, tumor necrosis factor.
Adapted from Appendix III—Cytokines and their receptors—Janeway's Immunobiology ninth edition.

have granules containing histamine, proteolytic enzymes, and inflammatory mediators. Additionally, basophils also have receptors for IgE-FcεRI receptors and are activated in the presence of neuropeptides, anaphylatoxins, f-Met-Leu-Phe, bacterial products/TLR ligands, and animal venom components.

Innate lymphoid cells: ILCs are similar in some ways to adaptive arm T cells as far as function and phenotype, in that their activation, expansion, and effector function mirror T cells (Travers et al., 2001). However, ILCs are activated in the presence of stress, microbial molecules, or cytokines in contrast to T cells, which require specific antigens for activation. Notably, ILCs are directly activated by tissue "danger" signals, and therefore are classified as part of the innate immune system. ILCs are divided into three subcategories, ILC1, ILC2, and ILC3, according to their function. ILC1 expands and secretes interferon (IFN)-γ in response to interleukin (IL)-12, IL-15, and IL-18, generated by intracellular microbe-infected cells. Activated ILC1 then leads to activation of macrophages, and induces cytotoxicity in infected cells. An important ILC closely related to but distinct from ILC1 is the NK cell, discussed next. ILC2 expands and secretes IL-4, IL-5, and IL-13 in response to IL-25, IL-33, thymic stroma lymphopoietin, basophil-derived IL-4, and products of the arachidonic acid pathway, in response to parasite infection, allergens, and epithelial injury. Activation of ILC2 leads to tissue repair, alternate macrophage activation, mucus production, and thermoregulation among other functions. ILC3 expands and secretes lymphotoxins, granulocyte-macrophage colony-stimulating factor (GM-CSF), IL-22, and IL-17 in the fetus, early after birth and during inflammation. Activation of ILC3 leads to epithelium survival, phagocytosis, and production of antimicrobial peptides.

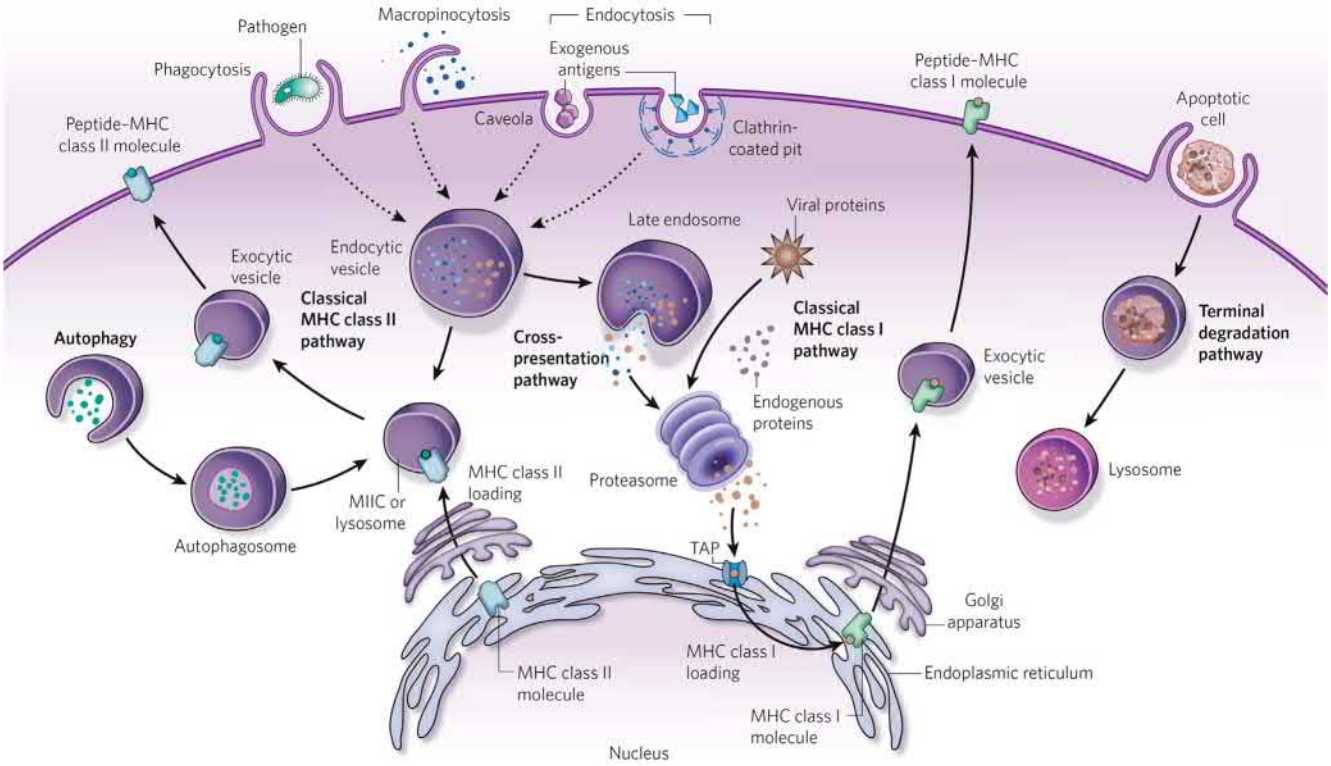
Natural killer cells: NK cells are large lymphocyte-like cells with a granular cytoplasm. These cells originate from common lymphoid progenitor cells in the bone marrow and were first discovered due to their ability to kill specific types of cancer cells and cells infected with herpesviruses. NK cells perform this function immediately upon recognizing the absence of "self" marker major histocompatibility complex (MHC) I, uniquely without requiring any further activation signals. NK cells respond to cellular stress and to infections by releasing cytolytic granules, which then cause apoptosis in infected cells. Moreover, NK cells can also release innate cytokines (Table 2.2.3.1), which then lead to activation of T lymphocytes and other NK cells. Importantly, NK cells are responsible for inducing early innate responses to viral infections before the adaptive immune responses are developed.

γδ T cells: γδ T cells are also called "unconventional" T cells, and are defined by expression of heterodimeric T cell receptors (TCRs) composed of γ and δ chains. Notably, γδ T cells recognize a broad array of infected or transformed cells. Moreover, once infected or transformed cells are recognized, γδ T cells produce cytokines such as IFN-γ, tumor necrosis factor (TNF)-α, and IL-17, produce chemokines such as RANTES, IP-10, and lymphotactin, and also cause the cytolysis of infected or transformed target cells using perforin, granzymes, and TRAIL. In addition to directly modulating the infected cells and initiating immune response, γδ T cells also interact with epithelial cells, monocytes, DCs, neutrophils, and B cells, and modulate their function.

Together, cells of the innate immune system act in concert to develop a robust innate immune response against pathogens. The innate immune response shapes the subsequent adaptive response. As mentioned, DCs act as a bridge between the innate and adaptive immune responses, being the key player in initiating and sustaining adaptive immune responses, where the distinguishing feature in this capacity is antigen processing and presentation.

Antigen Uptake, Processing, and Presentation

While there are multiple types of phagocytic cells, such as macrophages, monocytes, granulocytes (e.g., neutrophils, eosinophils, basophils), and multiple "professional" antigen-presenting cells (APCs) (DCs, macrophages, and B cells), DCs are the most efficient at antigen uptake, processing, and presentation. DCs sample antigenic sources from numerous compartments, utilizing multiple mechanisms such as phagocytosis, micropinocytosis, endocytosis, and autophagy, as illustrated in Fig. 2.2.3.11. Antigen components are degraded (e.g., proteins broken down to peptides and trimmed to appropriate lengths), then loaded onto MHCs I and II, and displayed on the APC surface (Yeung, 2012).

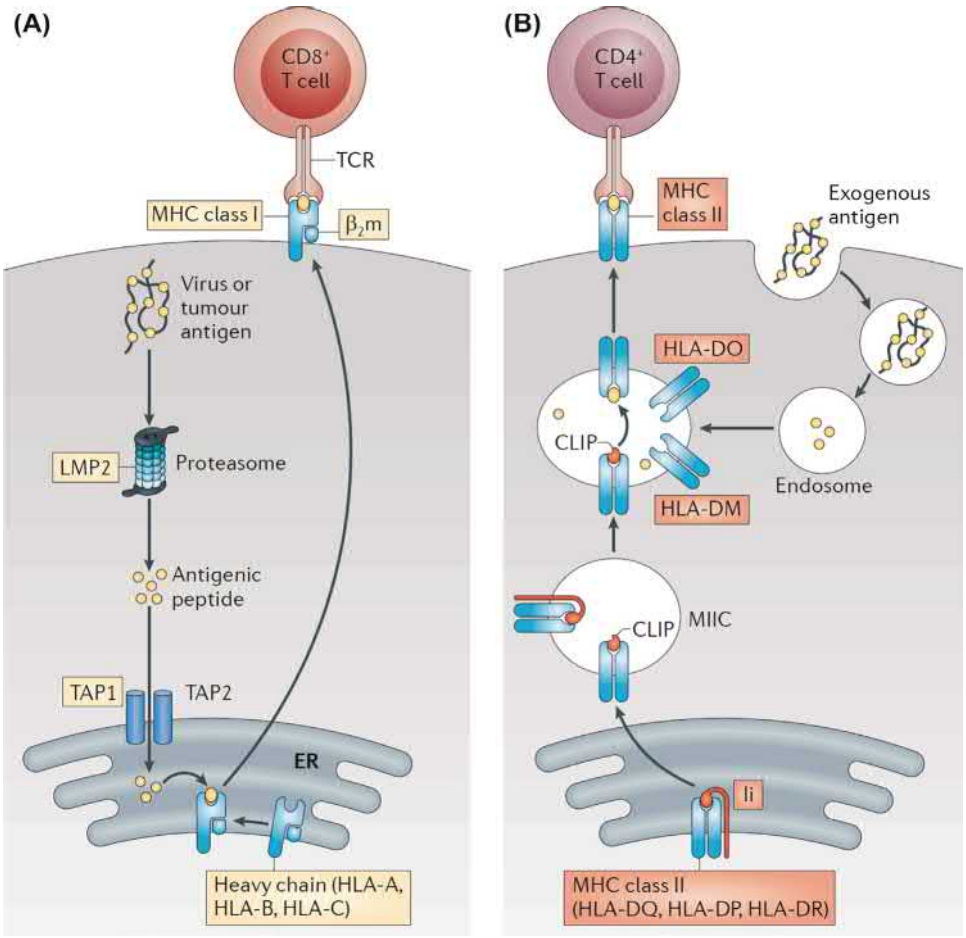


• **Figure 2.2.3.11** Intracellular pathways of dendritic cell antigen presentation. *Left*, exogenous particles, proteins, or pathogens can be taken into the cell through various pathways, including phagocytosis (for particles >1 μm), macropinocytosis (<1 μm), and endocytosis from caveolae (~60 nm) or clathrin-coated pits (~120 nm). Exogenous antigens are then processed in endocytic vesicles (phagosomes, endosomes, lysosomes, and/or endolysosomes; *dashed arrows* represent multiple vesicular steps). Processed antigen (peptide) is subsequently loaded onto major histocompatibility complex (MHC) class II molecules (which have been assembled in the endoplasmic reticulum, transported through the Golgi apparatus, and targeted to endocytic compartments) in a lysosome or MHC class II compartment. The peptide–MHC class II complexes then move through exocytic vesicles to the cell surface, where antigen presentation occurs. MHC class II loading of endogenous antigen provided by autophagy can also occur, particularly when the cell is under stress. *Right*, antigen can be loaded onto MHC class I molecules through two main pathways. In the classical pathway, endogenous or viral proteins in the cytosol are processed through the proteasome, transported into the endoplasmic reticulum through the molecule TAP (transporter associated with antigen processing), loaded onto MHC class I molecules, and then transported through the Golgi apparatus and exocytic vesicles to the cell surface for presentation. In addition, exogenous antigens that have been phagocytosed, macropinocytosed, or endocytosed can be cross-presented on MHC class I molecules by some subsets of dendritic cell. In this pathway, antigen either may be loaded in endocytic compartments (not shown) or may escape endosomes and arrive in the cytosol, where it is processed through the proteasome as usual, loaded onto MHC class I molecules, and transported to the surface. Finally, terminal degradation pathways can occur (for example, when apoptotic cells are internalized) (Acharya et al., 2016). (Nat Rev 2009 Nov; 462:26. https://doi.org/10.1038/nature08604).

In humans, the MHC gene cluster is located on chromosome 6 and the molecules are called the *human leukocyte antigens*. There are two major classes of MHC molecules, called *MHC class I* (*MHC I*) and *MHC class II* (*MHC II*). Structurally, these two classes diverge, with MHC I having only one transmembrane stalk and MHC II having two. However, they both have an extracellular domain that contains an elongated groove where peptide can bind. Although the antigen-processing and delivery pathways differ, antigen presentation on these two molecules has similarities. The peptide becomes trapped in the groove of the MHC molecule, which is then transported to the surface membrane and displayed to either $CD8^+$ or $CD4^+$ T cells via MHC I or MHC II, respectively (Fig. 2.2.3.12). All nucleated cells of the body possess MHC I molecules, whereas only professional APCs (DCs, B cells, and macrophages) express MHC II molecules. As such, it is primarily a distinct role of professional APCs to engage $CD4^+$ T cells to amplify immune responses (Germain, 1994).

Costimulatory Molecules

In addition to activating antigen processing and presentation functions, critically, activation of innate sensing pathways also leads to the induction of costimulatory molecules on APCs. For example, pathogen recognition via TLRs leads to expression of two important costimulatory molecules on the cell-surface proteins B7.1 (CD80) and B7.2 (CD86), which bind



• **Figure 2.2.3.12** Antigen presentation to T cells via the MHC class I and MHC class II antigen-presentation pathways. (A) Intracellular anti-gens, such as virus or tumour antigens, are processed into peptides by the immunoproteasome, which is composed of multiple subunits, including LMP2. Peptides are transported into the endoplasmic reticulum (ER), where they are loaded into the groove of the MHC class I complex, which is composed of a heavy chain and β2-microglobulin (β2m). MHC class I complexes present antigens on the cell sur-face to CD8+ T cells. Proteins in the MHC class I pathway that are encoded by genes regulated by the MHC class I transactivator NOD-, LRR- and CARD-containing 5 (NLRC5) are shown in yellow boxes. (B) Antigens from extracellular sources, such as bacterial antigens, are processed by endolysosomal enzymes into peptides. These peptides bind to the groove of the MHC class II complex by displacing the class II-associated invariant chain peptide (CLIP), which is derived from the MHC class II-associated invariant chain (Ii). HLA-DO and HLA-DM regulate the antigen-loading process. The MHC class II com-plex presents antigens to CD4+ T cells. Proteins in the MHC class II pathway that are encoded by genes regulated by the class II transactivator (CIITA) are shown in red boxes. *MIIC*, MHC class II compartment; *TAP*, transporter associated with antigen processing; *TCR*, T cell receptor. (Kobayashi et al., Nature Reviews Immunology volume 12, pages 813–820 (2012), Figure 1).

to the costimulatory coreceptors expressed on the surface of T cells. Both stimulation from antigen presentation and costimulation from APCs are necessary for T cell stimulation, and generation of adaptive immune responses (discussed later).

Chemokines and Cytokines

Chemokines and cytokines are important proteins that mediate the immune cell responses, which are produced by many cell types. For example, chemokines released by injured or infected cells (e.g., epithelial cells) are responsible for attracting innate immune cells (e.g., neutrophils) to the site of the infection. Examples of such chemokines include MIP1α, RANTES, GROα, GCP-2, and SDF-1α/β (for a comprehensive list of chemokines, refer to *Janeway's Immunobiology*, ninth edition—Appendix IV).

Cytokines also play a critical role in the development of an immune response against invading pathogens or a foreign material. Activated innate cells secrete cytokines to recruit other immune cells from the blood into the injured or infected tissues, a process known as inflammation. Cytokines are also released by epithelial cells that lead to vasodilation, and further infiltration of the cells at the site of the infection or injury (Table 2.2.3.1). Cytokines released by T-helper cells (see the section "Adaptive Immunity") play a role in eliminating intracellular pathogens in macrophages. Ultimately, immune cell functions are broadly directed by different sets of cytokines that determine the final outcome of the immune response.

Adaptive Immunity

The secondary phase of the immune response is *adaptive* immunity, which is sometimes referred to as *specific* or *acquired* immunity. This is attributed to the fact that the response becomes adapted to specific antigens. An *antigen* is a molecule that induces a specific immune response. Antigens can be proteins, carbohydrates, lipids, as well as other smaller molecules (e.g., dinitrophenol) when coupled to a carrier. Antigens can be from a foreign source or derived from the host and referred to as a *self-antigen*. The breadth of potential antigens represents an overwhelming number of possibilities. Unlike the innate immune system, which utilizes receptors with broad specificity, the adaptive immune system is equipped to recognize an enormous diversity of antigens, primarily through cells bearing antigen receptors of a single specificity. This feature is believed to be crafted through evolution out of necessity and is also seminal for the development of long-term memory to newly encountered antigens. As such, adaptive immunity is characterized by an extraordinary repertoire of receptor molecules that arise from *somatic gene recombination* and *immunological memory*. The major components of adaptive immunity are *lymphocytes* and *soluble mediators*. *Lymphocytes* are cells with a diverse repertoire of molecules on their surfaces that are important for antigen recognition. This class of cells can be categorized as either *T or B lymphocytes* (cells). The other arm of adaptive immunity is called *humoral immunity*, derived from the Latin word *humor*, which means *fluid*. The humoral response encompasses soluble molecules that act by binding to either antigenic material or specific immune cells. These molecules include *antibodies*, or *antikorpers* as they were first coined by the German scientist Paul Ehrlich in 1891. The cellular and humoral immune systems each have an antigen recognition capacity of 10^9–10^{11} distinct antigenic *determinants*. With such a diverse repertoire of cell surface and soluble receptors, the distinctive beauty of the adaptive arm of the immune system is that it has the armamentarium to be highly effective in tailoring immune reactions toward a new pathogen, while reducing collateral damage to host tissue. Following recognition of an invader, specific T cells and B cells undergo a rapid expansion phase. Altogether, these processes are called *clonal selection* and *expansion*, where a few hundred cells bearing receptors for the pathogenic antigens proliferate into thousands of responding daughter cells in just a few days (Liongue et al., 2011; Shanker, 2010; Langefeld et al., 2009).

A component of adaptive immunity is *immunological memory* as a secondary but critical outcome of clonal selection and expansion. The capacity for long-lasting response capability provides protective immunity from subsequent challenge by the same pathogen (Farber et al., 2016). After responding to the pathogenic threat, most effector cells will die. However, a small fraction of the clonally expanded cells persists after antigen elimination. These cells, called *memory cells*, remain for decades after the initial antigen encounter and are able to provide a rapid response upon reexposure to the pathogenic material. This concept is the basis of vaccination, one of the most effective and impactful medical interventions devised, saving millions of lives every year.

Components of Adaptive Immunity

The primary components of the adaptive immune response are:

1. T lymphocytes (or T cells): lymphocytes that develop in the *thymus* prior to migration to peripheral or secondary lymphoid tissues (e.g., spleen, lymph nodes). They are functionally divided into two main classes: *helper T cells* and *cytotoxic T cells.* Helper T cells (*Th cells*) are specialized for the production of *cytokines*, which orchestrate the activities of other cells, including those of the innate immune system. Cytotoxic T-lymphocytes (*CTLs*) are capable of directly killing cells that are infected with viruses. T cells can also be divided based on the expression of special surface proteins that are integral for communication with APCs and result in immune signaling. The proteins typically associated with Th cells are designated as *CD4* (*CD = cluster of differentiation*), whereas *CD8* is expressed on CTLs. All T cells have CD3, a protein complex part of the TCR, which is critical for antigen recognition and T cell activation (Vallejo et al., 2004).
2. Cytokines of the adaptive immune system: soluble factors typically secreted by helper T cells, but which can also be produced by various innate immune cells, APCs, and B cells. These small proteins (5–20 kDa) are released by cells and have specific functional effects on their target cells that bear receptors for them. Typically, multiple cytokines synergize to influence the phenotype of a particular effector cell. Some critical cytokines of the adaptive immune system and their effects are listed in Table 2.2.3.2.
3. B lymphocytes (or B cells): similar in size and morphology to T lymphocytes, B cells are small, round cells with a large nucleus and very little cytoplasm, particularly in the inactive state. However, in contrast to T cells, B cells undergo development in the bone marrow. The prominent feature of B cells is the B cell surface receptor, which is essentially a membrane-bound antibody. Upon activation through the binding of antigen, B cells differentiate into *plasma cells* to secrete antibodies, a soluble version of the B cell receptor (BCR).
4. Antibodies: large, Y-shaped proteins (~250 kDa) secreted by plasma cells with high-affinity binding sites, which recognize three-dimensional features of specific antigens (Fig. 2.2.3.13), further described later.

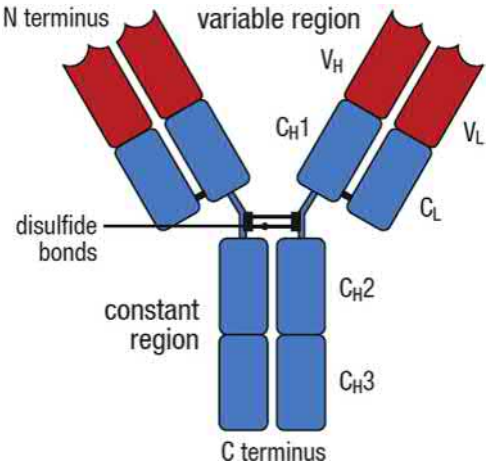
It should be noted that there is great complexity to the dynamics and kinetics of adaptive immune mediators. These effectors can work individually or collectively, synergistically or antagonistically at various phases to influence and dictate the outcome of an immune response to an antigen. For instance, in viral infections, early responses may be tilted toward the involvement of cytotoxic T cells. Later, B cells become important to produce neutralizing antibodies against extracellular viral particles to ward against the spread of infection from cells containing latent virus. Moreover, uncontrolled inflammation can lead to harmful collateral damage to host tissues, and must be kept in check. The adaptive immune system therefore has negative feedback

TABLE 2.2.3.2 The Cytokines of the Adaptive Immune System and Their Effects on Specific Immune Cells A (Travers et al., 2001)

		Effects on					
Cytokine	**T-Cell Source**	**B Cells**	**T Cells**	**Macrophages**	**Hematopoietic Cells**	**Other Tissue Cells**	**Effect of Gene Knockout**
Interleukin-2	Naïve, Th1, some CD8	Stimulates growth and J-chain synthesis	Growth and differentiation	–	Stimulates NK cell growth	–	Impaired Treg cell development and function
Interferon-γ	Th1, Tfh, CTL	Differentiation IgG2a synthesis (mouse)	Inhibits Th2 and Th17 cell differentiation	Activation, ↑MHC class I and class II	Activates NK cells	Antiviral ↑MHC class I and class II	Susceptible to mycobacteria, some viruses
Lymphotoxin-α (TNF-β)	Th1, some CTLs	Inhibits	Kills	Activates, induces NO production	Activates neutrophils	Kills fibroblasts and tumor cells	Absence of lymph nodes, disorganized spleen
Interleukin-4	Th2, Tfh	Activation, growth IgG1, IgE ↑MHC class II induction	Growth, survival	Promotes marginal zone macrophage activation	↑ Growth of mast cells	–	No Th2
Interleukin-5	Th2	Mouse: differentiation IgA synthesis	–	–	↑Eosinophil growth and differentiation	–	Reduced eosinophilia
Interleukin-13	Th2	IgG1, IgE class switch	–	Promotes marginal zone macrophage	–	↑ Production of mucus (goblet cell)	Impaired helminth expulsion
Interleukin-17	Th17	Promotes IgG2a, IgG2b, IgG3 (mouse)	–	–	Stimulates neutrophil recruitment (indirect)	Stimulates fibroblasts and epithelial cells to secrete chemokines	Impaired antibacterial defense
Interleukin-22	Th17	–	–	–	–	Stimulates mucosal epithelium and skin to produce antimicrobial peptides	Impaired antibacterial defense
Transforming growth factor-β	Treg	Inhibits growth IgA switch factor	Th17 and iTreg differentiation, inhibits Th1 and Th2	Inhibits activation	Activates neutrophils	Inhibits/stimulates cell growth	Impaired Treg cell development, multiorgan auto immunity, and death ~10 weeks

Interleukin-10	Treg, some Th1, Th2, Th17, CTL	↑MHC class II	Inhibits Th1	Inhibits inflammatory cytokine release	Costimulates mast cell growth	–	IBD
Interleukin-3	Th1, Th2, Th17, some CTLs	–	–	–	Growth factor for progenitor hematopoietic cells (multicolony-stimulating factor)	–	–
Tumor necrosis factor-α	Th1, Th17, some Th2, some CTLs	–	–	Activates, induces NO production	–	Activates microvascular endothelium	Susceptibility to Gram-negative sepsis
Granulocyte-macrophage colony-stimulating factor	Th1, Th17, some Th2, some CTLs	Differentiation	Inhibits growth?	Activation, differentiation to dendritic cells	↑ Production of granulocytes and macrophages (myelopoiesis) and dendritic cells	–	–

CTLs, Cytotoxic T lymphocytes; *IBD*, inflammatory bowel disease; *NO*, nitric oxide; *MHC*, major histocompatibility complex; *TNF-β*, tumor necrosis factor beta; *Treg*, regulatory T cells.
Janeway's Immunobiology, ninth edition; Chapter 9, Figure 9.40.



• **Figure 2.2.3.13** General antibody structure and effector functions. Antibodies most often adopt a "Y"-shaped structure composed of two light chains and two heavy chains. The N-termini are the antigen binding fragments (Fab) and are contained in the variable regions that allow the necessary diversity. Fab regions recognize three-dimensional features on specific antigens. The C-termini are constant for any particular immunoglobulin isotype (called the Fc fragment) (Travers et al., 2001). (Janeway's Immunobiology, ninth edition; Chapter 4, Figure 4.1c).

mechanisms to shut down inflammatory responses not long after their initiation. To a large extent, this inhibitory responsibility falls on a subset of helper T cells that produce biochemical messengers with regulatory effects.

Humoral Immunity

Soluble effectors of immunity found in bodily fluids, including antibodies, are collectively known as humoral immunity. Antibodies are a class of proteins known as *immunoglobulins* (*Igs*) that accounts for a significant portion of plasma proteins. In general, antibodies are "Y"-shaped molecules composed of four disulfide-linked polypeptide chains: two smaller (~25 kDa) light chains and two larger (~50 kDa) heavy chains (Fig. 2.2.3.13). The heavy chains in a given antibody are identical as are the light chains. The N-termini of a light and heavy chain combine to the *antigen-binding site*, which recognizes three-dimensional features on pathogens. Each antibody contains two identical antigen-binding sites that can result in pathogens with multiple antigenic regions such as viral surfaces to become cross-linked by multiple antibodies. The N-termini of different antibodies contain vast sequence variability and are the source of the immense antigen-binding capacity of the total antibody repertoire.

On the other hand, the C-termini of the polypeptide chains have relatively little sequence diversity and this portion of the two larger chains makes up the "body" of the Ig or the constant region, or the fragment crystallizable (Fc) region. This stem of the antibody has a critical role in interacting with other effector molecules and cells (Padlan, 1994). There are five different classes of Igs, based upon the variability in sequence, structure, and properties of the Fc region. These five major isotypes are IgM, IgD, IgG, IgA, and IgE; IgG has five subtypes and IgA has two (Salfeld, 2007; Brerski and Georgiou, 2016). All the major isotypes are soluble proteins with the exception of IgD, which is only found in the membrane-bound form as the antigen receptor for B cells and is critical for B cell activation and differentiation. The constant region of the soluble antibody determines its engagement with effector mechanisms that help to dispose of antibody-bound antigen. The structure of the antibody is thus well suited to its function to protect against pathogens or their products. Antibodies accomplish this goal through three primary effector modalities: *neutralization*, *opsonization*, and *complement activation* (discussed in the section "Effector Pathways in Adaptive Immunity").

Cell-Mediated Immunity

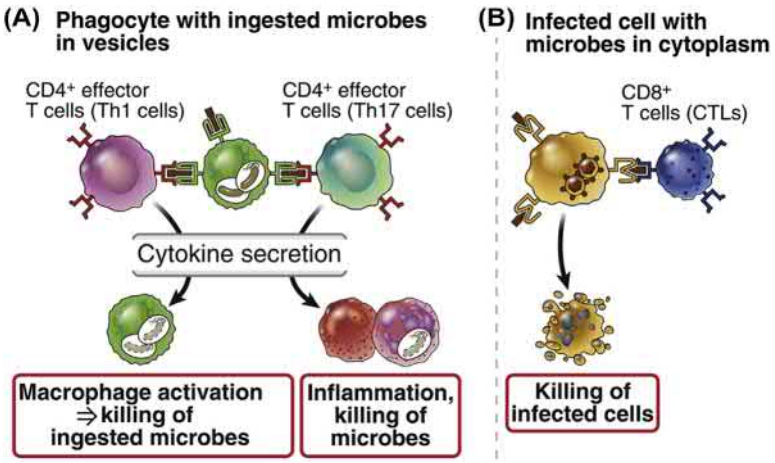
Antibodies are efficient at detecting and inducing removal of extracellular pathogenic material. Antibodies, however, lack access to intracellularly localized foreign agents (e.g., viruses and mycobacteria). In this case, other forms of immunity must be engaged. Cell-mediated immune responses, driven by T cells, are the primary catalysts behind mechanisms to rid the host of intracellular pathogens. Recall that there are two major functional classes of T lymphocytes: (1) cytotoxic T cells (CTLs) and (2) helper T cells (Sallusto et al., 1999).

Cytotoxic T Cells

Of the two major T cell classes, CTLs are the more direct in executing their antipathogen functions. These cells primarily express the CD8 coreceptor on their surfaces, and are critical for responding to cells that have been infected by viruses (Fig. 2.2.3.14). They recognize viral antigens on the surface of infected host cells presented via the MHC-I complex, which is found on all nucleated cells of the body. These CTLs bind to and directly kill virus-infected cells to control the infection through a number of effector mechanisms, including membrane pore formation, release of degradative enzymes, and apoptosis. Cytotoxic T cells can also secrete inflammatory cytokines (e.g., IFN-γ), which have direct and indirect actions that help to control the viral infection. For instance, IFN-γ inhibits viral replication directly while also promoting the expression of MHC-I and proteins important for the formation of the immunoproteasome, a modified form of the proteasome that efficiently generates small antigenic peptides to be loaded onto MHC-I molecules.

Helper T Cells

Helper T cells express and utilize the CD4 coreceptor. As the name suggests, the effector actions of these cells are indirect and often carried out by the cytokines they secrete (Fig. 2.2.3.14), serving to activate other immune cells. Helper T lymphocytes are integral to the control of bacterial infections, including intracellular mycobacteria that can proliferate in intracellular vacuoles of mammalian cells (Abbas et al., 1996). For example, *Mycobacterium tuberculosis* is the causative agent



• **Figure 2.2.3.14** T cell-mediated immunity. (A) CD8 T cells recruited to the site of infection/inflammation express surface molecules that are directly cytotoxic to infected target cells by inducing apoptosis and can also exert antiviral activity by secreting cytokines. (B) CD4 T cells are the earliest lymphocytes activated during an adaptive immune response. CD4 T cells are able to affect the behavior of other immune cells (thereby acting as "helpers") by secreting cytokines, for example, in the case of a Th1 or Th17 phenotype, that promote macrophage activation to enhance phagocytic and antimicrobial activity, as well as promoting local inflammation in general (Abbas and Pober, 2000). *CTLs*, Cytotoxic T lymphocytes. (Adapted from Abbas et al., Cellular and Molecular Immunology, seventh edition).

of tuberculosis. This pathogen grows in the macrophage intracellular vesicles where microorganisms are typically digested due to the caustic environment and the presence of enzymes and antimicrobial proteins. Such intracellular bacteria are able to flourish by inhibiting the fusion of these phagocytic vesicles with lysosomes containing the degradative elements. Controlling these intracellular pathogens requires the "help" of CD4 T cells, specifically the *Th1* subset, which induce the formation of the phagolysosome in macrophages through the release of activating cytokines (e.g., IFN-γ). Th1 cells also enhance macrophage functions such as respiratory burst and release of cytokines that boost local inflammation (e.g., TNF-α).

The *Tfh* subset of CD4 T cells, found in specialized regions in lymph nodes called germinal centers, is important for the activation of B cells, and therefore well suited for immunity to extracellular pathogens. While activation and differentiation of B cells into antibody-secreting cells is stimulated by antigen binding to the BCR, this process is greatly improved by the action of Tfh cells. Notably, however, Th1 and Th2 cells can also contribute to B cell activation, albeit to a lesser extent. The Th2 response is also important for responses to larger extracellular pathogens (e.g., hookworms) and a special class of polymeric antigens called allergens (e.g., tropomyosin from shellfish). Th2 cells secrete a particular host of cytokines, primarily IL-4, -5, -6, -10, and -13, which give rise to an array of actions in other cells, including increased antibody production from B cells, eosinophil activation, and inhibition of several macrophage functions, which provides a phagocyte-independent protective response (Zhu et al., 2010).

Another important helper T cell subset is the Th17 (Ouyang et al., 2008), which plays a critical role in responses to extracellular bacteria and is also involved in the induction of tissue inflammation by producing IL-17. The IL-17 cytokine induces numerous immune and nonimmune tissue-resident cell types to secrete many other inflammatory cytokines. Overproduction of IL-17 has emerged as a particularly significant proinflammatory factor linked to pathological tissue destruction associated with many chronic immune-inflammatory and autoimmune diseases, including rheumatoid arthritis (RA), multiple sclerosis, inflammatory bowel disease, and inflammatory skin disorders. Th17 cells are typically generated in the context of IL-23 or transforming growth factor (TGF)-β1 and IL-6 or IL-1, and Th17 cells are characterized by production of a specific cluster of cytokines, notably IL-17, IL-21, IL-22, and IL-26.

Having a shared lineage with Th17 cells are the *antiinflammatory, regulatory T cells* (*Tregs*), which are critical for controlling undesired inflammatory reactions such as those observed in autoimmune diseases like RA. This subset of CD4 T cells is integral for maintenance of peripheral tolerance by actively suppressing antigen-specific responses as well as localized "bystander suppression," typically through the secretion of the antiinflammatory cytokines TGF-β1 and IL-10. Other modes of action by these cells include contact-mediated apoptosis, inhibition of DC maturation, and metabolic disruption, where Treg metabolism (e.g., ATP to AMP catabolism) results in the deprivation of critical factors for neighboring effector T cell proliferation and survival (e.g., IL-2). This CD4 subset can be further subdivided into three major classes: classical regulatory T cells (Tregs; FOXP3 and CD25 expression), Th3 cells (denoted by IL-4, IL-10, and TGF-β1 production; localized in mucosal areas and responds to benign foreign antigen), and Tr1 cells (denoted by LAG-3 expression and IL-10 secretion) (Sakaguchi & et al., 2001; Sakaguchi, 2004; Weiner, 2001; Weiner et al., 2011). Induction or expansion of these regulatory T cell classes can lead to tolerance and reversal of autoimmune inflammation.

Recognition in Adaptive Immunity

A key principle in adaptive immunity is recognition of foreign material prior to activation and actuation of responses. To initiate an appropriate program of responses, proper recognition is critical to discern self from nonself tissue. It is believed that B cells, antibodies, and T cells can recognize up to 10^{11} different antigen epitopes and this receptor diversity is enabled by genetic processes, including somatic mutation and gene rearrangement (beyond the scope of this discussion). However, the basic tenets of how these immune elements recognize antigens is critical to our understanding of the interplay between the immune system and materials and is further discussed here.

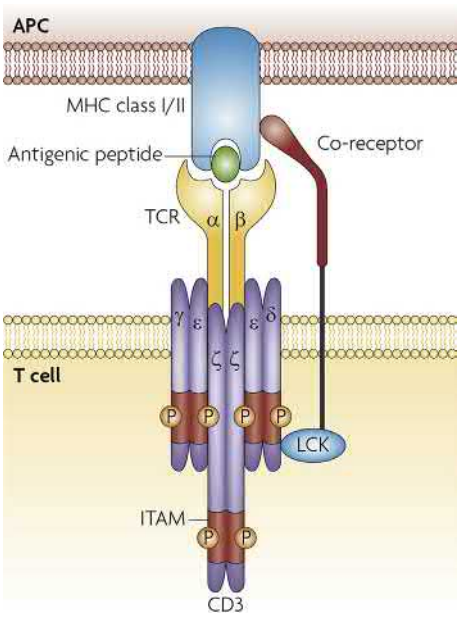
B Cell and Antibody Recognition

As already noted, antibodies, also known as Igs, are the antigen recognition apparatus of B cells. Antibodies are secreted by plasma cells, which are terminally differentiated B cells. Antibodies have a vast range of possible antigen specificities, with each individual B cell, or "clone," producing antibodies of a single specificity. Moreover, each B cell has a single variant of membrane-bound Ig that serves as a receptor for antigen and is called the BCR. Immobilized or solubilized, these Igs can bind to specific antigens. The antibody and its respective antigen form a complex primarily based on their structural complementarity. In other words, the primary, secondary, and tertiary aspects of protein structures of both the antibody and antigen determine their association. The portion of the antigenic molecule that interacts with the antibody is called the epitope (determinant), and a single antigen can have multiple epitopes. This property can sometimes activate B cells without help from CD4 T cells, as multiple epitopes can induce clustering and cross-linking of BCRs and lead to the production of IgM. Certain determinants may be internally folded and initially inaccessible to the Ig. Exposure of these hidden epitopes to antibodies can be subsequently realized via denaturation or enzymatic degradation at sites of inflammation (Treanor, 2012).

T Cell Recognition

In contrast to B cells and antibodies, T cells recognize only small antigenic regions that are displayed on the surfaces of the body's own cells. These antigens can be derived from extracellular (e.g., bacteria), intracellular (e.g., viruses), or even cellular (e.g., senescent cytosolic protein) sources. The TCR can only interact with proteolytically degraded peptide fragments ("processed antigen") presented in the context of being bound to the *major histocompatibility molecules* (*MHC-I or MHC-II*) displayed on the surface of APCs (both professional and nonprofessional), as illustrated in Fig. 2.2.3.15.

There is significant divergence on which classes of T cells are able to interact with the two different MHC molecules. The MHC I molecule presents peptide to CD8 T cells only,



• **Figure 2.2.3.15** The T cell receptor (TCR) interacts with peptide loaded onto the major histocompatibility complex (MHC). The coreceptor (CD4 or CD8) stabilizes this interaction by bringing the kinase LCK in the proximity of the TCR–CD3 complex. LCK can then phosphorylate the CD3-associated immunoreceptor tyrosine-based activation motifs (ITAMs) and engender intracellular signaling that leads to the generation of inflammatory mediators by the T cell (Kroczek et al., 2004). (Gascoigne, Nature Reviews Immunology 8, 895–900 (2008), Figure 1).

where the peptide is primarily cytosol derived. As such, any cell infected with virus can be detected and killed by CD8 T cells through their interaction with MHC I molecules. MHC I, along with the machinery for peptide processing and loading, is expressed in all nucleated cells of the body, and thus serves as a primary mechanism to defend against viral infection. In contrast, MHC II molecules are only expressed on the surfaces of "professional" APCs (discussed earlier): DCs, B cells, and macrophages. In the MHC II loading pathway, peptide typically originates from extracellular entities, such as bacteria that have been phagocytosed. *MHC restriction* also applies to this pathway in that only CD4 T cells can interact with MHC II molecules, including Th1, Th2, Th17, and regulatory T cells. It should be noted that there are instances where the MHC restriction rules have exceptions and extracellularly derived antigen is displayed on MHC I complexes, referred to as *cross-presentation* (Li et al., 2008; Kasturi and Pulendran, 2008).

Irrespective of the mechanism of communication, peptide–MHC complexation with T cells leads to *activation*. On T cells, the critical recognition molecule is the TCR, which is a multiprotein complex that spans the T cell membrane, and in which coreceptors (e.g., CD4) form an integral part. Furthermore, ligation of these coreceptor molecules to MHC is required for clonal expansion and differentiation. Antigen binding leads in conformational changes in the TCR complex that triggers intracellular signaling cascades and results in selective gene transcription (Zhong et al., 2011; Rappazzo and Birnbaum, 2017). Within this

Antibody isotype	Isotype-specific effector functions
IgG	Neutralization of microbes and toxins Opsonization of antigens for phagocytosis by macrophages and neutrophils Activation of the classical pathway of complement Antibody-dependent cellular cytotoxicity mediated by NK cells Neonatal immunity: transfer of maternal antibody across placenta and gut Feedback inhibition of B cell activation
IgM	Activation of the classical pathway of complement
IgA	Mucosal immunity: secretion of IgA into lumens of gastrointestinal and respiratory tracts, neutralization of microbes and toxins
IgE	Defense against helminths Mast cell degranulation (immediate hypersensitivity reactions)

• **Figure 2.2.3.16** Effector mechanisms of antibodies. (A) Antibodies can neutralize pathogens or toxins preventing infection of host cells. Antibodies can recruit other effector molecules such as complement, or activate effector cells via their fragment crystallizable (Fc) portion. Binding of the Fc region of an antibody to a specific Fc receptor expressed by innate cells can facilitate pathogen internalization and destruction by phagocytes (a process referred to as "opsonization") (Davies et al., 2013). (B) A list of antibody isotype and their function is shown. *NK*, Natural killer. (Adapted from Abbas and Lichtman: Basic Immunology, third edition, Copyright @ 2010 by Saunders, an imprint of Elsevier, Inc. All rights reserved).

molecular communication bridge between APC and T cell (or immune synapse), other molecules also play a role in enhancing intracellular signaling networks that lead to complete activation. These molecules are called *costimulators* (e.g., CD28 on T cells binding to CD86 on APCs). In their absence, there is insufficient stimulation of T cells resulting in a state of hyporesponsiveness to the antigen or *anergy* (Kroczek et al., 2004; McAdam et al., 1998; Suzuki et al., 1995). The ligation of CD28 on T cells by B7 molecules (e.g., CD86, CD80) is necessary for optimal clonal expansion as it induces the expression of IL-2, critical for T cell growth and division, and CD25 (the high-affinity receptor for IL-2). Other critical APC–T cell costimulatory complexes include: (1) CD70–CD27; (2) CD40–CD40L, and (3) OX40L–OX40. These costimulatory complexes all enhance clonal expansion and differentiation. Finally, adhesion molecules (e.g., leukocyte functional antigen-1 and intracellular adhesion molecule-2) also play a role in mediating initial interactions between the APC and T cell, and stabilize those interactions if an antigen match is made.

Effector Pathways in Adaptive Immunity

From the discussion thus far, it should be evident that the adaptive immune system is a major effector wing of the immune system, tailored to specific antigens and that different elements are activated based on the nature of the threat to the host. Fig. 2.2.3.16 summarizes the mechanisms engaged by antibodies, as a B cell effector molecule, to respond to extracellular pathogens. These include *neutralization*,

opsonization, and *complement activation*. Neutralization is the case where antibodies bind to pathogenic material, restricting the potential interaction of these foreign agents with host cells and thereby limiting pathogenicity. This functionality of antibodies is particularly important for defense against viruses and bacterial toxins, and is a major feature elicited by most vaccines. Opsonization is the case where antibodies coating pathogens initiate phagocytosis by phagocytic cells bearing Fc receptors to bind the constant region of the antibody (Joller et al., 2011). The third major function of antibodies is complement activation. While complement activation can also occur independently of antibody involvement, the pathway is much more efficient when the antibody constant region acts as the platform for complement activation on the pathogen surface. Together, antibodies, complement proteins, and antimicrobial peptides comprise the major components of humoral immunity.

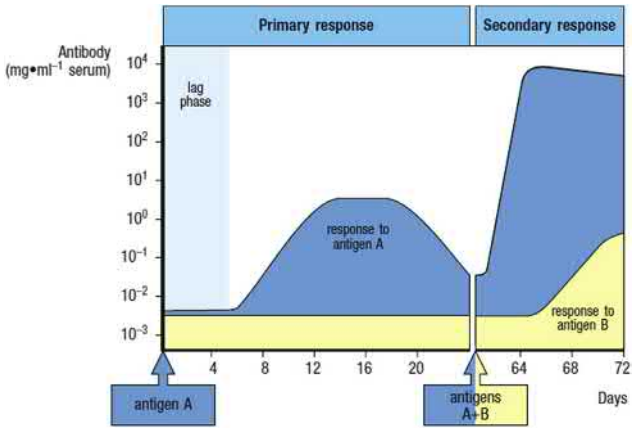
The fourth effector mechanism of antibodies depicted in this figure is *antibody-dependent cell-mediated cytotoxicity* (*ADCC*), which is triggered when the Fc portion of antibodies bound to pathogen interacts with Fc receptors on NK cells. NK cell killing of the Ig-coated pathogen is executed through mechanisms similar to those used by CTLs, involving perforin-based membrane pore formation and secretion of proteolytic enzymes. ADCC is important in controlling viral infection, as well as tumor cell proliferation (Wang et al., 2015). Finally, it has been recently demonstrated that antibody structure, pharmacokinetics, affinity, and function can be influenced by posttranslational modification of *N*-glycosylation motifs in the constant and variable regions of some antibodies. For instance, lower glycosylation of the constant region, which interacts with Fc receptors, is thought to enhance ADCC.

Effector measures for T cells, on the other hand, include the cytotoxic mechanisms of CD8 CTLs and the indirect chemokine/cytokine-based actions of CD4 helper T cells that enhance the efficacy of other immune system elements to clear pathogenic material. These pathways were outlined in the sections "Cytotoxic T Cells" and "Helper T Cells" and illustrated in Fig. 2.2.3.14.

Immunological Memory

The final distinguishing facet of the adaptive immune system is its ability to generate immunological memory, which is critical in protecting mammalian hosts from repeated exposure to an infectious agent. This concept is the core principle of vaccines, which have eradicated a number of infectious diseases (e.g., smallpox) over the past two centuries. As such, vaccinology is one of the most critical fields in human health, and biomaterial scientists are now working in concert with immunologists to devise new and effective ways to address limitations in current vaccines to generate long-term protective immunity.

Immunological memory is a cell-based phenomenon and a result of the clonal selection and expansion that occurs when a naïve T cell interacts with its cognate antigen (as presented bound to MHC molecules). A small fraction of the lymphocytes

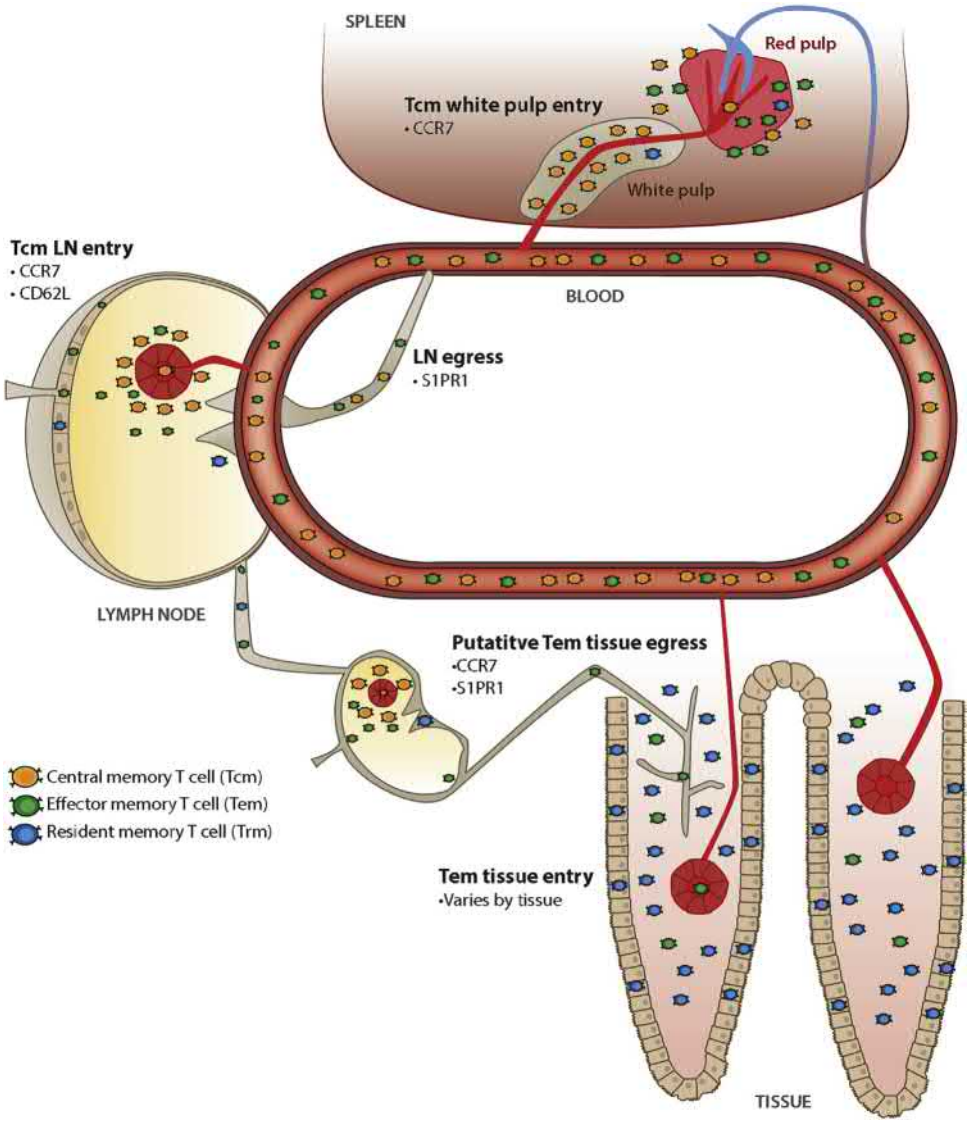


• **Figure 2.2.3.17** Immunological memory. A typical time course of production of immunoglobulins in response to antigen. When an animal is injected with antigen A, antibody is produced beginning around day 7 and peaking at about 14 days before declining. If the animal is reinjected 28 days later with the same antigen, there is a rapid and elevated production of immunoglobulin, indicating a secondary response (Travers et al., 2001). (Janeway's Immunobiology, ninth edition; Chapter 1, Figure 1.25).

generated by this event do not die after the pathogenic threat has been cleared. Instead, they persist for the lifetime of the host and can be reactivated much more quickly than naïve lymphocytes. Immunological memory is showcased by the antibody response to *primary* and *secondary (booster) immunization*, as illustrated in Fig. 2.2.3.17. The secondary antibody response is significantly quicker and a markedly higher titer is engendered (Ratajczak et al., 2018; Sprent, 2002).

In the secondary exposure to an antigen, memory B cells that had previously developed a high affinity for the antigen (undergone isotype switching and somatic mutation in germinal centers located in lymph nodes) now comprise a significant portion of the immune response. These cells are able to bind antigen with high avidity and respond rapidly via interaction with helper T cells to secrete high affinity IgG and IgA antibodies. This example illustrates the effector antibody response, but the same principles of memory generation and heightened and quicker responses hold true for T cells as well.

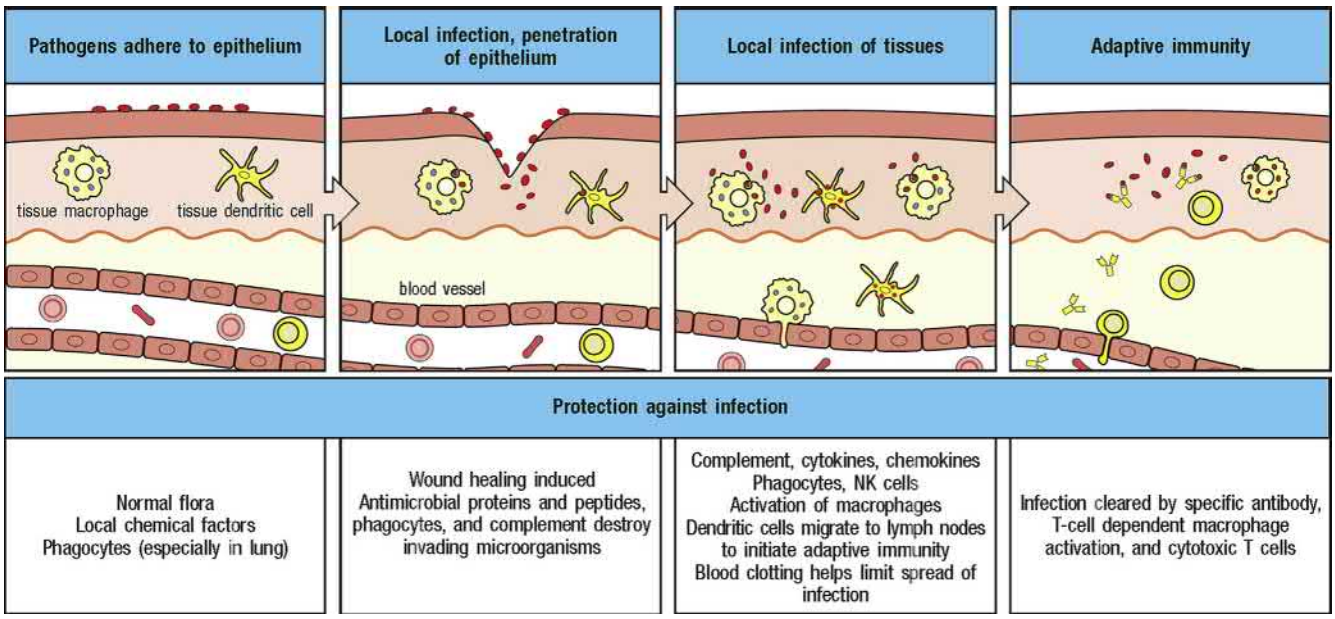
In pathogen reexposure events, memory T cells are also among the first responders. Memory T cells can be $CD4^+$ or $CD8^+$, and as such are typically divided into three major subsets: (1) central memory T cells—highly proliferative but poor effectors; (2) effector memory T cells—at-the-ready effectors, expressing the receptor S1PR1, enabling egress from lymph; and (3) tissue-resident memory T cells, which reside long term in peripheral tissues. The major differences among these subsets are centered on their migration patterns (Fig. 2.2.3.18). For instance, central memory T cells, expressing lymph-homing receptors CD62L as well as CCR7, exist primarily in secondary lymphoid tissues and in circulation. Effector memory T cells lack lymph node-homing receptor CD62L and express the receptor S1PR1, which drives egress from lymph, and are thus entirely found in circulation and peripheral tissues. Tissue-resident T cells have relatively low migratory capacity and exist in epithelial tissues without recirculating.



• **Figure 2.2.3.18** Memory T cell migration properties. Memory T cells can be classified into subsets based on their migration patterns. Central memory T (Tcm) cells recirculate through blood and constitutively migrate through lymph nodes (LNs) using high endothelial venules. Effector memory T (Tem) cells are also found in blood and exhibit diverse migration properties, but they do not enter uninflamed lymph nodes via high endothelial venules. Resident memory T (Trm) cells do not recirculate and remain local occupants of tissues during the steady state (Masopust D, 2019). Homing receptors: C–C chemokine receptor type 7 (CCR7) recognizes chemokines CCL19 and CCL21 produced in the lymph node; CD62L, or L-selectin, acts as a homing receptor for lymphocytes to enter secondary lymphoid tissues via recognizing ligands on high endothelial venules; sphingosine-1-phosphate receptor 1 (S1PR1) recognizes sphingosine-1-phosphate found in blood and is needed for the egress of immune cells from the lymphoid organs (Masopust D, 2019). (Figure 1 from Annu. Rev. Immunol. 2019. 37:521–546).

Overview of the Immune Response to Pathogens

Innate immunity is the first set of mechanisms deployed against pathogens. This immune response is rapid, occurring within minutes to hours and involves a number of effectors, including soluble proteins and phagocytes. The second line of defense, adaptive immunity, is prompted by intricate interplay between APCs, T cells, and B cells. Adaptive immune responses are highly coordinated based on the immune compartment of intercepted pathogenic material, either extracellular or cytosolic (intracellular) (Figs. 2.2.3.11 and 2.2.3.12). Extracellular pathogens may be eliminated quickly by the innate immune system, largely through phagocytic and complement effector mechanisms. In the case of prolonged infection, support from helper T cell responses (Th2 type) and B cell activation and differentiation results in the generation of pathogen-specific antibodies that can bind, neutralize, and opsonize extracellular pathogens. These effector mechanisms greatly aid the innate immune system in removing extracellular pathogens and their secreted toxins. Helper T cells also play a significant



• **Figure 2.2.3.19** Infection and the immune response directed toward it can be divided into a series of stages. These stages are illustrated for a pathogen entering the wound in the skin. Both innate and adaptive immune cells are required to act in concert to eliminate the pathogen (Travers et al., 2001). *NK*, Natural killer. (Janeway's Immunobiology ninth edition, Figure 2.8).

role by secreting cytokines that recruit first responder cells and boost their phagocytic ability by provoking phagosome–lysosome fusion and production and release of reactive oxygen species and nitric oxide. Secretion of proinflammatory cytokines (e.g., TNF-α) by innate and adaptive immune cells is also critical for inducing local inflammatory responses that minimize the spread of pathogens to other areas in the host.

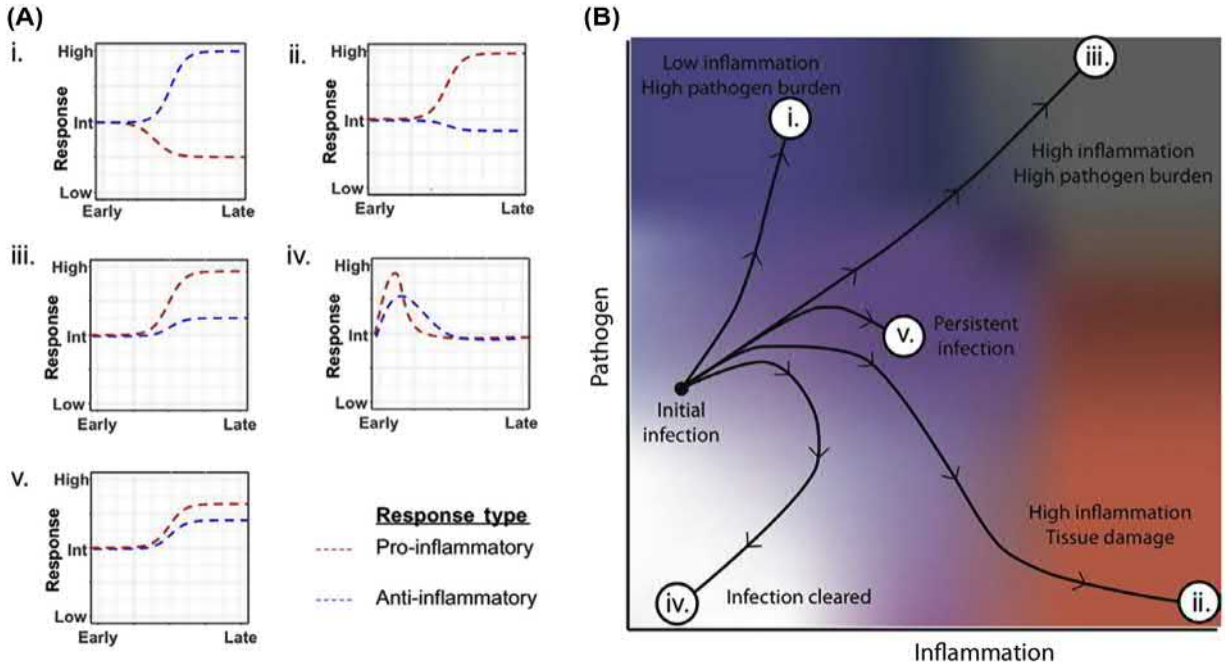
In the case where pathogens are present in cytosolic compartments, then antibodies, unable to traverse the plasma membrane, are ineffective. A different set of defensive measures are therefore employed to eliminate intracellular pathogens, including the activation of NK cells and CTLs. CD8 CTLs are effective saboteurs of virus-infected host cells and work in a coordinated fashion with helper T cell-activated macrophages to clear viral infections. Cytokines are also critical to this response, with IFN-γ perhaps the most important soluble mediator in responding to virally infected cells. IFN-β augments CTL activation, production of important molecules for immune cell recognition, interaction and activation (e.g., MHC-I, CD40), and formation of the immunoproteosome, which boosts presentation of viral antigens. Illustrated in Fig. 2.2.3.19 are representative stages and coordination between numerous components of the immune response toward infection.

Overview of Immune Regulation and Tolerance

From the discussion so far, it is clear that the mammalian immune system has an impressive array of weapons to defend against the constant microbial threats from the external environment. However, these same protective mechanisms can also become destructive against the host. It is imperative for an immune response to be commensurate to the danger. The inflammatory response includes indiscriminate degradative components damaging to host tissue, resulting in unnecessary collateral damage if left unchecked. The immune system therefore has built-in regulatory safeguards to turn inflammation off. For example, the same stimuli-triggering inflammatory signaling pathways often also initiate antiinflammatory signaling responses. These may be tuned to become fully engaged after an appropriate delay, and with complex dynamic interplay between interlinked pathways with feedback responses, the balance of which determines the outcome of pathogen clearance and host tissue sparing and healing responses, as illustrated in Fig. 2.2.3.20 (Cicchese et al., 2018). Most immune cell types display at least some regulatory activities in certain circumstances (Immunity in the tissues, 2013). Other immune regulatory mechanisms facilitate maintenance of healthy tissue homeostasis, such as the antiinflammatory clearance of apoptotic cells by macrophages, maintenance of stem cell populations, and promotion of wound healing by Tregs (Ali et al., 2017; Burzyn et al., 2013; Davies et al., 2013).

In some cases, the immune system is persistently destructive against host tissues in a targeted, self-antigen (autoantigen)-specific manner, described as a loss of *immune tolerance* and leading to *autoimmune disease*. Autoimmune diseases are characterized by chronic, dysregulated immune reactions and vary in their severity, tissue distribution, and mechanisms of tissue damage. Some common autoimmune diseases are listed in Table 2.2.3.3. The incidence of autoimmune diseases is below 5% in the developed world, although it is on the rise.

Mechanisms of tolerance inherent in the development and maintenance of the immune system aim to ward against



• **Figure 2.2.3.20** Dynamics of pro- and antiinflammatory immune responses steer disease progression along various trajectories. Schematic of relative pro- and antiinflammatory responses to a pathogen over time corresponding to various host outcomes (A). Schematic of disease trajectories corresponding to qualitative ratios of pro- and antiinflammatory responses (B). The outcomes are (i) high pathogen burden (blue); (ii) severe tissue damage (red); (iii) high pathogen burden along with a large amount of tissue damage (gray); (iv) a cleared infection and return to base levels of inflammation (white); and (v) a dynamically balanced pro- and antiinflammatory response to control pathogen growth and limit host pathology (purple) (Zaveri & et al., 2017). (Adapted from Immunol Rev. (2018) September; 285(1): 147–167. https://doi.org/10.1111/imr.12671, Figure 1).

such attacks on self. The generation of autoimmunity can be partially attributed to the same mechanisms that are used to create the diversity of the adaptive immune system–somatic gene rearrangement. Pathogen exposure is also thought to be important, as autoimmune disease is prevented in various experimental models by infection with different bacteria, viruses, and parasites. During the development of the adaptive immune system, emergent lymphocytes may have receptors capable of binding to antigens from self-proteins. Such lymphocytes are typically removed from the repertoire or restrained by a number of mechanisms, collectively referred to as immune tolerance. Immune tolerance describes an inability to mount an inflammatory response against a self-antigen. This lack of response is vital for maintenance of immune homeostasis and is an accomplished mechanism that can be grouped into two categories: (1) *central tolerance*, which occurs during the development of adaptive immune cells from stem cells, and (2) *peripheral tolerance*, a continuous process of immune regulation throughout the host's lifetime.

Central immune tolerance is defined by the negative selection of T and B cells that have a high affinity to self-epitopes during lymphocyte development. Newly formed lymphocytes are quite sensitive to strong signaling through their membrane-bound antigen receptors and undergo cell death or inactivation upon strong recognition, culling self-reactive clones. For T cells, this occurs in the thymus, and for B cells, in the bone marrow. Peripheral tolerance, on the other hand, is induced in lymphocytes that have already left the primary organs and utilize mechanisms such anergy, apoptosis, ignorance, and receptor editing in peripheral tissue to mitigate autoimmune damage (Halverson et al., 2004). Anergy is defined as a state of functional inactivity. It arises due to incomplete T cell stimulation by APCs, where antigen may be presented but there is a lack of costimulation. This scenario can also result in deletion of engaged T cells through apoptosis, a process in which cells undergo programmed cell death and can also be induced through Fas/Fas ligand interactions found between T cells and thymic epithelial cells. Some self-reactive lymphocytes simply do not have access to their cognate antigen because it is in an immunologically privileged site (e.g., testis), and are termed ignorant. Such ignorant lymphocytes normally go unstimulated and can eventually undergo apoptosis. Persistence, however, can cause autoimmunity if antigen is released from privileged tissues undergoing damage. A recently discovered mechanism of tolerance is receptor editing where self-reactive receptors from the B cell repertoire are purged, by the same genetic process that drives affinity maturation, and replaced with inoffensive receptors.

A special subset of T cells, Tregs, exploit multiple tolerance mechanisms. Tregs are the immune system workhorse

TABLE 2.2.3.3 Autoimmune Diseases and Their Known Autoantigens (Acharya et al., 2017)

Organ-Specific Diseases		Nonorgan-Specific Diseases	
Disease	**Antigen(s)**	**Disease**	**Antigen(s)**
Addison's disease	Adrenal cortical cells[a]	Ankylosing spondylitis	Vertebral
Autoimmune hemolytic anemia	RBC membrane antigens	Chronic active hepatitis	Nuclei, DNA
Graves' disease	TSH receptor	Multiple sclerosis	Brain/myelin basic protein
Guillain–Barré syndrome	Peripheral nerves (gangliosides)	Rheumatoid arthritis	IgG (rheumatoid factor) connective tissues
Hashimoto's thyroiditis	Thyroid peroxidase thyroglobulin/T4	Scleroderma	Nuclei, elastin, nucleoli centromeres, topoisomerase 1
Insulin-dependent diabetes mellitus	β cells in the pancreas (GAD), tyrosine phosphatase	Sjögren's syndrome	Exocrine glands, kidney, liver, thyroid
Pemphigus	Desmosal antigens in keratinocytes	Systemic lupus erythematosus	Double-stranded DNA, nuclear antigens
Pernicious anemia	Intrinsic factor	Wegener's granulomatosis	Proteinase 3
Polymyositis	Muscle (histidine tRNA synthetase)	Celiac disease	Small intestine
Primary biliary cirrhosis	Pyruvate dehydrogenase		
Several Organs Affected			
Goodpasture syndrome	Basement membrane of kidney and lung (type IV collagen)		
Polyendocrine	Multiple endocrine organs (hepatic cytochrome p450; intestinal tryptophan hydroxylase)		

GAD, Glutamic acid decarboxylase; *RBC*, red blood cell; *TSH*, thyroid-stimulating hormone.

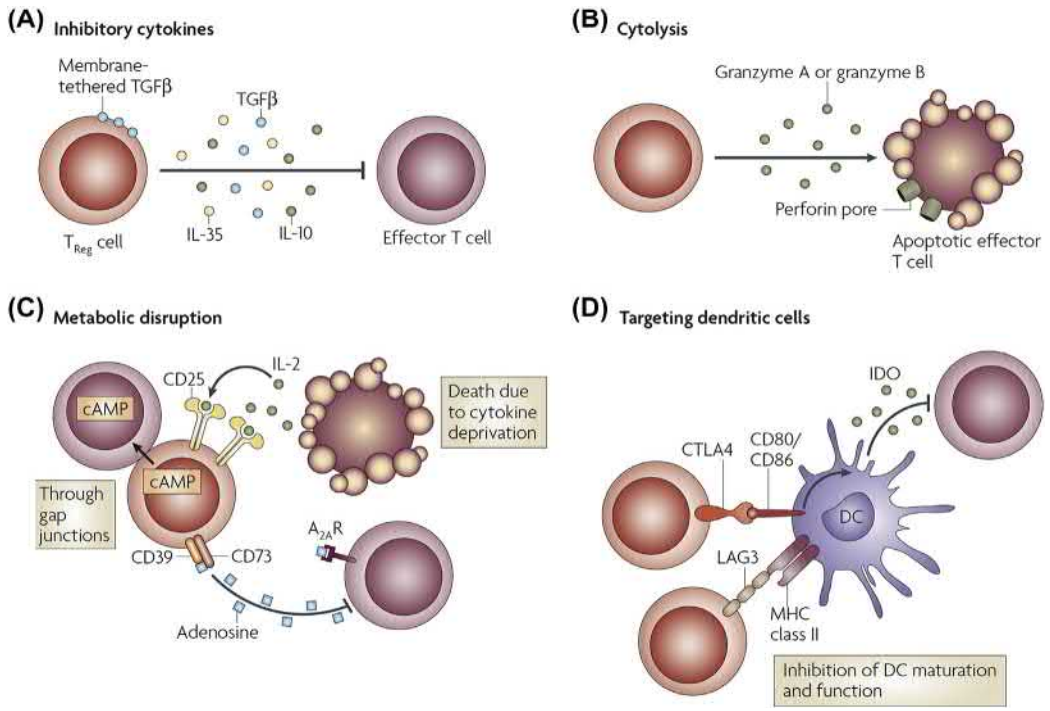
for the maintenance of peripheral tolerance, keeping autoreactive cells in check to avoid autoimmunity. Incidentally, Tregs arise during the negative selection process of central tolerance from TCR binding, which is too weak to provoke deletion but at an affinity too great for positive selection. Furthermore, Tregs can be induced from naïve T cells that recognize their antigen in the presence of certain antiinflammatory cytokines (e.g., TGF-β1). Tregs take a number of functionally distinct forms, including $CD4^+$ $CD25^+$ FoxP3-expressing Tregs and IL-10-producing Type 1 regulatory cells. The plurality of Treg types is representative of the multiplicity of mechanisms employed by these cells to inhibit autoimmune reactions (Fig. 2.2.3.21). These mechanisms range from modulation of APC stimulatory capacity, to inhibition of activation and cytolysis of naïve T cells, as well as metabolic disruption where Tregs "starve" effector cells of key nutrients or cytokines needed for survival. Moreover, activated Tregs secrete antiinflammatory cytokines that act in an autocrine as well as a paracrine manner on nearby bystander cells. In this way, all autoreactive cells, including those without the specific antigenicity of the secreting Treg, may be locally suppressed. This phenomenon can be referred to as *infectious tolerance* to a growing pool of antigens. These multiple mechanisms of regulation may act and in a complementary or synergistic manner.

Intersection of Biomaterials and Immunology

Whether or not the biomaterial scientist intends for a material or device to engage the immune system, it is clear that interactions with major components of the immune system are an inescapable reality for the vast majority of applications. This is true even in the case of implantation of what may be considered an inert synthetic material, as illustrated in Fig. 2.2.3.22. For example, implanted biomaterial surfaces induce adsorption



• **Figure 2.2.3.21** Effector mechanisms of regulatory T cells. Regulatory T cells exercise regulatory roles through various contact–dependent and –independent mechanisms, such as: (A) inhibiting effector T cell proliferation through inflammatory cytokine production, inducing effector T cell death by (B) granzyme secretion, and (C) metabolic disruption, as well as (D) inducing a suppressive phenotype of dendritic cells (DCs) to limit their capacity to activate effector T cells (Allen et al., 2018). *CD,* cluster of differentiation; *CTLA4*, cytotoxic T-lymphocyte-associated protein 4; *IDO,* indoleamine 2 3-dioxygenase; *IL*, interleukin; *LAG3*, Lymphocyte Activating gene 3; *MHC,* Major histocompatibility complex; *TGFb,* Transforming growth factor beta. of blood proteins, activation of the coagulation cascade, and activation of complement and platelets resulting in the priming and activation of PMNs, monocytes, and macrophages (Zaveri et al., 2014; Zaveri et al., 2017; Keselowsky and Lewis, 2017; Lewis et al., 2015). These innate system components also employ adaptive system cells, which helps shape the overall immune response to the implanted biomaterial.

Adaptive immunity plays an even more active role in cases where the implanted material is of biological origin (e.g., silk, decellularized extracellular matrix), and when cells or tissues are incorporated, as is typical in tissue engineering, regenerative medicine, and immunoisolation applications. In these cases, the implants serve as a depot of foreign antigens, some of which may be capable of initiating specific immune responses. With this in mind, researchers are investigating the potential that immune responses can be skewed to enhance immune responses toward activation or suppression in the context of biomaterials, a conceptualization of which is illustrated in Fig. 2.2.3.23. For example, parameters such as the availability of antigen, biomaterial surface chemistry, surface topography/roughness (Kou et al., 2011), and protein adsorption can be modulated to skew toward either a pro- or antiinflammatory response.

Biomaterial scientists are also utilizing drug delivery capabilities as well as manipulating material properties to productively engage both the innate and adaptive immune systems, as illustrated in Fig. 2.2.3.24, from a transplant and tissue-engineering perspective. For example, scaffolds housing a foreign islet transplant can also serve as a drug delivery depot to provide controlled release of agents that inhibit monocyte migration and/or macrophage maturation, repel macrophage infiltration, scavenge detrimental products from activated macrophages, or promote an M2-like macrophage phenotype. Release or surface presentation of factors to modulate adaptive immunity is also possible, where strategies such as promoting tolerogenic phenotypes, inhibiting T cell egress from the lymph node, and locally inducing immune cell apoptosis are all being investigated. Biomaterials are being utilized to act as immunoisolation devices, where material encapsulation of a foreign transplant serves to block direct antigen presentation pathways. This approach relies on a material pore size large enough to allow exchange of nutrients and metabolites, with pores being small enough to block cell ingress/egress. However, this approach still allows activation of indirect pathways, where soluble-shed antigens can pass through the material barrier, be taken up by host APCs, and stimulate antigen-specific responses, which are capable of directing cell killing of the transplant through release of soluble mediators. To address this unwanted activation of adaptive immunity, immunomodulatory agents can be incorporated within the biomaterial or tethered to the material surface for local modulation of APCs and/or

• **Figure 2.2.3.22** Immune response toward biomaterials. (A) Adsorption of blood proteins and activation of the coagulation cascade, complement, and platelets result in the priming and activation of polymorphonuclear neutrophils (PMNs), monocytes, and resident macrophages. (B) Danger signals (alarmins) released from damaged tissue additionally prime the immune cells for enhanced function via pattern recognition receptor (PRR) engagement. (C) The acute inflammatory response is dominated by the action of PMNs. PMNs secrete proteolytic enzymes and reactive oxygen species (ROS), corroding the biomaterial surface. IL-8 released from PMNs enhances PMN influx and priming. In the transition from acute to chronic inflammation, PMNs stop secreting IL-8 in favor of cytokines promoting migration and activation of monocytes and macrophages. (D) Macrophages are the driving force of chronic inflammation. Constant release of inflammatory mediators like TNF-β, IL-6, and MCP-1 results in permanent activation of macrophages. Fusion-inducing stimuli like IL-4 and IL-13 promote the fusion of macrophages to foreign body giant cells (FBGCs), which form a highly degradative environment on the biomaterial surface. Furthermore, FBGCs promote extracellular (ECM) remodeling and fibroblast activation resulting in excessive fibrosis and biomaterial encapsulation. (E) Macrophage-derived cytokines and PRR engagement activate dendritic cells (DCs) on the biomaterial surface. Depending on the nature of the stimulus, DCs mature to either immunogenic or tolerogenic subtypes, amplifying or suppressing the inflammatory response (Jewell et al., 2011). *bm*, Bone marrow; *HA*, hydroxyapatite; *PDGF*, platelet-derived growth factor; *TGF-β*, transforming growth factor beta;*TLR*, toll-like receptor. T cells to instruct toward apoptotic or tolerogenic pathways, with local antigen delivery from the transplanted cells providing antigen specificity.

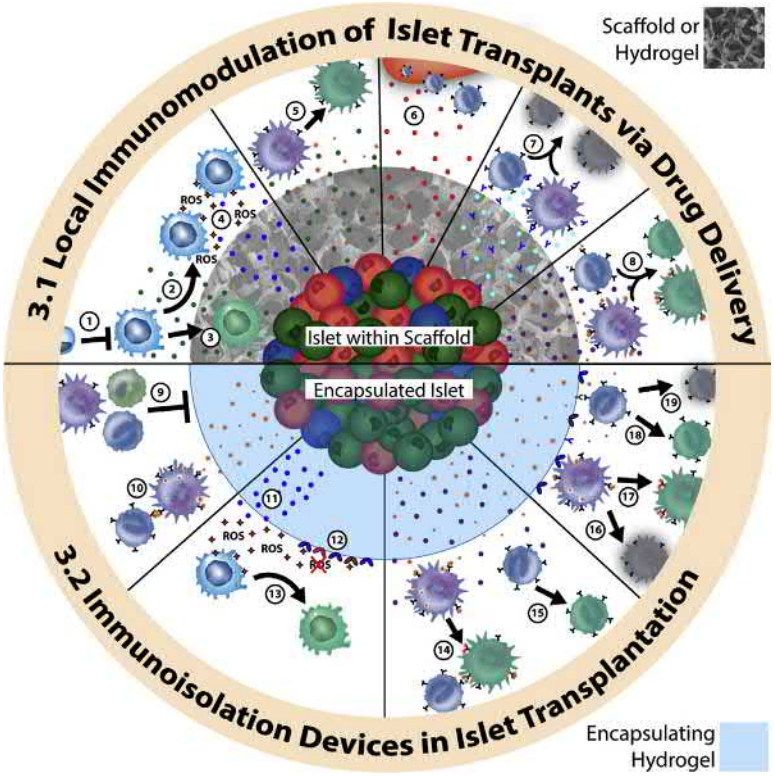
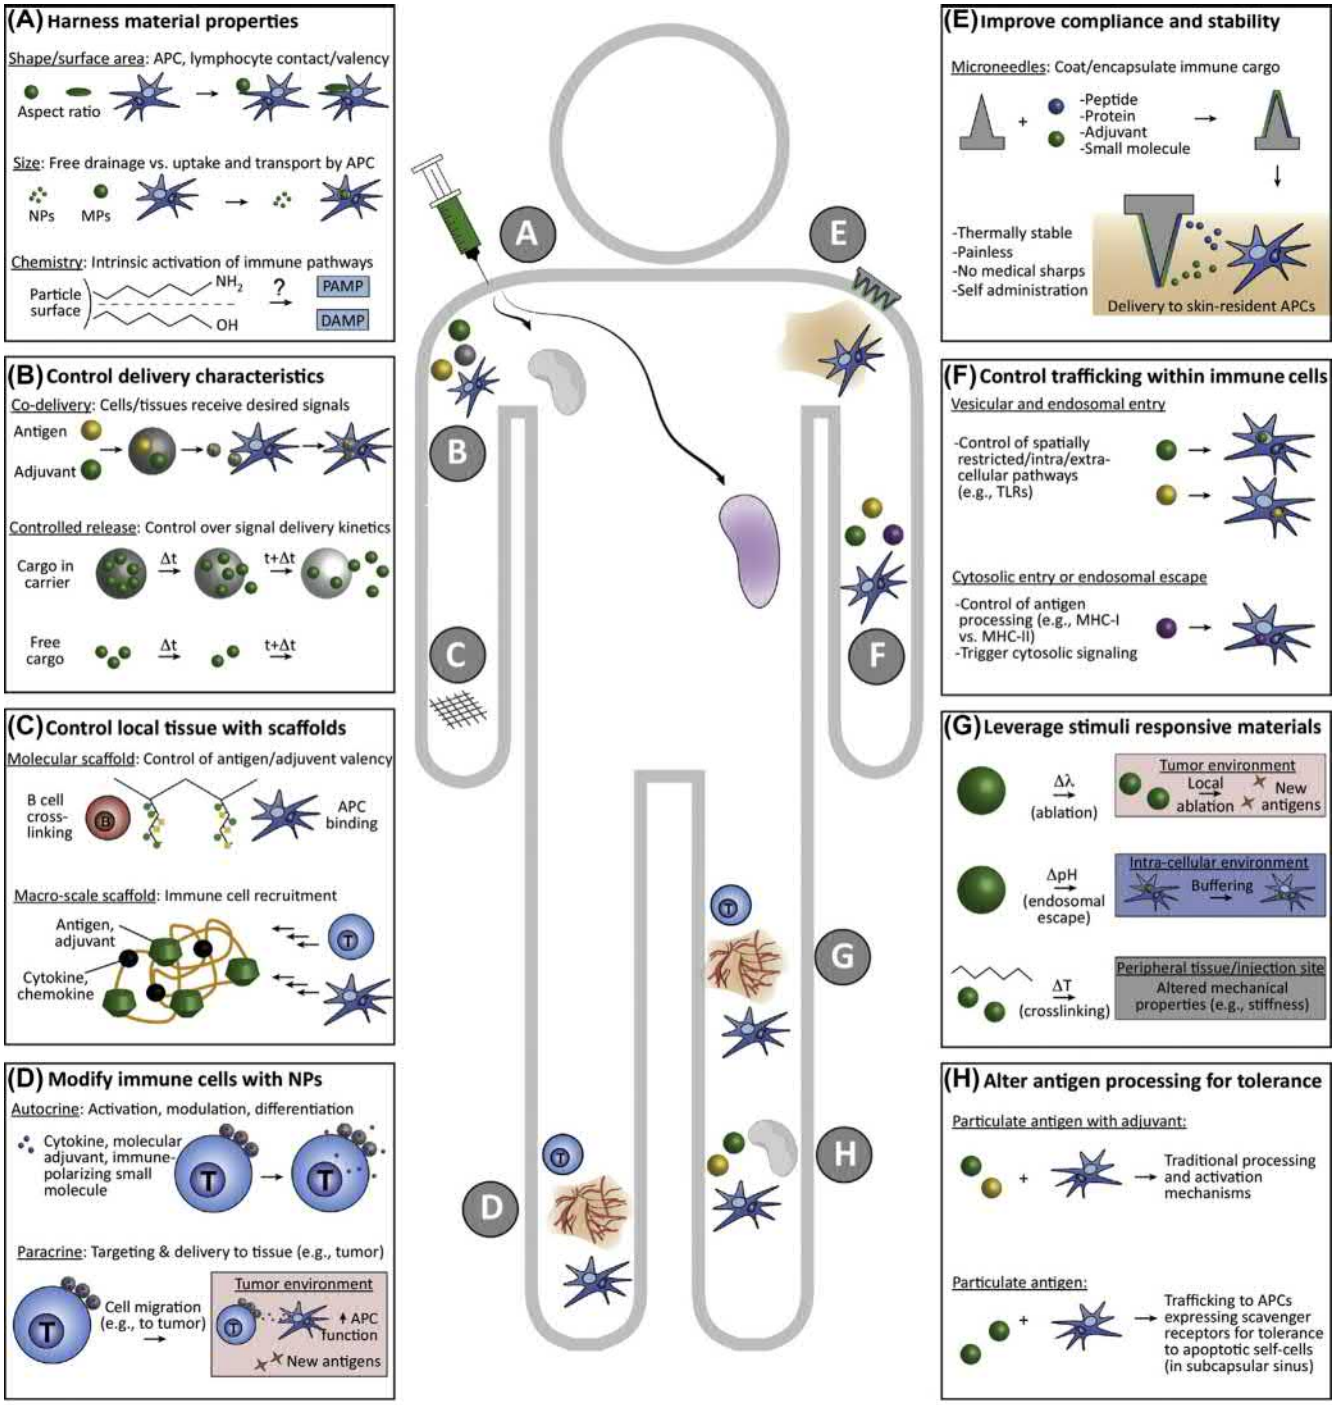
Taking a cue from the nanoscale features of alum as a vaccine adjuvant material, approaches using biomaterial nanoparticles and microparticles are actively being investigated in numerous compositions and forms to modulate immune functions, mimicking characteristics of pathogen internalization and processing by APCs (Acharya et al., 2017). Strategies illustrating biomaterial approaches directing immune function, paying particular attention to particle-based systems, are illustrated in Fig. 2.2.3.25. For example, the size and shape of particles, along with material interfacial chemistry, ligand coupling (Lewis et al., 2012), and other physicochemical properties (Allen et al., 2018) and responsiveness can be readily tuned to impact delivery of factors to either cell surface receptors or intracellular compartments, drainage to lymphatics, interactions with APCs, and the intrinsic immunogenicity of many common polymers (Champion and Mitragotri, 2009; Doshi



• **Figure 2.2.3.24** Immunomodulatory biomaterial approaches for islet and B cell transplantation. *Top*: Local immunomodulation via drug delivery. Scaffolds housing the foreign islet transplant can serve as a drug delivery depot. For modulation of inflammation, scaffolds can release agents that inhibit monocyte migration and/or macrophage maturation (1), repel macrophage infiltration (2), scavenge detrimental products from activated macrophages, such as reactive oxygen species (ROS) (3), and/or promote an M2-like macrophage phenotype (4). For modulation of adaptive immunity, drugs are released/presented to inhibit antigen uptake or promote a tolerogenic dendritic phenotype (5), inhibit activated T cell egress from the lymph node (6), induce immune cell apoptosis (7), and/or promote tolerogenic phenotype (8). The presence of the islet graft also provides antigen delivery (orange). *Bottom*: Immunoisolation devices. Encapsulation of the foreign transplant serves to block direct antigen presentation pathways (9) but indirect pathways (10) can still be activated. Drugs incorporated within the biomaterial (11) or tethered to the material surface (12) can serve to dampen inflammatory response to the material and cells via inhibition of macrophage activation, scavenging of detrimental agents, and/or promotion of an M2-like phenotype (13). To dampen adaptive immune responses, immunomodulatory agents can be incorporated into the encapsulating material and released for local modulation of antigen-presenting cell (14) and/or T cell (15) activation. Conjugation of immunomodulatory agents to the surface of the biomaterial can also serve to instruct immune cells toward apoptotic (16 andand 18) and/or tolerogenic (17 andand 19) pathways with local antigen delivery (from the transplanted cells) to provide antigen specificity (Sunshine et al., 2014). (Keselowsky et al., 2019 Nature Materials Reviews).

and Mitragotri, 2010). Biomaterial particle configurations can be used to control the combinations and relative concentrations (Yoon et al., 2015) of immune cargos (antigens, immunomodulatory factors) reaching APCs and lymphocytes, or, by designing polymers with a desired degradation rate, the cargo delivery kinetics (Acharya et al., 2016; Joshi et al., 2014; Jewell et al., 2011). In addition to APCs, T cells and other immune cells can also be targeted with nanoparticles incorporating immune signals (Sunshine et al., 2014; Fadel et al., 2014; Smith et al., 2017).

While explored to a lesser extent, biomaterial systems are also being utilized to develop immunosuppressive responses. For example, delivery of vitamin D3, TGF-β1, and GM-CSF in the presence of disease-relevant antigens showed marked improvement in type 1 diabetes, multiple sclerosis, and rheumatoid arthritis mouse models (Lewis et al., 2015; Yoon et al., 2015; Allen et al., 2019; Lewis et al., 2019). Additionally, scaffolds can be used to deliver antigens and adjuvants, and as a local environment to recruit APCs or lymphocytes for either immune activation or tolerance (Ali et al., 2009; Verbeke & et al., 2017). Other material configurations such as microneedles incorporating immune cues are also being investigated (Sullivan & et al., 2010; Demuth & et al., 2013). Overall, biomaterials provide numerous precisely definable and facile tools to target specific immune cells, and modulate responses for pathologies ranging from cancer, autoimmune disease, and infections. Both biomaterials science and immunology stand to gain tremendously from the continued integration of these disparate but synergistic fields.



• **Figure 2.2.3.25** Strategies involving biomaterials for engineering immune function. (A) Material shape, size, chemistry, and other physicochemical properties impact drainage through lymphatics, interactions with antigen-presenting cells (APCs), and the intrinsic immunogenicity of many common polymers. (B) Biomaterials can be used to control the combinations and relative concentrations of immune cargos reaching APCs and lymphocytes, or, by designing polymers with a desired degradation rate, the cargo delivery kinetics. (C) Scaffolds can be used to control the context or density in which antigens and adjuvants are displayed, and as local environments to recruit APCs or lymphocytes (e.g., by incorporation of chemokines). (D) T cells, APCs, and other immune cells can be modified with nanoparticles (NPs) incorporating immune signals to exert autocrine effects on the modified cells, or to exert paracrine effects on target cells and tissue to which the modified cell will migrate (e.g., a tumor). (E) Microneedles coated with or incorporating immune cues increase safety and patient compliance by efficiently targeting skin-resident immune cells without pain, generation of medical sharps, or need for refrigeration. (F) Biomaterial carriers can be engineered with specific moieties to control cellular entry and intracellular trafficking for directing spatially restricted immune processes (e.g., toll-like receptor [TLR] signaling and antigen processing). (G) Stimuli responsive materials can exploit physiological (e.g., changes in pH or temperature) or external (e.g., ultraviolet light) cues to provide environment-specific control within cells, target tissues, or tumors (e.g., access to neoantigens during NP-enabled local ablation via photothermal exposure). (H) NPs and microparticles (MPs) can alter how antigens are processed to modulate responses away from proimmune and toward regulation. *DAMP*, Damage-associated molecular pattern; *MHC*, major histocompatibility complex; *PAMP*, pathogen-associated molecular pattern (Trends in Immunology, February 2018, Vol. 39, No. 2 https://doi.org/10.1016/j.it.2017.10.002, Figure 2).

Chapter Exercises

Innate Immunity

1. What is the first defense mechanism and what are its salient features?

   Answer: Epithelial surfaces of the body provide the first line of dense against foreign materials. The salient features are (1) microbiota, (2) chemical–pH, enzymes, fatty acids, mucosa, surfactants, and cilia, and (3) mechanical–epithelial tight junctions, mucous flow, flow of air, and fluid.
2. What is the first protein complex in the classical pathway of complement activation?

   Answer: C1.
3. Name three main pathogen recognition receptors?

   Answer: TLRs, NLRs, and RLRs.
4. How many TLRs have been identified to date in humans and mice?

   Answer: Humans TLR1–10 and mice TLR1–13.
5. What type of innate immune cells are activated by stress, microbial molecules, or cytokines and are responsible for chemokine-based attraction of APCs? What are their major classifications?

   Answer: ILCs. ILC1—IFNγ producing proinflammatory phenotype; ILC2—IL-4 producing tissue repair phenotype; and ILC3—IL-17, IL-22, and GM-CSF producing chemoattractive cells.

Adaptive Immunity

1. What are the major constituents of the adaptive immune response?

   Answer: T lymphocytes, adaptive immune cytokines, B lymphocytes, and antibodies comprise the major components of the adaptive immune response.
2. True or false: Antibodies, in general, have four polypeptide chains of similar size that are connected at the "hinge" by disulfide bonds.

   Answer: False; antibodies have two light chains and two heavy chains, which are much larger than the former.
3. All of the following are effector mechanisms of antibodies except:
   a. Neutralization
   b. Opsonization
   c. ADCC
   d. Agglomeration

   Answer: d. Agglomeration.
4. Briefly explain what is meant by the term "anergy."

   Answer: Within the molecular communication bridge between APC and T cell (or immune synapse), other molecules also play a role in enhancing intracellular signaling networks that lead to complete activation. These molecules are called costimulators (e.g., CD28 on T cells binding to CD86 on APCs). In their absence, there is insufficient stimulation of T cells resulting in a state of hyporesponsiveness to the antigen or anergy.
5. Outline five general biomaterial-based strategies employed to harness the function of the immune system.

   Answer: Any explanation, including five of the following strategies is an acceptable response:
   a. Material shape, size, chemistry, and other physicochemical properties impact drainage through lymphatics, interactions with APCs, and the intrinsic immunogenicity of many common polymers.
   b. Biomaterials can be used to control the combinations and relative concentrations of immune cargos reaching APCs and lymphocytes, or, by designing polymers with a desired degradation rate, the cargo delivery kinetics.
   c. Scaffolds can be used to control the context or density in which antigens and adjuvants are displayed, and as local environments to recruit APCs or lymphocytes (e.g., by incorporation of chemokines).
   d. T cells, APCs, and other immune cells can be modified with nanoparticles incorporating immune signals to exert autocrine effects on the modified cells, or to exert paracrine effects on target cells and tissue to which the modified cell will migrate (e.g., a tumor).
   e. Microneedles coated with or incorporating immune cues increase safety and patient compliance by efficiently targeting skin-resident immune cells without pain, generation of medical sharps, or need for refrigeration.
   f. Biomaterial carriers can be engineered with specific moieties to control cellular entry and intracellular trafficking for directing spatially restricted immune processes (e.g., TLR signaling and antigen processing).
   g. Stimuli responsive materials can exploit physiological (e.g., changes in pH or temperature) or external (e.g., ultraviolet light) cues to provide environment-specific control within cells, target tissues, or tumors (e.g., access to neoantigens during nanoparticle-enabled local ablation via photothermal exposure).
   h. Nanoparticles and microparticles can alter how antigens are processed to modulate responses away from proimmune and toward regulation.

2.2.4

The Complement System

RICHARD J. JOHNSON

BioPhia Consulting, Lake Forest, IL, United States

As discussed in the previous chapter, the immune system acts to protect each of us from the constant exposure to pathogenic agents such as bacteria, fungi, viruses, and cancerous cells that pose a threat to our lives. The sheer multitude of structures that the immune system must recognize, differentiate from "self," and mount an effective response against has driven the evolution of this system into a complex network of proteins, cells, and distinct organs. An immune response to any foreign element involves all of these components, acting in concert, to defend the host from intrusion. Historically, the immune system has been viewed from two perspectives: cellular or humoral. This is a somewhat subjective distinction, since most humoral components (such as antibodies, complement components, and cytokines) are made by the various cells of the immune system and, in turn, often function to regulate the activity of the multiple types of immune cells. The goal of this chapter will be to provide a basic understanding of the biochemistry and pathobiology of the complement system, including its interaction with both cells and the coagulation pathway, underscoring its relevance to biomaterials research and development.

Introduction

Complement is a term devised by Paul Ehrlich to refer to plasma components that were known to be necessary for antibody-mediated bactericidal activity (Ross, 1986). We now know that the complement system is composed of more than 30 distinct plasma- and membrane-bound proteins involving three separate pathways: classical, alternative, and lectin pathways. The complement system directly and indirectly contributes to both innate inflammatory reactions, as well as cellular (i.e., adaptive) immune responses (West et al., 2018). This array of effector functions is due to the activity of a number of complement components and their receptors on various cells. These activities are summarized in Table 2.2.4.1, along with the responsible complement protein(s). One of the principal functions of complement is to serve as a primitive self–nonself discriminatory defense system. This is accomplished by coating a foreign material with complement fragments and recruiting phagocytic cells that attempt to destroy and digest the "intruder." Although the system evolved to protect the host from the invasion of adventitious pathogens, the nonspecific and spontaneous nature of the alternative pathway (AP) permits activation by various biomaterial surfaces. The adsorption of proteins onto biomaterial surfaces, such as IgG or ficolins, drives activation of the classical and lectin pathways, respectively. Because complement activation can follow three distinct but interacting pathways, the various ways of activating the cascade will be outlined separately in the following.

One of the principal functions of complement is to serve as a primitive self–nonself discriminatory defense system. This is accomplished by coating a foreign material with complement fragments and recruiting phagocytic cells that attempt to destroy and digest the "intruder." Although the system evolved to protect the host from the invasion of adventitious pathogens, the nonspecific and spontaneous nature of the alternative pathway (AP) permits activation by various biomaterial surfaces.

Classical Pathway

The classical pathway (CP) is activated primarily by immune complexes (ICs) composed of antigen and specific antibody, although other proteins, such as C-reactive protein, serum amyloid protein, and amyloid fibrils, as well as apoptotic bodies, can also activate the CP (Bohlson et al., 2007; Cooper, 1985). The proteins of this pathway are C1, C2, C4, C1 inhibitor (C1-Inh), and C4 binding protein (C4bp). Some of their basic characteristics are summarized in Table 2.2.4.2.

Complement activation by the CP is illustrated in Fig. 2.2.4.1. This system is an example of an enzyme cascade in which each step in the series, from initiation to the final product, involves enzymatic reactions (in this case, proteolytic cleavage reactions) that result in some degree of amplification. Research with knockout mice (mice deficient in C1q, C2, C4, or IgG) has shown that the CP is in a state of continuous low-level activation, essentially primed to react vigorously in the presence of an IC (Manderson et al., 2001). When an IC forms, the cascade is initiated when

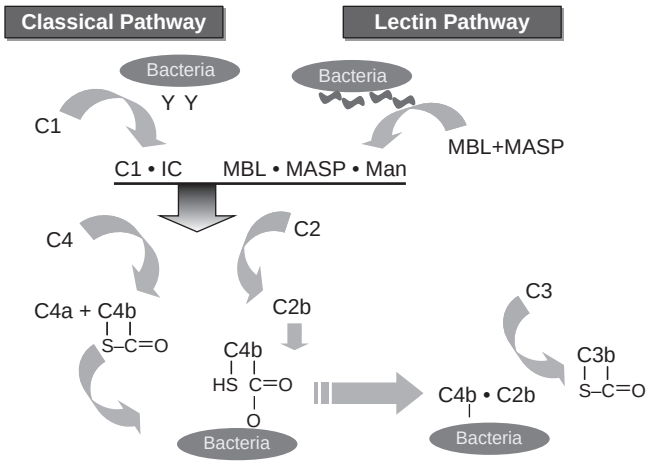
TABLE 2.2.4.1 Complement Activities

Activity	Complement Protein
Identification/opsonization of pathogens	C3, C4
Recruitment/activation of inflammatory cells	C3a, C5a
Lysis of pathogens/cytotoxicity	C5b-9 (MAC)
Clearing immune complexes and apoptotic cells	C1q, C3b, C4b
Augment cellular immune responses (T and B cells)	C3, C4, C3a, C5a, DAF(CD55)

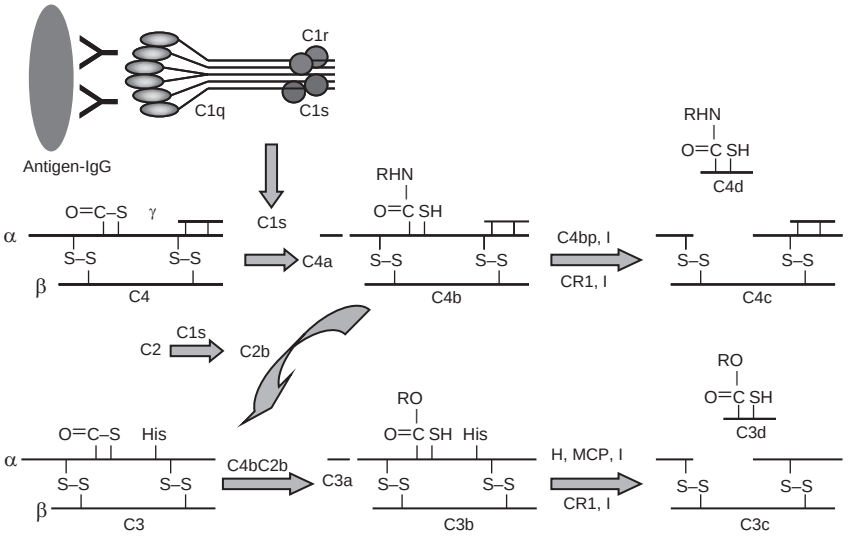
TABLE 2.2.4.2 Proteins of the Classical Pathway of Complement

Protein	Molecular Weight	Subunits	Plasma Concentration (μg/mL)
C1q	410,000	6A, 6B, 6C	70
C1r	85,000	1	35
C1s	85,000	1	35
C2	102,000	1	25
C4	200,000	α, β, γ	600
C1-Inh	104,000	1	200
C4bp	570,000	8	230

C1 binds to the Fc portion of an antigen–antibody complex. The C1 protein is composed of three different types of subunits called C1q, C1r, and C1s (Fig. 2.2.4.2). One end of C1q binds to an IC formed between an antigen and one molecule of (pentameric) immunoglobulin (Ig) M or several closely spaced IgG molecules. This interaction may produce a conformational change in the C1q that results in activation (i.e., autocatalytic proteolysis) of the two C1r



• **Figure 2.2.4.1** Complement activation by the classical pathway (CP). Upon binding to the Fc region of an immune complex, C1 is activated and cleaves C4, exposing its thioester, which permits covalent attachment of C4b to the activating surface. C2 is cleaved, producing C2b, which binds to C4b to form the CP C3 convertase. C2b is a serine protease that specifically acts on C3 to generate C3b and C3a. The lectin pathway is also illustrated. Mannose-binding lectin (MBL) recognizes certain sugar residues (mannose, *N*-acetylglucosamine) on the surface of an activator (bacteria). MBL-associated serine protease 1 (MASP-1) appears to activate MASP-2, which then cleaves both C4 and C2 of the CP, generating the CP C3 convertase.



• **Figure 2.2.4.2** Schematic illustration of C4 and C3 protein structures. O=C–S represents the reactive thioester bond that permits covalent attachment to surface nucleophiles (hydroxyl or amino groups). The pattern of proteolytic degradation and the resulting fragments are also shown. Although factor I is the relevant in vivo protease, some of these same fragments can be generated with trypsin, plasmin, and thrombin.

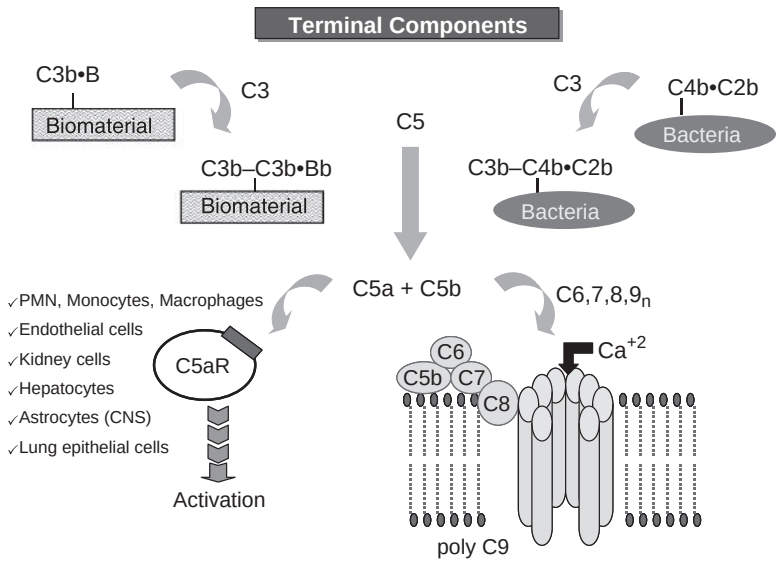
and then the two C1s subunits bound to the other end of the C1q protein. Recent work suggests that activation may also occur through intramolecular contact between two C1 molecules bound closely together (Mortensen et al., 2017), bringing the C1r proteins in close juxtaposition. Both C1r and C1s are zymogen serine proteases that are bound to the C1q in a calcium-dependent manner that is inhibited by calcium chelators such as citrate or ethylenediaminetetraacetic acid (EDTA). The proteolysis of C1s completes the activation of C1, which then proceeds to act on the next proteins in the cascade, C4 and C2.

C4 is composed of three separate chains, α, β, and γ (Fig. 2.2.4.2), bound together by disulfide bonds. Activated C1s cleaves C4 near the amino terminus of the α chain, yielding a 77-amino acid polypeptide called C4a and a much larger C4b fragment. The C4 protein contains a unique structural element called a thioester (Fig. 2.2.4.2), which has only been detected in two other plasma proteins, α2-macroglobulin and C3. Upon cleavage of C4, the buried thioester becomes exposed and available to react with surface-containing amino or hydroxyl moieties. About 5% of the C4b molecules produced react through the thioester, and become covalently attached to the surface. This represents the first amplification step in the pathway, since each molecule of C1 produces a number of surface-bound C4b sites.

The C4b protein, attached to the surface, acts as a receptor for C2. After binding to C4b, C2 becomes a substrate for C1s. Cleavage of C2 yields two fragments: a smaller C2a portion diffuses into the plasma, while the larger C2b remains bound to the C4b. The C2b protein is another serine protease that, in association with C4b, represents the CP C3/C5 convertase.

As the name implies, the function of the C4b•C2b complex is to bind and cleave C3. The C3 protein sits at the juncture of the classical and alternative pathways, and represents one of the critical control points. Cleavage of C3 by C2b yields a 9 kDa C3a fragment and a 175 kDa C3b fragment that are very similar to C4b in both structure and function. Cleavage of C3 produces a conformational change in the C3b protein that results in exposure of its thioester group (Fig. 2.2.4.2). Condensation with surface nucleophiles (such as carbohydrates) results in covalent attachment of 10%–15% of the C3b to the surface of the activator. This is the second amplification step in the sequence, since as many as 200 molecules of C3b can become attached to the surface surrounding every C4b•C2b complex. Eventually one of the C3b molecules reacts with a site on the C4b protein, creating a C3b–C4b•C2b complex that acts as a C5 convertase (Fig. 2.2.4.3). The C4b•C2b complex can also cleave C5 at very low rates, but the addition of C3b to the complex increases the affinity for (and thus the turnover of) C5 by approximately 1000-fold (Rawal et al., 2008).

In contrast to C3, which can be cleaved in the fluid phase (see later discussion), proteolytic activation of C5 occurs only after it is bound to the C3b portion of the C5 convertase on the surface of an activator (e.g., the immune complex). Like C3, C5 is also cleaved by C2b to produce fragments designated C5a (16 kDa) and C5b (170 kDa). The C5b molecule combines with the proteins of the terminal components to form the membrane attack complex (MAC) described later. C5a is a potent inflammatory mediator, and is responsible for many of the adverse reactions normally attributed to complement activation in various clinical settings.



• **Figure 2.2.4.3** Conversion of C5 produces C5a and C5b, the latter leads to formation of the membrane attack complex. C5a binds to receptors on a variety of cells and results in numerous activities. C5b, formed by the classical pathway, lectin pathway, or the alternative pathway, binds C6 and C7 to form a complex that associates with the plasma membrane. This C5b67 multimer then binds C8, which results in the formation of a small hole in the lipid bilayer that allows small molecules to pass through. Association of multiple C9 proteins enlarges the pore, leading to loss of membrane integrity and cell death. *PMN*, polymorphonuclear neutrophil.

TABLE 2.2.4.3 Proteins of the Lectin Pathway of Complement

Protein	Molecular Weight	Subunits	Plasma Concentration (μg/mL)
MBL	270–650,000	18	1–3
MASP-1	93,000	2 (H,L)	6
MASP-2	76,000	2 (H,L)	0.4
MASP-3	110,000	2 (H,L)	

MASP, MBL-associated serine protease; *MBL*, mannose-binding lectin.

TABLE 2.2.4.4 Proteins of the Alternative Pathway of Complement

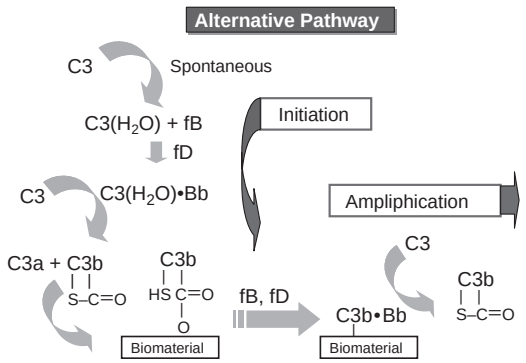
Protein	Molecular Weight	Subunits	Plasma Concentration (μg/mL)
C3	185,000	α, β	1300
B	93,000	1	210
D	24,000	1	1
H	150,000	1	500
I	88,000	α, β	34
P	106–212,000	2–4	20

Lectin Pathway

In the 1990s, investigators working with a protein called mannose-binding lectin (MBL) discovered a third pathway that leads to complement activation (Matsushita, 1996). This scheme is called the lectin pathway (LP), and is composed of lectins like MBL and three MBL-associated serine proteases or MASPs (Table 2.2.4.3). MBL is an acute-phase protein, so its concentration in plasma increases substantially during an infection. MBL binds to terminal mannose, *N*-acetyl-glucosamine, and *N*-acetyl-mannosamine residues in complex carbohydrate structures. MBL has long been recognized as an opsonin, i.e., a protein that facilitates phagocytosis of bacteria. Low concentrations of MBL in children are associated with recurrent bacterial infections. MBL is similar in structure to C1q, having an amino terminal domain with a collagen-like structure that binds the MASP proteins, followed by a globular carbohydrate recognition domain that binds to sugar residues. There are three MASP proteins, called MASP-1, MASP-2, and MASP-3, which are very similar in structure to C1r and C1s (Wong et al., 1999). MASP-2 can cleave both C4 and C2, forming a CP C3 convertase (Fig. 2.2.4.1), while MASP-1 cleaves MASP-2 to help accelerate convertase formation (Heja et al., 2012). MASP-3 competes with MASP-2 for binding to MBL, acting to slow LP activation, but also appears to be the primary activator of the AP protease, factor D, in resting human blood (Dobo et al., 2016). The LP can also be activated by other proteins, including ficolins (ficolin-1, -2, and -3) and collectin-11.

Alternative Pathway

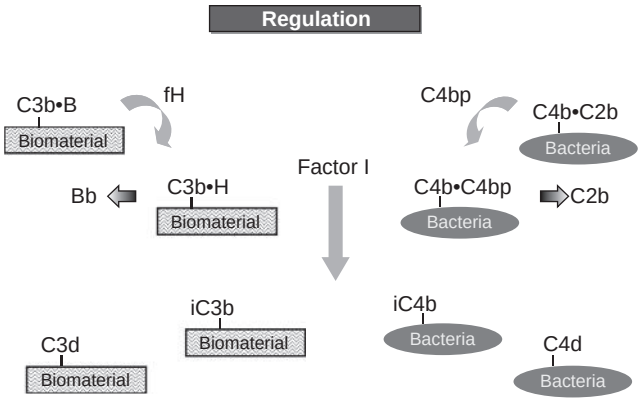
The AP was originally discovered in the early 1950s by Pillemer et al. (1954). Pillemer's group studied the ability of a yeast cell wall preparation, called zymosan, to consume C3 without affecting the amount of C1, C2, or C4. A new protein, called properdin, was isolated and implicated in initiating C3 activation independent of the CP. This new scheme was called the properdin pathway. However, this work fell into disrepute when it was realized that plasma contains natural antibodies against zymosan, which implied CP involvement in Pillemer's experiments. The pathway was rediscovered in the late 1960s with the study of complement activation by bacterial lipopolysaccharide (LPS), and with the discovery of a C4-deficient guinea pig. The 1970s witnessed the isolation and characterization of each of the proteins of this pathway until it was possible to completely reconstruct the entire AP by recombining each of the purified proteins (Schreiber et al., 1978). While some biomaterials can activate complement through either the CP (Andersson et al., 2005) or the LP (Banda et al., 2014), most biomaterials activate the AP, either directly or by recognizing surface-bound C3b produced during activation by the CP/LP.



• **Figure 2.2.4.4** Complement activation by the alternative pathway. The spontaneous conversion of C3 to C3(H_2O) permits the continuous production of C3b from C3, a process called C3 tickover. In the presence of an activating surface, the C3b is covalently bound and becomes the focal point for subsequent interactions. The bound C3b is recognized by factor B, which is then cleaved by factor D to produce a surface-bound C3 convertase (C3b•Bb). This results in amplification of the original signal to produce more convertase.

While some biomaterials can activate complement through either the CP (Andersson et al., 2005) or the LP (Banda et al., 2014), most biomaterials activate the AP, either directly or by recognizing surface-bound C3b produced during activation by the CP/LP.

The proteins of this pathway are described in Table 2.2.4.4. Their actions can be conceptually divided into three phases: initiation, amplification, and regulation (Figs. 2.2.4.4 and 2.2.4.5). Initiation is a spontaneous process that



• **Figure 2.2.4.5** Control of complement activation by factors H, I, and C4 binding protein. The extent to which complement activation occurs on different surfaces is dependent on the ability of fH or C4BP to recognize C3b or C4b on the surface. Degradation by factor I results in irreversible inactivation and the production of C3 and C4 fragments recognized by various complement receptors on white blood cells.

is responsible for the nonselective nature of complement. During this stage, a small portion of the C3 molecules in plasma undergo a conformational change that results in hydrolysis of the thioester group, producing an activated form of C3 called C3(H_2O) ("C3-water") that will bind to factor B. The C3(H_2O)•B complex is a substrate for factor D (a protease), which cleaves the B protein to form a solution-phase AP C3 convertase: C3(H_2O)•Bb. Analogous to C2b in the CP, Bb is a serine protease that (in association with C3(H_2O)) will cleave more C3 to form C3b. Under normal physiological conditions, most of the exposed thioester in the C3b produced is hydrolyzed and inactivated, a process that has been termed "C3 tickover." C3 tickover is a continuous process that ensures a constant supply of reactive C3b molecules to deposit on foreign surfaces, such as cellulosic- or nylon-based biomaterials. Recognition of the C3b by factor B, cleavage by factor D, and generation of more C3 convertase leads to the amplification phase (Fig. 2.2.4.4). During this stage, many more C3b molecules are produced, bind to the surface, and in turn lead to additional C3b•Bb sites. Eventually, a C3b molecule attaches to one of the C3 convertase sites by direct attachment to the C3b protein component of the enzyme. This C3b–C3b•Bb complex is the AP C5 convertase and, in a manner reminiscent of the CP C5 convertase, converts C5 to C5b and C5a (Fig. 2.2.4.3).

Recent work with purified proteins and techniques to measure direct interactions with polymer surfaces has revealed an additional potential mechanism for AP activation (Andersson et al., 2002). Both C3b and C3 will adsorb to (not react with) polystyrene. A portion (about 10%) of the bound C3 or C3b binds factor B. This complex is recognized by factor D, which then catalyzes the formation of an AP C3 convertase. This process is facilitated by properdin, which increases the amount of convertase formed under these conditions. Interestingly, while the C3b•Bb convertase is controlled by factors H and I (see later), the surface-bound C3•Bb convertase is not. The adsorption of C3 does not occur if the polystyrene surface is precoated with fibrinogen, so the extent to which this occurs in whole blood, where many other proteins can compete with C3 for binding to a biomaterial surface, has not been demonstrated.

TABLE 2.2.4.5 Proteins of the Membrane Attack Complex

Protein	Molecular Weight	Subunits	Plasma Concentration (μg/mL)
C5	190,000	α, β	70
C6	120,000	1	60
C7	105,000	1	60
C8	150,000	α, β	55
C9	75,000	1	55
S-protein	80,000	1	500

Membrane Attack Complex

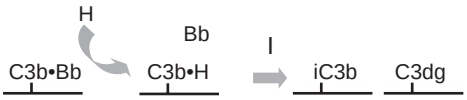
All three pathways lead to a common point: cleavage of C5 to produce C5b and C5a. C5a is a potent inflammatory mediator and is discussed later in the context of receptor-mediated white blood cell (WBC) activation. The production of C5b initiates the formation of a macromolecular complex of proteins called the MAC that disrupts the cellular lipid bilayer, leading to cell death (Table 2.2.4.5). The sequence of events in MAC formation is outlined in Fig. 2.2.4.3.

Following cleavage of C5 by C5 convertase, the C5b remains weakly bound to C3b in an activated state in which it can bind C6 to form a stable complex called C5b6. This complex binds to C7 to form C5b67, which has amphiphilic properties that allow it to bind to, and partially insert into, lipid bilayers. The C5b67 complex then binds C8 and inserts itself into the lipid bilayer. The C5b678 complex disrupts the plasma membrane and produces small pores ($r \sim 1$ nm) that permit leakage of small molecules. The final step occurs when multiple copies of C9 bind to the C5b678 complex and insert into the membrane. This enlarges the pore to about 10 nm, and can lead to lysis and cell death. Even at sublytic levels, formation of MAC on host cells results in a number of activation responses (elevated Ca^{+2}, arachidonic acid metabolism, cytokine production).

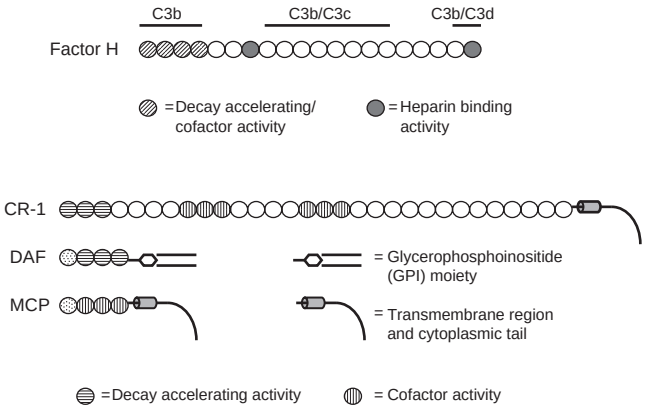
In addition to the usual means of generating C5b (i.e., through C5 convertase activity), several groups (Vogt, 1996; Vogt et al., 1992) have shown that C5 can be modified by a variety of oxidizing agents (H_2O_2, superoxide anion, and others) to convert C5 into a C5b-like structure that will bind C6. The oxidized C5•C6 complex can bind C7, C8, and C9 to form lytic MAC. This mechanism of MAC formation may be relevant at sites where neutrophils and macrophages attempt to phagocytize a biomaterial, producing a variety of reactive oxygen species, or in hypoxia/reperfusion settings (angioplasty, cardiopulmonary bypass [CPB], etc.).

Control of Complement Activation

Decay Acceleration	Cofactor Activity	Protease/ Inhibitor	MAC Inhibitor
CR1	CR1	Factor I	CD59
Factor H	Factor H	C1Inh	S Protein
DAF/CD55	MCP/CD46	sCPN	Clusterin
C4BP	C4BP		



• **Figure 2.2.4.6** Control of complement activation occurs by various mechanisms, and is facilitated by a number of different proteins in the plasma (fH, fI, C1 Inh, C4BP, sCPN, S protein, and clusterin) or on cell surfaces (CR1s, DAF, MCP, and CD59). Decay acceleration refers to the increased rate of displacement of either C2b or fBb from classical pathway or alternative pathway convertases. Cofactor activity refers to the increased rate of factor I-mediated proteolysis facilitated by some proteins; *MAC*, membrane attack complex.



• **Figure 2.2.4.7** Structure–activity relationships for complement control proteins. Each circle represents one short consensus repeat (SCR) domain, made up of about 60 amino acids. These SCR domains are strung together to create the different structures shown; *CR-1*, complement receptor 1; *DAF*, decay-accelerating factor; *MCP*, membrane cofactor protein.

Control Mechanisms

Various types of control mechanisms have evolved to regulate the activity of the complement system at numerous points in the cascade (Liszewski et al., 1996; Bajic et al., 2015). These mechanisms are shown in Fig. 2.2.4.6 and include: (1) decay (dissociation) of convertase complexes; (2) proteolytic degradation of active components that is facilitated by several cofactors; (3) protease inhibitors; and (4) association of control proteins with terminal components that interfere with MAC formation. Without these important control elements, unregulated activation of the cascade results in overt inflammatory damage to various tissues, and has been demonstrated to contribute to the pathology of many diseases (discussed later). Some of these regulatory components have been leveraged to control complement activation by biomaterials (discussed later).

Starting at the top of the cascade, control of classical and lectin pathway activation is mediated by a protein called C1-Inh. C1-Inh acts by binding to activated C1r and C1s subunits in C1, as well as MASP proteases bound to MBL. C1-Inh actually forms a covalent bond with these proteases, thus irreversibly inactivating these proteins. The effectiveness of this interaction is illustrated by the short half-life of C1s under physiological conditions (13 s). The classical/lectin pathway C3/C5 convertase (C4b•C2b complex) spontaneously "decays" by dissociation of the C2b catalytic subunit. The rate of dissociation is increased by C4bp, which competes with C2 for a binding site on C4b. C4bp also acts as a cofactor for another control protein called factor I, which destroys the C4b by proteolytic degradation (Figs. 2.2.4.2 and 2.2.4.6).

The AP is also highly regulated by mechanisms that are very similar to the CP. The intrinsic instability of the C3b thioester bond (half-life = 60 μs) ensures that most of the C3b (80%–90%) is inactivated in the fluid phase. Once formed, the C3 convertase (C3b•Bb complex) also spontaneously dissociates, and the rate of "decay" is increased by factor H. Aside from accelerating the decay of C3 convertase activity, factor H also promotes the proteolytic degradation of C3b by factor I (Figs. 2.2.4.2 and 2.2.4.6). Factors H and I also combine to limit the amount of active C3(H_2O) produced in the fluid phase.

In addition to factor H, there are several cell membrane-bound proteins that have similar activities and structures (Fig. 2.2.4.7). These proteins act to limit complement-mediated damage to autologous bystander cells. Decay-accelerating factor, or DAF, displaces Bb from the C3 convertase and thus destroys the enzyme activity. DAF is found on all cells in the blood (bound to the plasma membrane through a unique glycosylphosphatidylinositol [GPI] lipid group), but is absent in a disease called paroxysmal nocturnal hemoglobinuria, which manifests a high spontaneous rate of red blood cell (RBC) lysis. In addition to DAF, there are two other cell-bound control proteins: membrane cofactor protein (MCP) and complement receptor 1 (CR1; see later discussion). MCP is found on all blood cells except erythrocytes, while CR1 is expressed on most blood cells as well as cells in tissues such as the kidney. Both of these proteins display cofactor activity for the factor I-mediated cleavage of C3b. CR1 also acts like factor H and DAF to displace Bb from the C3 convertase. A soluble recombinant form of CR1 (sCR1) was originally described by Weisman et al. (1990), and later produced commercially (Avant [now Celldex] Immunotherapeutics). A number of investigations have used sCR1 to limit complement activation in various disease models (Couser et al., 1995; Larsson et al., 1997).

In contrast to the inhibitory proteins already discussed, properdin functions by binding to surface-bound C3b and stabilizing the C3 and C5 convertase enzymes. Work from several labs has suggested that properdin can bind to a number of AP activators (rabbit erythrocytes, zymosan, LPS, and apoptotic and necrotic cells) independent of C3b. This has led to an alternative model for AP activation on some surfaces, where properdin plays the initial role in

TABLE 2.2.4.6 Receptors for Complement Proteins

Receptor Name/Ligand	Structure	Cellular Distribution/Response
CR1/C3b, C4b	200,000 Da single chain	RBC, PMN, monocytes, B, and T cells/clearance of immune complexes, phagocytosis, facilitates cleavage of C3b to C3dg by factor I
CR2/C3dg	140,000 Da single chain	B cells/regulate B cell proliferation
CR4	150,000 Da α chain 95,000 Da β chain	PMN, platelets, B cells/leukocyte—endothelial cell interaction
CR3/iC3b, ICAM-1, β-glucan, fibrinogen, factor Xa	185,000 Da α chain 95,000 Da β chain	PMN, monocyte/phagocytosis of microorganisms, respiratory burst activity
C5a/$C5a_{des\ Arg}$	40,000 Da	PMN, monocytes, mast cells, T cells, epithelial and endothelial cells, hepatocytes, CNS, fibroblasts/chemotaxis, degranulation, hyperadherence, respiratory burst, cytokine production (IL-6, IL-8)
C3a/$C3a_{des\ Arg}$	65,000 Da	Mast cells, eosinophils (various tissues)/histamine release, IL-6 production
C1q/C1q	70,000 Da	PMN, monocytes, B cells/respiratory burst activity
H/H	50,000 Da (three chains)	B cells, monocytes/secretion of factor I, respiratory burst activity

PMN, polymorphonuclear neutrophil; *RBC*, red blood cell.

surface recognition, binds C3b, facilitates factor B binding, and helps drive AP activation (Spitzer et al., 2007; Kimura et al., 2008). Saggu et al. (2013) demonstrated that purified and gel-filtered properdin binds to activated but not resting platelets and facilitates complement activation on the platelet surface providing a mechanism for local complement activation at sites of thrombosis. Using purified and gel-filtered properdin is important in assessing the relevance of these experiments as Harboe et al. (2017) has recently demonstrated that some AP activators (zymosan, *E. coli*, *Neisseria meningitidis*, and human umbilical vein endothelial cells [ECs]) do appear to require prior deposition of C3b to bind properdin.

As with the other stages of the cascade, there are several control mechanisms that operate to limit MAC formation and the potential for random lysis of "bystander" cells. The short half-life of the activated C5b (2 min), and the propensity of the C5b67 complex to self-aggregate into a nonlytic form, helps limit MAC formation. In addition, a MAC inhibitor, originally called S protein and subsequently shown to be identical to vitronectin, binds to C5b67 (also C5b678 and C5b6789) and prevents cell lysis. Another way to control MAC on the surface of the cell is through the action of CD59. Like DAF/CD55, CD59 is a GPI lipid-linked membrane protein. It is widely distributed and found on erythrocytes, WBCs, ECs, epithelial cells, and hepatocytes. CD59 functions by interacting with C8 and C9, preventing functional assembly of MAC complexes on the cell membrane. Finally, cells are also able to form outward vesicles or exosomes, releasing a portion of their plasma membrane. These microvesicles have been shown to contain MAC, and MAC has been shown to stimulate vesicle formation, leading to the suggestion that this may be a mechanism used by cells to physically remove MAC from the plasma membrane.

Complement Receptors

Except for the cytotoxic action of the MAC, most of the biological responses elicited by complement proteins result from ligand–receptor-mediated cellular activation (Sengelov, 1995; Bajic et al., 2015). These ligands are listed in Table 2.2.4.6 and are discussed briefly here.

The ability of complement to function in the opsonization of foreign elements is accomplished in large part by a set of receptors that recognize various C3 and C4 fragments bound to these foreign surfaces. These receptors are called CR1, CR2, CR3, and CR4. CR1 is found on a variety of cells, including RBCs, neutrophils, monocytes, B cells, and some T cells, and recognizes a site within the C3c region of C3b (Fig. 2.2.4.2). On neutrophils and monocytes, activated CR1 will facilitate the phagocytosis of C3b- and C4b-coated particles. On RBCs, CR1 acts to transport C3b-immune complexes to the liver for metabolism. As discussed earlier, CR1 is also a complement regulatory protein. CR2 is structurally similar to CR1 (with 16 short consensus repeat [SCR] domains; see Fig. 2.2.4.7), but recognizes the C3d fragment of C3b that is bound to antigen. CR2 is expressed on antigen-presenting cells, such as follicular dendritic cells and B cells, where it facilitates the process of antigen-immune complex-driven B cell proliferation, providing a link between innate and adaptive immunity. CR3 represents another complement receptor that binds to iC3b and β-glucan structures found on zymosan (yeast cell wall).

Also, on activated monocytes, CR3 has been shown to bind fibrinogen and factor Xa (of the coagulation cascade). CR3 is a member ($\alpha_M\beta_2$) of the β2-integrin family of cell adhesion proteins that includes leukocyte functional antigen-1 (LFA-1) and CR4. LFA-1, CR3, and CR4 are routinely referred to as CD11a, CD11b, and CD11c, respectively. Each of these proteins associates with a molecule of CD18 to form an α-β heterodimer that is then transported and expressed on the cell surface. These proteins help mediate the cell–cell interactions necessary for activities such as chemotaxis and cytotoxic killing. A genetic deficiency in CR3/LFA proteins leads to recurrent life-threatening infections. CR4 is found on neutrophils and platelets, and binds C3d and iC3b. CR4 may facilitate the accumulation of neutrophils and platelets at sites of immune complex deposition.

In contrast to the ligands discussed earlier, which remain attached to activating surfaces, C3a, C4a, and C5a are small cationic polypeptides that diffuse into the surrounding medium to activate specific cells. These peptides are called anaphylatoxins because they stimulate histamine release from mast cells and cause smooth muscle contraction, which can produce increased vascular permeability and lead to a fatal form of shock called anaphylactic shock. These activities are lost when the peptides are converted to their des Arg analogs (i.e., with the loss of their carboxyl terminal arginine residue, referred to as $C3a_{des\ Arg}$, $C5a_{des\ Arg}$, etc.). This occurs rapidly in vivo (intravascularly) and is catalyzed by serum carboxypeptidase N (Mueller-Ortiz et al., 2009).

In addition to their anaphylatoxic properties, C5a and $C5a_{des\ Arg}$ bind to specific receptors originally found on neutrophils and monocytes. The receptors for both C5a and C3a have been cloned and sequenced. C5aR (CD88) has been shown to be expressed on ECs, hepatocytes, epithelial cells (lung and kidney tubules), T cells, and cells in the CNS, as well as on the myeloid cell lines (Monk et al., 2007). In addition, expression levels of C5aRs are increased on ECs and hepatocytes by exposure to LPS and IL-6. In myeloid cells (neutrophils and monocytes), the C5a–receptor interaction leads to a variety of responses, including chemotaxis of these cells into an inflammatory locus; activation of the cells to release the contents of several types of secretory vesicles and produce reactive oxygen species that mediate cell killing; increased expression of CR1, CR3, and LFA-1, resulting in cellular hyperadherence; and the production of other mediators such as various arachidonic acid metabolites and cytokines, e.g., IL-1, -6, and -8. Many of the adverse reactions seen during extracorporeal therapies, such as hemodialysis, are directly attributable to C5a production. C3aRs are expressed on a variety of cell types, including eosinophils, neutrophils, monocytes, mast cells, and astrocytes (in the CNS), as well as γ-IFN-activated T cells. In eosinophils, C3a elicits responses similar to C5a, including intracellular calcium elevation, increased endothelial cell adhesion, and the generation of reactive oxygen intermediates. In contrast, C3a has been shown to limit migration of neutrophils from the bone marrow into the blood, suggesting it may have antiinflammatory activity in some settings (Coulthard and Woodruff, 2015).

Measurement of Complement Activation

There are numerous methods that have been developed over the decades to measure complement activation in biological fluids (Harboe et al., 2011). This discussion will be limited to those assays that are most common and commercially available, while also noting specific assays that have been suggested by regulatory authorities for use in characterizing the complement activating potential of materials used in medical devices. The oldest method to measure complement activation is the CH50 assay, which measures the residual hemolytic activity of complement in a plasma or serum sample. This assay was optimized in the early 1900s and utilizes a rabbit IgM antibody bound to sheep RBCs and largely measures the CP. A hemolytic assay for AP that uses rabbit RBCs is also available. These types of assays are not very sensitive and have been largely replaced by more sensitive and selective assays. These include enzyme-linked immunoassays (EIAs) for C4a, C3a, C5a, iC3b, SC5b-9, and other proteolytic split products generated during complement activation. The most commonly used assay is for C3a, which is an excellent marker for the early stages of complement activation, but does not distinguish between CP, LP, and AP activation mechanisms. Measuring C4a levels can help define pathway mechanisms, or, for in vitro experiments, measuring C3a levels with 5–10 mM EGTA-Mg (to bind excess calcium and inhibit CP/LP while permitting AP activation) can also be performed. EIAs for C5a and SC5b-9 are used to determine production of the C5a inflammatory mediator and activation of the terminal pathway. In whole blood samples, C5a is difficult to measure since it is rapidly bound up to cellular receptors and internalized. For this reason, many investigators prefer the SC5b-9 assay, which does not have this issue. However, in contrast to C5a, SC5b-9 has no biological activity, so some investigators prefer to measure biomaterial complement-activating potential in plasma samples where C5a can be assayed without the interference of C5a receptors. Regulatory groups such as the International Standards Organization (ISO) provide guidance on various aspects of measuring the suitability of medical plastics used in medical devices. ISO 10993-Part 4 defines methods for measuring blood–material interactions and suggests using the EIAs for C3a and SC5b-9 for this purpose.

Measurement of complement activity will depend on the type and dose of anticoagulant used in the study. For in vitro experiments using whole blood or plasma samples, heparin at 1–2 IU/mL is the preferred anticoagulant. Hirudin or its analogs can also be used but is more expensive than heparin and not as clinically relevant. Citrate should be avoided as it will bind up calcium (and some magnesium) and, depending on the citrate concentration, will partially or completely inhibit complement activation (Huang et al., 2015). For clinical samples, for control in vitro samples, or for any sample where further complement activation is to be stopped, EDTA at 5–10 mM should be used.

TABLE 2.2.4.7 Complement–Coagulation Interactions

Complement Component(s)	Coagulation Component(s)	Type of Interaction
C3, C5, factor B	Thrombin	Proteolysis of C3, C5, FB by thrombin
C3, C5, C1s	Plasmin	Proteolysis of C3, C5, FB during fibrinolysis
C3, factor B	Kallikrein, thrombin	Kallikrein cleaves C3 and FB; C3 convertase (Bb) cleaves thrombin
C5a	Tissue factor	C5a stimulates TF production from platelets and endothelial cells
C5b-9	Platelets	Sublytic MAC activates platelets
C3, properdin	Platelets	Platelets act as a complement-activating surface

MAC, membrane attack complex; *TF*, tissue factor.

Complement–Coagulation System Interactions

Evidence accumulated over the last three decades has demonstrated numerous interactions between the complement and coagulation cascades (reviewed in Oikonomopoulou et al., 2012). The interactions can be classified into two distinct types: (1) protein–protein interactions and (2) protein–cell or platelet interactions. Some examples of this crosstalk between complement and coagulation are shown in Table 2.2.4.7 and are discussed in more detail later.

A number of studies have shown that activated coagulation proteins can cleave both C3 and C5, generating active fragments that result in further complement activation and inflammatory responses. Amara et al. (2010) demonstrated that the order of efficiency in the cleavage of C3 by various coagulation proteases is: FXa > plasmin > thrombin > FIXa > FXIa. This activity is consistent with the long-standing observation that background values of C3a and C5a are 5–10-fold greater in serum compared to EDTA-anticoagulated plasma (see the section "Measurement of Complement"). Conversely, it has also been shown that C3 convertase (C3bBb) and MASP-1 and MASP-2 (Fair et al., 1981; La Bonte, 2012) can cleave prothrombin to thrombin. Several reports (Ritis et al., 2006; Redecha et al., 2007) have demonstrated that C5a can stimulate WBCs to express tissue factor (TF). TF can then activate prothrombin-to-thrombin conversion via the extrinsic pathway of coagulation. Hemodialysis on complement-activating membranes has been shown to correlate with increased expression of WBC TF and decreased prothrombin time values during clinical hemodialysis (Kourtzelis et al., 2010). Finally, C1 esterase inhibitor binds to FXIIa and activated kallikrein to inhibit their activity (in addition to its ability to inhibit C1r, C1s, and MASP proteases). A genetic deficiency of C1INH underlies the pathology of hereditary angioedema, a life-threatening condition where uncontrolled bradykinin production (generated from prokallikrein) can lead to severe edema in the airways.

The second type of interaction occurs when complement proteins bind to platelets, ECs, or WBCs. Stimulation of TF on WBCs by C5a was discussed earlier. Complement activation has also been shown to stimulate TF expression on ECs, involving both C5a and MAC (Oikonomopouloi et al., 2012). C1q has been shown to bind to a receptor on platelets and inhibit collagen-induced platelet aggregation. Factor D has been shown to compete with thrombin for binding to protease-activated receptors on platelets and inhibit thrombin-induced platelet aggregation. Binding of C5b-9 to platelets (at sublytic levels) has been shown to result in platelet activation (due to increased intracellular calcium concentrations), including degranulation of α-granules and release of microvesicles that are enriched in prothrombinase activity (Sims and Wiedmer, 1991). Activated platelets in turn have been demonstrated to promote complement activation on their surface (Peerschke et al., 2010).

Clinical Correlates

The normal function of complement is to mediate a localized inflammatory response to a foreign material. The complement system can become clinically relevant in situations where it either fails to function or where it is activated inappropriately; some of these settings are shown in Table 2.2.4.8 (Markiewski and Lambris, 2007; Unsworth, 2008; Nilsson et al., 2007). In the first instance, a lack of activity due to a genetic deficiency in one or more complement proteins has been associated with increased incidence of recurrent infections (MBL deficiency in children), autoimmune disease (over 90% of C1-deficient patients develop systemic lupus erythematosus), and other pathologies (for example, a deficiency of C1 inhibitor is the cause of hereditary angioedema, as already noted). A recent genomic analysis has linked a mutation in factor H to various diseases. The strongest association has been made with the development of adult macular degeneration (AMD; Klein et al., 2005). The mutation has been shown to decrease the interaction of factor H with cell surface sugars, linking this loss in cell surface control of complement to the development of AMD and other diseases (Schmidt et al., 2008). This is

TABLE 2.2.4.8 Clinical Settings Involving Complement

Hemodialysis and Cardiopulmonary Bypass

Systemic lupus erythematosus
Asthma
Alzheimer's disease
Hereditary angioedema
Adult macular degeneration

also an example of inappropriate activation, which can occur in a variety of circumstances. It is now recognized that ECs exposed to hypoxic conditions (ischemia due to angioplasty or a blocked artery due to atherosclerosis) activate complement following reperfusion of the blocked vessel. This results in further damage to the vessel wall, and eventually to the surrounding tissue. Activation of the CP by immune complexes occurs in various autoimmune diseases, such as systemic lupus erythematosus and rheumatoid arthritis. Glomerular deposition of immune complexes results in local inflammation that can contribute to a type of kidney damage called glomerulonephritis (GN). Quite a bit of experimental and clinical data have accumulated demonstrating that complement directly contributes to the initiation and/or progression of GN (Table 2.2.4.9), resulting in the development of end stage renal disease, and the necessity of hemodialysis therapy.

One of the major settings where complement has been implicated in adverse clinical reactions is during extracorporeal therapies such as hemodialysis, cardiopulmonary bypass, and apheresis therapy. The same nonspecific mechanism, which permits the AP to recognize microbes, results in complement activation by the various biomaterials found in different medical devices. The following discussion summarizes the clinical experience with hemodialysis and cardiopulmonary bypass, but many of the observations concerning complement activation and WBC activation are relevant to other medical biomaterial applications.

One of the major settings where complement has been implicated in adverse clinical reactions is during extracorporeal therapies such as hemodialysis, cardiopulmonary bypass, and apheresis therapy. The same nonspecific mechanism, which permits the AP to recognize microbes, results in complement activation by the various biomaterials found in different medical devices.

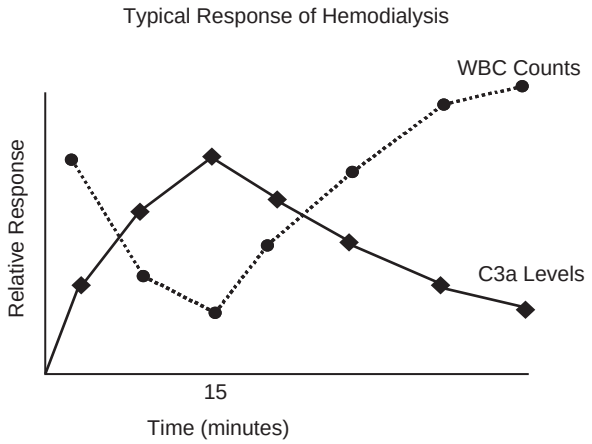
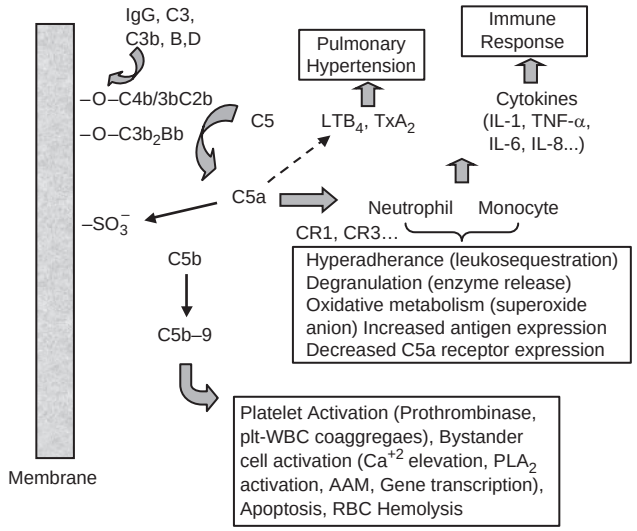
TABLE 2.2.4.10 Clinical Symptoms Associated With Cuprophan-Induced Biocompatibility Reactions

Cardiopulmonary	Pulmonary hypertension, hypoxemia, respiratory distress (dyspnea), neutropenia (pulmonary leukosequestration), tachycardia, angina pectoris, cardiac arrest
Other	Nausea, vomiting, diarrhea, fever, chills, malaise, urticaria, pruritus, headache

One of the most investigated materials (from the perspective of complement activation) is the cellulosic Cuprophan membrane used extensively for hemodialysis. Some of the adverse reactions that occur during clinical use of a Cuprophan dialyzer are listed in Table 2.2.4.10. Craddock et al (1977) showed that some of these same manifestations (neutropenia, leukosequestration, and pulmonary hypertension) could be reproduced in rabbits and sheep when the animals were infused with autologous plasma that had been incubated in vitro with either Cuprophan or zymosan. This effect could be abrogated by treatment of the plasma to inhibit complement activation (heating to 56°C or addition of EDTA), thus linking these effects with complement. The development and use of specific radioimmunoassays to measure C3a and C5a by Dennis Chenoweth (1984) led to the identification of these complement components in the plasma of patients during dialysis therapy. A typical patient response to a Cuprophan membrane is shown schematically in Fig. 2.2.4.8. The C3a (and C5a) levels rise during the first 5–15 min, peaking between 10 and 20 min. For a Cuprophan membrane, typical peak C3a levels range from 4000 to 6000 ng/mL. During this period the WBCs become hyperadherent and are trapped in the lung, resulting in a peripheral loss of these cells (neutropenia). As complement activation is controlled (e.g., by factor H), the C3a and C5a levels decrease to baseline levels, and the WBC returns to the peripheral circulation, now in a more activated (primed) state. This is a very consistent response, and many authors have noted a direct correlation between the extent of complement



• **Figure 2.2.4.8** A typical response pattern to dialysis with a complement-activating hemodialysis membrane. Many investigators have noted that the extent of C3a production is directly proportional to the degree of neutropenia at the same time points; *WBC*, white blood cells.



• **Figure 2.2.4.9** The biochemical basis for complement-mediated adverse reactions during extracorporeal therapy. Production of C5a leads to receptor-dependent white blood cell activation. This results in profound neutropenia, increased concentrations of degradative enzymes, and reactive oxygen species that ultimately may lead to tissue damage and dysfunction of these important immune cells. Generation of secondary mediators, such as arachidonic acid metabolites (TxA2, LTB4) and cytokines, can have profound consequences on whole organ systems. Finally, formation of the membrane attack complex (C5b-9) has been linked with increased hemolysis during cardiopulmonary bypass, formation of microparticles, and has been shown to increase platelet prothrombinase activity in vitro. This last observation suggests that surfaces that activate complement aggressively may be more thrombogenic; *RBC*, red blood cell; *WBC*, white blood cell.

activation and the degree of neutropenia (as well as other responses such as CR3 expression) seen with various dialysis membranes.

Based on our understanding of the biochemistry of complement and its biological actions, the following scenario can be drawn (Fig. 2.2.4.9). Contact by blood with the membrane results in initial protein deposition, including IgG, C3, and especially C3b, eventually leading to the formation of C3 and C5 convertase enzymes. Conversion of C5 results in C5a production, which leads to receptor-mediated neutrophil and monocyte activation. Production of C5b leads to MAC formation, which binds to bystander cells and results in subsequent activation of these cells through calcium-dependent mechanisms. Recognition of biomaterial-bound C3 and C4 fragments by WBC results in cell adherence and further activation of these cells. These various responses account for much of the pathophysiology seen clinically. The critical role of C5a in mediating many of these adverse reactions was confirmed in experiments employing purified sheep C5a. Infusion of this isolated peptide into sheep, in a manner that would simulate exposure to this molecule during hemodialysis, produced dose-dependent responses identical to those seen when the sheep are subjected to dialysis (Johnson et al., 1996). In addition, numerous in vivo and in vitro studies have documented the relationship between complement activation by biomaterials, the extent of WBC activation, and the resulting inflammatory response illustrated in Fig. 2.2.4.9 (Lewis and Van Epps, 1987; Gemmell et al., 1996; Larsson et al., 1997; Tang et al., 1998).

In the same timeframe that clinicians were linking complement with leukopenia in the hemodialysis setting, a number of cardiovascular scientists were demonstrating complement activation by the materials used to make cardiopulmonary bypass circuits. Typical levels of C3a produced in these procedures ranged from 300 to 2400 ng/mL. These investigations soon associated C3a and C5a production with a group of symptoms known as "postperfusion" or "postpump" syndrome (Table 2.2.4.11). Further analysis showed that complement was activated by the materials in the circuit (such as the polypropylene membranes and the nylon filters), but was also activated during neutralization of the heparin anticoagulant with the protamine sulfate that was given to each patient at the end of the operation. This was further exacerbated by complement activation that occurred in the ischemic vascular bed upon reperfusion of the tissue that also occurred at the end of the procedure. The importance of complement activation, and C5 conversion in particular, to the clinical outcome of CPB patients was clearly demonstrated in a study by Fitch et al. (1999). These investigators showed, using a single chain anti-C5 antibody fragment that inhibited C5a and MAC generation during the procedure, that this antibody fragment

Leukocytosis (increased white blood cell counts)
Organ dysfunction: heart, liver, kidney, brain, and gastrointestinal tract

lowered WBC activation, blood loss, cognitive deficits, and myocardial injury. Subsequent studies demonstrated that this complement inhibitor significantly reduced mortality in higher risk cardiac surgical patients (Haverich et al., 2006). These results are consistent with other studies (Velthuis et al., 1996; Hsu, 2001) using heparin-coated CPB circuits that demonstrate lower inflammatory indices (complement, cytokine, and elastase levels) that are associated with improved clinical outcomes (less blood loss, shorter ICU stays, and lower morbidity).

The CPB experience with heparin-coated devices demonstrates that modification of device materials (or the blood-contacting surfaces of those materials) can dramatically limit complement activation and the subsequent inflammatory response. Based in part on this and similar observations, hemodialyzer/membrane manufacturers began developing new membranes to produce more biocompatible (i.e., less complement-activating) devices. These new membranes tend to fall into two groups: moderately activating modified cellulosics (such as cellulose acetate, hemophane, and cellulose triacetate) and low activating synthetics (such as polyacrylonitrile [AN69], polymethylmethacrylate, and polysulfone). Moderately activating modified cellulosics produce C3a levels and neutropenic responses that are about 50% of Cuprophan levels, while the synthetic materials display 0%–20% activation compared to Cuprophan. Based on the known properties of complement, and the structures of these membranes, the reasons for the improved biocompatibility can be rationalized as follows. Most of these materials have a diminished level of surface nucleophiles. In theory, this should result in lower deposition of C3b, and in fact this has been verified experimentally. The diminished capacity to bind C3b results in lower levels of C3 and C5 convertase activity, and consequently a reduced production of C3a and C5a. Patient exposure to C5a is reduced even further by materials that allow for transport through the membrane to the dialysate (for example, high-flux membranes such as polysulfone will do this) or by absorbing the peptide back onto the surface (the negatively charged AN69 has been shown to have a high capacity for binding cationic C5a). Thus limiting C3b deposition and C5a exposure are two proven mechanisms of avoiding the clinical consequences of complement activation.

The same result can also be accomplished by facilitating the normal control of C3 convertase by factor H. Kazatchkine et al. (1979) have shown that heparin, coupled to either zymosan or Sepharose, limits the normal complement activation that occurs on these surfaces by augmenting C3b inactivation through factors H and I. Presumably, this accounts for the improved biocompatibility of heparin-coated circuits used in CPB described earlier. Mauzac et al. (1985) prepared heparin-like dextran derivatives that are extensively modified with carboxymethyl and benzylamine sulfonate groups. These researchers have shown that these modifications diminish complement activation by the dextran substrate. A simple modification of cellulose membranes (Cuprophan) with maleic anhydride has been shown to limit the complement-activating potential of these materials by over 90% (Johnson et al., 1990). Again, increased binding of factor H to surface-bound C3b appears to account for the improved biocompatibility of maleated cellulose. Wu eta al (2011) discovered peptides that displayed a high affinity for factor H. When these peptides were coupled to a biomaterial, the surface was protected from complement attack. Thus materials that limit complement activation through normal regulatory mechanisms are on hand, and may prove to be the next generation of complement-compatible materials. In addition, pharmaceutical control of complement is now possible with agents that are FDA approved (Alexion's Solaris) or now in clinical development (Ricklin et al., 2017).

Thus materials that limit complement activation through normal regulatory mechanisms are on hand, and may prove to be the next generation of complement-compatible materials. In addition, pharmaceutical control of complement is now possible with agents that are FDA approved (Alexion's Solaris) or now in clinical development (Ricklin et al., 2017).

Summary and Future Directions

The immune response to a biomaterial involves both humoral and cellular components. Activation of the complement cascade by either classical, lectin, or alternative pathways leads to the deposition of C4b and C3b proteins. Recognition of these molecules by receptors on granulocytes can cause activation of these cells, leading to the production of degradative enzymes and destructive oxygen metabolites. Recognition of C4b or C3b by other proteins in the cascade leads to enzyme formation (C3 and C5 convertases), which amplifies the response and can lead to the production of a potent inflammatory mediator, C5a. C5a binds to specific receptors found on polymorphonuclear leukocytes and monocytes. The interaction of C5a with these cells elicits a variety of responses, including hyperadherence, degranulation, superoxide production, chemotaxis, and cytokine production. Systemic exposure to C5a during extracorporeal therapies has been associated with neutropenia and cardiopulmonary manifestations (Tables 2.2.4.10 and 2.2.4.11) that can have pathologic consequences. The other portion of the C5 protein, C5b, leads to the formation of a MAC that activates cells at sublytic levels and has cytotoxic potential if produced in large amounts. The control of these processes is understood well enough to begin designing materials that are more biocompatible. Limiting C3b deposition (nucleophilicity), adsorbing C5a to negatively charged surface groups, and facilitating the role of factors H and I are three approaches that have been shown to be effective. Translating the last mechanism into commercial materials is one of the major challenges facing the development of truly complement-compatible membranes. Pharmacological control of complement activation is also possible with several inhibitors that are either FDA approved or are in late-stage clinical development.

Chapter Questions

1. Identify the typical activators of the (a) classical pathway, (b) lectin pathway, and (c) alternative pathway.
2. Name three approaches to limit complement activation by biomaterials.
3. ISO guidelines suggests two ways to monitor complement activation on blood-contacting materials, what are they?
4. Hemodialysis on complement-activating membranes produces a significant neutropenia within 15 min of initiating therapy. What complement component is responsible for this adverse event?
5. Explain why C3a and C5a levels are higher in serum compared to anticoagulated plasma.
6. Based on surface properties, rank these biomaterials in order of increasing potential to activate complement: Cuprophan hemodialysis (HD) membrane, cellulose triacetate HD membrane, polypropylene oxygenator membrane, nylon apheresis membrane, sulfonated nanomaterials.
7. Omeros is a biotechnology company developing inhibitors to MASP-2 and MASP-3 for the treatment of various pathologies. How would this help control AP activation?
8. During collection of plasma with an apheresis device containing a nylon membrane, both C3a and C5a levels are observed to increase modestly in both the collected plasma and in the blood returned to the donors. Citrate is the standard anticoagulant used in these procedures. Predict what would happen if heparin would be substituted for citrate in this clinical setting.

Answers to questions: 1. (a) Immune complexes, CRP; (b) mannose-containing polysaccharides, ficolins; (c) yeast or bacterial cell walls, biomaterials. 2. Limit surface nucleophiles for C3b attachment, remove C5a by filtration or binding to negatively charged groups, facilitate control by factor H (e.g., heparin coating), or pharmacologically. 3. C3a and SC5b-9 EIA methods. 4. C5a. 5. Thrombin produced during coagulation cleaves both C3 and C5 producing the anaphylatoxins. 6. Cuprophan > nylon membrane > cellulose triacetate > polypropylene oxygenator membrane > sulfonated materials. 7. MASP-3 cleaves profactor D to active factor D in blood, providing this important AP component. MASP-2 indirectly affects AP by activating C1, which forms the CP C3 convertase and produces C3b. C3b can then bind factor B and form the AP C3 convertase in an amplification loop. 8. Much higher levels of C3a and C5a would be produced since citrate partially inhibits complement activation.

2.2.5

Systemic and Immune Toxicity of Implanted Materials

AARON BARCHOWSKY

Department of Environmental and Occupational Health, University of Pittsburgh, Pittsburgh, PA, United States

Local adverse pathological effects, as well as distal organ and organ system effects, can result from absorption and distribution of materials leached from implanted devices and implant-associated compounds (e.g., cements and adhesives). Medical implants are composed of a large range of materials, including metals, metallic alloys, polymers, ceramics, hydrogels, and composites. In addition, the implants are often fixed into tissues with glues or cements that contain additional, potentially toxic compounds. Before they are clinically and commercially viable, all materials, devices, and degradation by-products must meet regulatory standards for biocompatibility and be proven to be nontoxic.

International and national regulatory agencies define biocompatibility for any sterile or nonsterile device that comes into direct or indirect contact with the human body as the potential for unacceptable adverse biological responses resulting from the contact. Biocompatibility endpoints that could be impacted by the materials in, on, or from an implanted device include cytotoxicity, sensitization, irritation or intracutaneous reactivity, acute, subchronic, and chronic systemic toxicity, material-mediated pyrogenicity, genotoxicity, hemocompatibility (hemolysis, complement activation, thrombosis), carcinogenicity, reproductive or developmental toxicity, and biodegradation (for absorbable materials). However, the expected duration of device contact and its expected permanence dictate which toxic endpoints might be expected and need to be confirmed not to occur. ISO 10993-1 guidelines triage toxicity testing by categorizing contact duration into three categories: limited (i.e., <24 h), prolonged (i.e., >24 h to 30 days), or permanent/long term (i.e., >30 days). Thus a device that is used for less than 30 days would not need to be tested for carcinogenicity and devices implanted in adults beyond developmental or reproductive age would not need to be tested for developmental and reproductive toxicity.

The fundamental principle of toxicology is that the dose makes the poison. The implication for implanted medical devices and associated materials is that, whether they are designed to deliver bioactive compounds, degrade over time, or remain in place for a prolonged time or permanently, the materials they are made of must never be in a toxic concentration at the point of contact or be released from the device in a toxic concentration. This chapter will not discuss potential toxicities from drug delivery devices, but will discuss toxicities from materials released from implanted devices that are designed to degrade after providing benefit or that are permanently implanted. With the exception of pathologic calcification of certain polymer implants, the surface changes may not be significant for degrading the mechanical strength or intended use of the implant. However, the substances released have potential for biological incompatibilities in surrounding tissues and systemically in remote organs and in the immune system. The following discussion focuses on systemic toxic or hypersensitivity reactions caused by device-derived metals, chemicals, and composites.

Basic Principles of Systemic Distribution and Toxicity of Biomaterial Constituents

Conventionally, the major routes of exposure for toxic substances are the gastrointestinal tract (ingestion), the lungs (inhalation), and the skin (topical, percutaneous, or dermal). In contrast, exposure to the elemental and chemical constituents of implanted biomaterials results from absorption into local tissue and distribution systemically by blood and lymph vessels. Similar to conventional exposures, the elements and chemicals have to cross cell membranes and tissue layers for distribution through the body, for metabolism to either more toxic or less toxic compounds, and ultimately for excretion into urine, feces, sweat, hair, and nails. These are the basic kinetic principles of absorption, distribution, metabolism, and elimination for biological actions of device materials. Biomaterials would not be toxic if they were not absorbed or distributed to a target organ

in sufficient concentrations to elicit an adverse biological response. Nor would they be toxic if they were not metabolized to a more potent toxicant or eliminated rapidly enough to keep concentrations below toxic thresholds.

Simple diffusion of chemicals into surrounding tissues is possible, but is often limited by the chemical and physical properties of the released constituents. Small lipophilic chemicals readily cross the lipid bilayers of cells, but have limited solubility in the aqueous media of blood or lymph. In contrast, particulates, metals, and other charged molecules are not soluble in membranes and have limited access to cells. In both cases, distribution in aqueous media or across cell and organelle membranes is facilitated by binding to protein carriers, by transmembrane uptake mechanisms, or by channel proteins. Binding to serum proteins and lipid particles, especially albumin, globulins, and lipoproteins, allows systemic distribution of metals and lipophilic compounds in the blood and lymphatic system. Only the unbound or "free" fraction of the metals or chemicals is available for uptake into target cells and biological actions. In fact, many "free" endogenous and device-derived metal ions are toxic and it is extremely rare that metals have appreciable "free" fractions in the circulation or in cells, as they are chaperoned by carrier proteins and transported by relatively specific ion channels. As a defense mechanism that supplements elimination, metals or chemicals are stored away from biologic action by being deposited in bone, adipose tissues, and specialized storage proteins (e.g., metallothionein and ferritins). However, this deposition can ultimately be detrimental as the metal or chemical can have local effects in the deposits (e.g., stimulation of osteolysis in bone) or be a source of low-level chronic exposure (e.g., lead in bone, organic carcinogens in adipose tissues).

The blood and lymph flow in different tissues and organs varies greatly, which results in differences in both degradation pressure on the device and the volume of degradation by-products distributed away from the device. Physical or wear pressure can be substantial and result in catastrophic device failure with the release of both small and large particulate matter. There is a significant concern that distribution of large particles will cause life-threatening physical hazards of clogging capillaries or small blood vessels, especially in the lung (pulmonary embolism) and brain (stroke). However, it is more likely that due to their size or insolubility they will cause only local inflammation, foreign body reactions, and tissue necrosis. Small micron and submicron particulate matter can distribute systemically and be engulfed by cells through phagocytosis and endosomal processing. Lysosomal processing of the particles can liberate metal and chemical constituents within the cells if they are not eliminated through vesical release or secreted through channels.

The range of constituents and contaminants in biomaterials is immense given that devices are made from multiple classes of elements, alloys, chemicals, and composites. In turn, possible contaminants also include residual monomers, chemical initiators, plasticizers, antioxidants, bonding agents, and cements. Released constituents are subject to further metabolic oxidation, reduction, hydrolysis, and conjugation reactions as the body attempts to utilize, detoxify, and eliminate the foreign compound. In general, highly lipophilic chemicals are oxidized by Phase I metabolizing enzymes (e.g., cytochrome p450 enzymes) to make them more reactive and soluble. The reactive metabolite can cause toxicity by covalently binding to proteins and nucleic acids (i.e., genotoxic). However, the reactive metabolite is more often reduced and conjugated by Phase II metabolism to produce aqueous soluble compounds for elimination. Reactive metabolites are generally not toxic unless they reach concentrations sufficient to overwhelm the Phase II metabolism. Even metals can be metabolized and most commonly are oxidized or reduced to form more or less reactive species. Ion channels that transport metals across cell membranes are highly charge specific and changing the charge or valence of the metal greatly affects cellular uptake and responses. Chromium is a prime example, as toxic hexavalent chromium(VI) is readily taken into the cell through sulfate and phosphate channels, while oxidation to chromium(III) creates an octahedral cation that does not cross the membrane (Standeven and Wetterhahn, 1989). Thus chromium(VI) is toxic and chromium(III) is relatively inert and nontoxic.

The key kinetic question is whether there is sufficient reactivity to implant constituents at point of contact to cause local toxicity or sufficient release of constituents to allow concentration-dependent toxic actions or immune responses in distal organs. Acute tissue injury and cell death are generally caused by much higher concentrations than morbidities or disease caused by chronic, low-level exposures. Carcinogenicity, for example, is generally promoted by low chronic levels of metals (e.g., chromium or tungsten), and it is more difficult to test for carcinogenicity given that there may be a latency period of years, even after removal of a device, before cancers appear. Acute release of constituents due to excessive wear or catastrophic device failure is the most common source of local and systemic toxicities.

Rapid degradation can result in physical tissue damage from acid/base reactions (e.g., metal oxides acting as Lewis acids) or creation of pockets of liberated gases. For example, in physiological medium, acute degradation of magnesium (Mg)-based degradable implants can release Mg^{2+} in sufficient quantities to release hydrogen to create gas pockets as the Mg reacts with water to form $Mg(OH)_2$. In turn, physiologic levels of chloride results in the formation of $MgCl_2$ from the $Mg(OH)_2$, and in the process releases hydroxide ions that increase local pH (Kamrani and Fleck, 2019).

Release of large amounts of metals and chemicals that are similar to essential metals or endogenous compounds can produce systemic injuries by mimicking or displacing the essential metals (e.g., nickel or cobalt inhibition of cardiac calcium channels, manganese toxicity in neural tissue) or creating tissue damage in metabolizing organs (e.g., liver toxicity). Chronic low-level release can affect cell-signaling pathways that regulate distal organ metabolism or function (e.g., chronic acrylamide and other type-2 alkene inhibitions of presynaptic membrane proteins in neurotransmission). Chronic low levels of certain metals (e.g., cobalt) and organic

compounds (e.g., plasticizers, bisphenol A, phthalates, acrylamide) disrupt endocrine systems to cause systemic metabolic and reproductive toxicities. Thus complete testing for biocompatibility must address both possible tissue damage in target organs (e.g., histological assessment of pathology) and markers of target organ or homeostatic dysfunction (e.g., abnormal heart function, neurological disturbance, disturbed motor function, reproductive effects, and abnormal blood metabolite levels). The ISO 10993-1 (ISO, 2018) guidelines provide a risk assessment and triage system to identify which types of toxicity testing must be done based on the nature, organ placement, and duration of the implanted device. Standardized toxicity testing for regulatory approval of materials and devices should be performed using the internationally accepted guidelines and is facilitated by focusing on regulatory agency recommendations (e.g., FDA, 2019a).

Metals and Metal Alloy Toxicity

Metals comprise a substantial portion of medical implant materials and pose unique systemic toxicities relative to organic chemical constituents. The US Food and Drug Administration (FDA) Center for Devices and Radiological Health recently released a comprehensive review of biological responses to metal implants (FDA, 2019a). This was the result of extensive postmarket reviews of data associated with specific metal-containing implants after safety concerns were raised for metal-on-metal (MoM) or metal-on-polyethylene total hip arthroplasty systems, as well as metal-based intrauterine devices. In addition to being concerned with metal wear debris being associated with local pseudotumors and aseptic loosening of the prosthesis with subsequent need for revision, the review was concerned with broad systemic effects and symptoms that reflect susceptibility of recipient immune systems to metals in and from the devices.

The most common metals used in durable implants are stainless steel (iron-based alloys), cobalt-based alloys, chromium alloys, pure titanium, and nickel–titanium-based alloys. Various refractory metals (metals that are difficult to fuse or corrode), such as molybdenum, tungsten, vanadium, and tantalum, have also been used as alloying elements in implantation materials. Noble metals, such as gold, silver, platinum, and iridium, are common in implants with electronic components. Recently developed implants designed to degrade after they provide benefit are primarily based on pure magnesium, or magnesium and/or zinc alloys containing alkaline and rare earth metals (e.g., strontium, yttrium, lanthanides, etc.) (see Chapter 1.3.3D).

Many metals used in implants are "essential" metals that in appropriate amounts are critical to the structure and function of numerous human proteins and enzymes. For example, zinc is the second most abundant transition metal in the body (iron is the first) and is essential in 100–300 enzymatic reactions. Magnesium is the fourth most abundant element in the body and the second most abundant intracellular cation. However, when in an excess free concentration or in an inappropriate oxidation or valence state, these essential metals become toxic. Free metal concentrations and their access to intracellular compartments and proteins is tightly controlled by chaperoning proteins, transport proteins, and ion channels. For example, there are over 30 highly conserved transporters and channels that maintain functional zinc levels. Toxicity to zinc will occur when these transport and chaperone systems fail or are overwhelmed, leading to neurologic disorders (e.g., ataxia, lethargy), impaired absorption of other essential metals, and tissue destruction from high zinc oxide levels that act as a strong Lewis acid. Displacement of or competition for zinc by other metals in these channels and enzymes can result in potentially toxic-free zinc concentrations or toxicity from loss of zinc-dependent function.

The metal transporters can also provide the beneficial effects of the essential metals. An example would be the TRPM7 ion channel that, in addition to transporting magnesium, zinc, and calcium into cells, can act as a signaling enzyme and epigenetic regulator of DNA changes (Wrighton, 2014; Krapivinsky et al., 2014). In this manner, magnesium transport through and activation of the channel stimulates angiogenesis and cell motility that promotes wound healing. However, excess activity of the channel can provide growth advantages to dysplastic tissues and cancers (Trapani et al., 2013).

Table 2.2.5.1 lists essential metals used in medical devices and their potential systemic toxicities. The systemic toxicities of cobalt (Co) illustrate the concerns in evaluating systemic toxicity from metals, as well as potential mechanisms for metal-promoted toxicity. MoM or metal-on-polyethylene articulated implants represent the most prevalent nondietary and nonoccupational exposures to Co in the general population, with millions of articulations being implanted (Leyssens et al., 2017; Reich et al., 2019). Cobalt in trace amounts is an essential cofactor for vitamin B12 and lack of cobalt causes vitamin B12 deficiency. However, when cobalt levels rise above 300 μg/L in the blood of normal individuals, a syndrome of systemic toxicities, known as "arthroprosthetic cobaltism" syndrome, occurs (Leyssens et al., 2017). The blood levels needed to trigger the syndrome can be much less in susceptible individuals (FDA, 2019a; Leyssens et al., 2017; Reich et al., 2019). Co–chromium (Cr) is a common alloy for MoM implants due to resistance to corrosion and wear. Unfortunately, nanosized wear particles of CoCr can be liberated from the MoM implant. Although modern MoM implants are highly resistant to wear, particle release can be substantial in patients who received an MoM implant to replace a failed ceramic implant (i.e., more debris to grind the MoM implant), in patients with mixed manufacturers of MoM implants, and in poor placement or bilateral hip replacements (Leyssens et al., 2017; FDA, 2019a). Studies of periprosthetic tissues find insoluble Cr^{3+}-containing nanoparticles, but the highly soluble Co^{2+} ions bind to synovial fluid proteins and adjacent tissue surfaces and are distributed in peripheral blood and lymph. There is a consensus that blood levels of 10 μg/L or less indicate normal implant wear and are not of concern. However, again this may not be protective of susceptible patients (Reich et al., 2019; Leyssens et al., 2017).

Ionized Co^{2+} is the primary toxic form for systemic toxicity and the free fraction of Co^{2+} ions is bioavailable for interaction with ion channels and cellular targets (Madl et al., 2015).

TABLE 2.2.5.1 Common Essential Metals in Implants (FDA, 2019a)

Metal	Major Physiological Roles of Proteins Utilizing the Metal	Potential Toxicities of Excess Metal
Chromium	Glucose metabolism/tolerance Lipid metabolism	Cr^{3+} • Potential liver issues • Potential kidney issues Cr^{6+} • Respiratory symptoms • Dermatitis/ulcerations • Gastrointestinal (GI) symptoms • Lung cancer
Cobalt	Metabolism of purines/pyrimidines amino acids, fatty acids, folate	Allergic contact dermatitis Cardiomyopathy Cardiac electrical abnormalities Polycythemia Neuropathy Altered thyroid function
Copper	Collagen cross-linking Bone formation Iron metabolism Hemostasis/thrombosis Neurotransmitter synthesis Free radical control	GI symptoms Hemolysis Cardiac failure Renal failure Hepatic dysfunction Alzheimer's Disease
Iron	Oxygen transport Oxygen storage DNA synthesis/repair RNA transcription Synthesis of collagen, neurotransmitters Energy metabolism Immune function	Free radical generation GI symptoms (acute) Hemochromatosis • Cardiomyopathy • Cirrhosis • Diabetes • Arthritis
Magnesium	Mitochondrial respiration Bone structure Vitamin D metabolism	GI symptoms (acute) Cardiac electrical abnormalities Neurotoxicity Local generation of H_2 and hydroxide (high pH)
Manganese	Metabolism of carbohydrates, lipids Neurotransmitter synthesis Bone/cartilage formation Urea metabolism Control of free radicals	Headache Psychiatric symptoms GI symptoms Parkinson's-like signs/symptoms
Molybdenum	Metabolism of amino acids Metabolism of purine/nucleotides, uric acid Metabolism of drugs/prodrugs Metabolism of neurotransmitters	Elevated uric acid/gout Secondary copper deficiency Reduced testosterone
Zinc	Protein and carbohydrate metabolism Immune function Wound healing DNA synthesis and repair Control of free radicals Stabilization of protein structure Intracellular signaling	GI symptoms (acute) Copper deficiency Myeloneuropathy
Vanadium	Phosphate metabolism Insulin enhancement Lipid metabolism	GI symptoms Headache Weakness Tremor

A shift in the distribution of free versus bound cobalt toward a larger portion of free Co^{2+} ions can occur in various disease states, such as renal failure, iron deficiency, sepsis, malnutrition, alcoholism, or in response to certain medications. This may be why individual patients present with toxic responses at a much lower total blood concentration. At the molecular level, high levels of Co^{2+} ions elicit pathological responses by generating reactive oxygen species (ROS), causing lipid peroxidation, interrupted mitochondrial respiration, and altered calcium and iron homeostasis (Madl et al., 2015; Leyssens

et al., 2017). They can also trigger erythropoiesis, interrupt thyroid iodine uptake (goiterogenic), promote genotoxicity, and possibly impair DNA repair processes (Madl et al., 2015; Leyssens et al., 2017). The generation of ROS and lipid peroxides is worth noting as it occurs by catalyzing the Fenton reaction that is common to all metal cations that can undergo sequential two-electron reduction. Unpaired electrons are donated to oxygen or lipids to create protein and nucleic acid damaging free radical species.

Systemic Co or other MoM constituent toxicities are infrequent; however, the syndrome once elicited includes variable presentation of neurological, cardiovascular, immunological, and endocrine symptoms, depending on the systemic cobalt levels found in the blood or urine (Leyssens et al., 2017; Pacheco, 2019; Reich et al., 2019). Many endpoints that progress over the years with permanent implants reverse once the failing implant is replaced with one of a more compatible composition. This suggests that the device constituents cause the toxicities.

Co-related neurotoxicity can cause central and peripheral deficits with loss of hearing, balance, cognitive function, and sensory motor performance (Leyssens et al., 2017). Cardiovascular myopathies caused by Co have long been recognized and include both cardiac rhythm disturbances and destruction of cardiac tissues (Leyssens et al., 2017). These symptoms occur when free levels of Co in the heart tissue are very high and might be exacerbated by alcohol consumption or malnutrition (Barceloux, 1999). Unfortunately, injured cardiac tissue does not repair, although rhythm disturbances have reversed (Leyssens et al., 2017; Reich et al., 2019). Increased red blood cell counts (polycythemia) and hemoglobin levels are rare markers of systemic Co toxicity, and are reversible (Leyssens et al., 2017). Co interference with iodide uptake and synthesis of thyroid hormone (hypothyroidism) can have wide-ranging metabolic and cardiovascular effects, as well as affect homeostasis of other essential metals (e.g., calcium and iron) (Leyssens et al., 2017; Reich et al., 2019).

Immune responses can manifest as rheumatoid symptoms of muscle (polymyalgia) and joint (polyarthralgia) pain, low-grade fevers, dermatological rashes, and sensitization (Reich et al., 2019). Immune responses are also highly associated with implant loosening or failure, and a majority of individuals with failed prosthesis test positive in skin patch testing for metal sensitization or allergies (Pacheco, 2019). Fortunately, there is insufficient evidence from multiple large-scale patient studies to implicate MoM implants in increasing the overall risk of cancers (FDA, 2019a; Leyssens et al., 2017).

Table 2.2.5.2 presents metals used in medical devices that are not essential for human health, and may produce pathological responses in humans. It is important to note that most of the adverse effects have been investigated in therapeutic or occupational exposures other than from implants where concentrations may be higher (FDA, 2019a). A general principle is that nonessential metals have biological effects by mimicking or displacing essential metals. The ability to mimic or displace essential metals depends on the physical properties and valence of the nonessential metal. The immune system often recognizes nonessential metals as foreign, which is the basis for common delayed hypersensitivity reactions elicited by the metals (e.g., nickel allergy). Patch testing for metal sensitivity is a useful means of identifying sensitive individuals and determining which metal alloy might be biocompatible in their implant (Pacheco, 2019).

Mercury is a nonessential metal released from dental amalgams, and has long created public concern with health impacts to patients and practitioners. The European Commission (2014) and its Scientific Committee of Emerging and Newly Identified Health Risks, as well as the US FDA in a systematic review (FDA, 2019b), investigated possible adverse

TABLE 2.2.5.2 Common Nonessential Metals in Implants (FDA, 2019a)

Metal	Potential Adverse Effects
Aluminum	Osteomalacia Hepatic dysfunction Anemia Dialysis encephalopathy (dementia, myoclonus) Weak association with Alzheimer's Disease
Gold	Bone marrow suppression Dermatitis Glomerulonephritis Vasculitis Hepatotoxicity Neuropathy
Iridium	Some salts may cause allergic reactions
Mercury	Neurotoxicity Neuropathy Renal toxicities
Nickel	Delayed hypersensitivity Acute: Gastrointestinal (GI) symptoms, headache, vertigo, vision changes Chronic: • Altered iron metabolism • Cardiovascular, respiratory or kidney disease • Alteration in hemostasis of calcium, magnesium, manganese, zinc
Palladium	Lip edema Itching Respiratory symptoms
Platinum	Certain platinum-containing compounds may cause respiratory symptoms, including kidney toxicity, hearing loss, bone marrow damage
Silver	Local argyria (blue-gray skin or organ discoloration)
Tin	Acute: GI symptoms, headache Altered metabolism of zinc, iron, copper Cholesterol metabolism
Titanium	Suppression of osteogenic differentiation Yellow nail syndrome
Tungsten	Certain compounds may antagonize molybdenum Immune suppression Enhances cobalt toxicity

effects of mercury-containing dental amalgams on neurological, renal, immunological, psychological, reproductive, and other potential systemic toxicities. Both agencies concluded that patients' blood mercury levels can be significantly elevated depending on the number of amalgam fillings, but that there is little epidemiological evidence to show that the levels of mercury released are sufficient to increase the risk of adverse effects or systemic diseases. The dose makes the poison.

Hypersensitivity and Immunotoxicity

While it is clear that the dose makes the poison, almost all foreign compounds and even essential metals can elicit a memory of exposure with acquired hypersensitivity or allergic reactions in susceptible individuals. Innate immune or inflammatory responses are an essential part of wound healing with potentials to become pathological foreign body reactions. This is critical to acute acceptance of the implant, but an excessive foreign body immune response can include local osteolysis, necrosis, pseudotumor formation, tissue granulation (e.g., giant cell formation), and fibrous capsule contractions. Immediately following implantation, host protein adsorption to the implant surface initiates the local inflammatory response. Injury to host tissues is rapidly followed by activation of coagulation and complement pathways and adsorption of proteins to the implant surface to form an encapsulating matrix of stress and structural proteins. This phase is followed by phagocytic and immune cell recruitment designed to eliminate or seal the offending material away from the body. However, if prolonged, normal surrounding tissues are injured and the device may be subject to degradation and liberation of more offending materials. In general, metal, plastic, or composite implants produce rapid inflammation and innate immune responses that resolve/heal within 1 to 2 weeks following implantation. This resolution is critical to limiting tissue pathology and precluding subsequent implant failure. Thus selection of materials for implants and manufacturing processes must be tested in advance for eliciting the foreign body reactions to ensure compatibility with normal wound healing and resolution to limit device failure. Procedures for premarket testing of hypersensitivity and immune responses to implanted materials are outlined in ISO 10993-20:2006 Biological evaluation of medical devices—Part 20: Principles and methods for immunotoxicology testing of medical devices (ISO, 2006).

Debris and wear particles taken into phagocytic cells can elicit inflammatory responses that produce systemic responses, such as aseptic low-grade fever or systemic histamine release. Current understanding of the mechanisms involved in the inflammatory and innate immune responses to metal and implant particles has been reviewed in the recent FDA white paper on Biological Responses to Metal Implants (FDA, 2019a). In brief, pattern recognition receptors in the innate immune cells, as well as contacted tissues, recognize particles as foreign and elicit release of inflammatory cytokines to recruit more inflammatory cells and responses to eliminate the particles. If persistent, this process may enhance local tissue destruction and device failure.

Acquired immune or delayed hypersensitivity responses or allergies require exposure to a foreign substance, but the response becomes disproportionate to the level of exposure through amplification of lymphocytes bearing antibodies that target the foreign substance. The response requires uptake and processing of nonself antigens by antigen-presenting cells to initiate cell-mediated and humoral responses by T and B lymphocytes, respectively. The most important allergens based on the large volumes of procedures are metals (e.g., nickel, cobalt, and chromium) and constituents of bone cement in orthopedic and dental implants. Metal allergies are among the most common contact hypersensitivities with nickel allergies being prevalent in approximately 40% of the general population. While there is concern with nickel-containing cardiovascular, neurological, and reproductive devices causing systemic delayed hypersensitivity reactions, there is a large amount of controversy regarding causative relationships between allergic reactions and adverse outcomes from metal implants (FDA, 2019a; Pacheco, 2019). The incidences of acquired immune and hypersensitivity reactions to surgical implants are relatively rare, since, in addition to exposure, the implant recipient must be genetically susceptible and the metals and cement constituents must form complexes with larger protein structures (i.e., hapten formation) to be recognized as allergens. Once the initial antibody-generating response occurs, however, the metal or small molecule itself can elicit a full systemic allergic reaction. Thus an individual who has sensitivity to nickel or cobalt due an exposure prior to receiving the implant might have a large allergic reaction to modest amounts of metal released from the implant. There are suggestions that patients be tested for allergies to device constituents prior to implantation to reduce the risk of hypersensitivity reactions or device failures (Pacheco, 2019; FDA, 2019a). However, this is complicated by the fact that not all those who test positive for allergies will have an immune response sufficient to require replacement (FDA, 2019a).

Delayed hypersensitivity or allergic reactions are categorized in four major types (Types I–IV) based on the formation of humoral antibodies initiated by B cells (Types I–III) or cell-mediated reactions caused by T lymphocytes (Type IV). Types II and III allergies comprise antigen–antibody encounters that include complement activation, cell lysis, release of vasoactive substances, inflammatory reaction, and tissue damage. However, they are very rare with surgical implants. Instead, Type I B cell and Type IV T cell reactions are the more important responses to consider.

The Type I reaction is based on an interaction between antigens and B cell-derived IgE and IgM immunoglobulins located on mast cells, basophils, eosinophils, and platelets. Antigen binding to IgE or IgM antibodies stimulates release of inflammatory mediators, such as histamine, prostaglandins, and other vasoactive substances within a short timeframe (e.g., minutes to hours). Again, these processes are part of the normal wound repair response. However, in pathological metal hip implant failures, elevated levels of B cells are consistently found in the tissues adjacent to MoM total hip replacement, and B cells isolated from patients

with metal implants activate in response to stimulation with metals (FDA, 2019a; Pacheco, 2019). While antibodies to haptenized metal ions are also found in patients with stable cobalt–chromium or metal composite implants, there is a much higher incidence of patients with failed implants who have high antibody titers (Pacheco, 2019).

Type IV T cell-mediated hypersensitivity is referred to as delayed, since it requires more than 12 h and sometimes days to develop. The T cells initiating the response must be sensitized by prior encounter with the allergen to produce T cell recognition receptors. Activation occurs from cognate interaction between the T cell receptors and antigenic peptide (hapten) embedded in major histocompatibility proteins found on the surface of antigen-presenting cells. The interaction elicits release of inflammatory mediators, cytokines, and cytotoxic agents that cause tissue damage, as well as further production and attraction of T cells. The responses become systemic and the time delay involves cell expansion and recruitment of associated lymphocytes, macrophages, and mononuclear phagocytes. The predominance of lymphocytes in implant-associated ectopic lymphoid structures led to the categorization of these adverse cell-mediated responses as aseptic lymphocytic vasculitis-associated lesions (FDA, 2019a; Pacheco, 2019; Willert et al., 2005). While the prevalence of this reaction is low, the persistence or early reappearance of symptoms, including a marked joint effusion and the development of osteolysis, after primary implantation suggests that these reactions are a real concern (Willert et al., 2005; FDA, 2019a). Again, as the Type IV response requires prior exposure to the antigen or hapten formation, patient risk can be mitigated by screening for allergic reactions prior to device implantation. A large number of device and device cement constituents have been recognized as possible allergens and have been suggested to be included in dermal patch testing (Pacheco, 2019).

Organ Localization of Inflammatory and Immune Responses to Device Materials

Localized and tissue-specific responses to devices and device materials can inform the pathological pathways through which the materials, devices, and host responses interact. However, it is often difficult to prove there is an immune component to device failure or toxicity. Common symptoms of failure include pain, swelling, warmth, decreased range of motion, loosening or instability, and sometimes itching or burning. Dermatitis over the surgical site is a well-recognized indication of hypersensitivity to an implant, but this rarely occurs. It is important to note that these systemic toxicities may take years or even decades to develop and the implanted device is often not recognized as the source of a given adverse organ response by physicians treating the pathologic symptoms (Reich et al., 2019). Overall, the local tissue response may dictate the local and systemic effects of the implanted materials.

As orthopedic devices have largely been discussed, it is important to note the local, bone-specific effects of immune responses to these devices. Aseptic loosening and instability can be triggered by local inflammatory responses caused by sensitization to metal or bone cement components, cement failure, or poor bone formation. Periprosthetic osteolysis (bone loss) may lead to loosening of the device, causing pain and possibly failure. Osteoclasts promote bone resorption, and the balance of osteoclastogenesis and osteogenesis by osteoblasts is a dynamic process that integrates inflammatory, metabolic, and immune inputs for maintenance of skeletal integrity. Osteoclasts couple production of proinflammatory cytokines and chemokines to corrosive oxidation and uptake of metal particulates that can promote delayed hypersensitivity. Implant metals and materials can be selected that suppress osteoclast inflammatory responses (e.g., gold and zinc) or are osteogenic (e.g., magnesium or calcium phosphate bone cements) (FDA, 2019a). According to the FDA, metal ions released by oxidative metal corrosion may not trigger osteolysis, but may instead serve as critical amplifiers of inflammatory pathways that contribute to osteoclastogenic development, programming of osteoclastic functions, and crosstalk with other immune and inflammatory mediators. Targeted inhibitors of osteoclastogenesis are under investigation for a variety of osteolytic disorders, including osteolysis associated with prosthetics (FDA, 2019a).

Neurological devices present a number of organ-specific challenges and toxicities. The large number of responsive cell types and structures in the brain and neural tissue are potential targets of implants and their materials. There are case reports of reactions to neurostimulators that include localized burning and itching and generation of rashes near implantation sites (FDA, 2019a; Pacheco, 2019). Nickel–titanium (Nitinol) has been used in a number of neurological applications, and adverse outcomes have occurred in nickel allergic patients. Triggering of oxidative responses in brain microglia may liberate nickel ions that can be disruptive to ion signaling, as well as being immunogenic (FDA, 2019a). These potentially toxic pathways are not restricted to neuronal tissues, but implantation in neural tissue results in unique toxicities in the anatomical compartment.

Due to their interface with blood, complications and adverse events associated with metallic cardiac and vascular implants result from coagulation cascade activation and thrombus formation. The endothelial cells lining blood vessels are sensitive to metals and their injury results in platelet activation, as well as recruitment of circulating leukocytes. Loss of endothelial function, increased leukocyte deposition, and stimulation of underlying smooth muscle hyperplasia result in stent failure and vessel restenosis. Thus effects of materials on the cells of the vessel walls should be tested in addition to testing materials for thrombogenicity. The proximity to the circulation also enhances occurrence of systemic effects from cardiovascular devices. There are reports of nickel allergies and dermal reaction being elicited by peripheral Nitinol stent failure (Pacheco, 2019). Cardiac and neurostimulators present a number of potential sensitization hazards as they are composed of many metal alloys, plastics,

resins, and glues. In addition to the structural metals, metals in wire leads also pose hazards that have been associated with local as well as systemic sensitization and immune responses (Pacheco, 2019). In most cases, symptoms resolve when the offending device is removed, which implicates aseptic responses to the device materials as the cause.

Summary and Conclusions

Failure of medical implants due to systemic toxicities and/or pathogenic immunological responses is relatively rare based on the low rate of adverse events found with the tens of millions of medical implantations performed globally (e.g., orthopedic, dental, neurological, cardiovascular implants). The low rates of toxicity and failures due to biological incompatibility are testaments to the rigorous premarket testing and postmarket reviews for biocompatibility of all implanted materials and devices. This testing follows international (e.g., ISO 10993) and national (e.g., FDA) standards and guidelines that outline cell-based and animal testing that must be performed to ensure the safety of implanted devices and their complex list of metal and chemical constituents. Testing for both implantation site and systemic toxicities has greatly reduced, but has not eliminated, risks of adverse effects and device failures. The main concern is the dose of potentially toxic materials that are released locally and available for distribution to distant organs, which might be particularly sensitive to the toxic effects of the materials (i.e., systemic toxicities). In addition, given the nature of delayed or acquired immune responses, clinicians need to be vigilant not to implant an offending material in a susceptible individual, or should change the implant to a more compatible material when adverse immune responses arise. It is also important to consider not just the materials contained in a device, but also all of the materials involved in implanting devices, since adhesives, cements, and surgical materials can pose toxic risks. The intent of this overview is to increase student awareness of the potential hazards from implanted device constituents and incorporation of biocompatibility considerations in biomaterials and device systems design.

CASE STUDY: SYSTEMIC AND IMMUNE TOXICITY OF IMPLANTED MATERIALS

What Problem was Addressed?

Failure of medical implants due to systemic toxicities and/or pathogenic immunological responses to the metals and chemicals associated with the implants are relatively rare. However, they can be highly significant, debilitating, and life threatening for individual patients. An example is the case of a 45-year-old woman who had chronic systemic metal ion toxicity from wear on a revised cobalt–chromium trunnion (Reich et al., 2019). She had received total hip arthroplasty at age 22 and then revision surgery 11 years later due to developing acetabular osteolysis. Two years after the revision surgery, she developed a constellation of medical symptoms, including polymyalgia, polyarthralgia, oral ulcers, body aches, headaches, intermittent low-grade fevers, fatigue, and a malar rash. She had a family history of rheumatoid arthritis, Hashimoto's thyroiditis, and Grave's disease. She sought treatment from her primary physician and a rheumatologist. In addition, she saw a cardiologist for lightheadedness and syncope, and her tilt-table test was positive. She was diagnosed with systemic lupus erythematosus, mixed connective tissue disease, fibromyalgia, and postural orthostatic tachycardia syndrome (POTS). Despite drug treatments, her symptoms remained after 8 years (10 years after revision), and she had developed intermittent, disseminated, and pruritic facial, hand, and arm rash, as well as nondermatomal paresthesia in her upper and lower extremities and "brain fog." Extensive testing did not reveal the cause of her symptoms, but upon returning to her orthopedic surgeon for joint pain 12 years after revision, she was diagnosed with cobalt ion toxicity. She received a second revision, and the cobalt–chromium components were replaced with a titanium alloy stem and ceramic femoral head. Within 6 months, her cognitive abilities improved, and 15 months later, her POTS and dermatological symptoms resolved. However, while improved, not all systemic symptoms disappeared (Reich et al., 2019).

What Properties were Required of the Biomaterials?

The low rates of toxicity to implant materials and failures due to biological incompatibility were testament to rigorous premarket testing and postmarket reviews for biocompatibility of all implanted materials and devices. This testing follows international (e.g., ISO 10993) and national (e.g., FDA) standards and testing guidelines that outline cell-based and animal testing that must be performed to ensure the safety of implanted devices and their complex list of metal and chemical constituents. Testing for both implantation site and systemic toxicities has greatly reduced, but has not eliminated, risks of adverse effects and device failures. The main concern is the dose of potentially toxic materials that are released locally and available for distribution to distant organs, which might be particularly sensitive to the toxic effects of the materials. Despite a strong safety record with the materials, this woman's case illustrates complications that might arise in susceptible individuals and that were enhanced by the selection of materials used in the original surgery and her revisions. Her family history and early need for replacement may have indicated that she would be susceptible. The mixed materials in her first revision increased wear debris from the trunnion. The long timeline for symptom development and misdiagnoses suggest the need for increased awareness of potential systemic toxic syndromes that might result from implant constituents, even when low levels of constituent metal ions are found in the blood.

What Approach and Biomaterials Could Be Used?

Diligent premarket testing for biocompatibility and implant material safety is essential to reduce risks of systemic pathologies and local device failures. ISO 10993-1 guidelines should be consulted for assessing the risks that should be addressed with toxicity testing appropriate to the device application. ISO 10993-20 guidelines specifically address tests for immunotoxicity. However, in the clinic, care should be taken when mixing manufacturers' components, since mixed components, as in revision of some but not all of the prostheses, may increase risk of generating wear debris or introducing chemical interactions that were not tested by the individual manufacturers. Also at the clinical level, care should be taken to identify patients who are susceptible to toxicities and to select materials that are compatible with the individual.

Chapter Exercises

1. You are developing magnesium alloy-based orthopedic plates and screws designed to support healing of a bone fracture, which then degrades. This avoids the need for a second surgery to remove the plates and screws. The plates need to retain structural integrity for 6 weeks and then degrade over another 6 weeks to a year. What local and systemic toxicity testing would be required by the regulatory agencies to approve the safety of the magnesium alloy implants? What rationale would allow you to eliminate certain toxicity tests (e.g., carcinogenesis, reproductive toxicity) and provide patient selection recommendations instead?
   Answer: Dissolution rate and cytotoxic dose response to local cell types; histological evaluation of local site for osteolysis/osteogenesis and gas pocket formation; blood ion level disturbance; histological evaluation of brain, liver, heart, and kidney tissues; immunological testing if alloy contains an allergenic metal or metal of unknown allergenicity; carcinogenesis if the alloy contains a potentially carcinogenic metal or metal of unknown carcinogenesis; etc.

   The alloy would not need to be tested for carcinogenesis if it does not contain any potential carcinogenic metals. However, magnesium can promote tumor growth and a recommendation for concern with implanting the device in a cancer patient might be made. Magnesium is beneficial in pregnancy and development. However, if the alloy contains a metal with known reproductive effects, a recommendation might be made to avoid implantation in pregnant women. This is of course relevant to those who would still be pregnant when the device degrades.
2. You have optimized the design and manufacturing process for a novel trunnion for total hip arthroplasty, and have been highly diligent in testing for potential toxicities. The FDA gives approval for its use and you want to maintain an impeccable safety record to grow sales. What instructions would you provide clinicians to ensure that their selection of patients, placement of the trunnion, and postsurgery monitoring reduce risks of failure and/or systemic toxicity in the patient? Suggest a postimplantation monitoring program that allows you to provide postmarket safety data to the FDA (e.g., Phase III clinical trial data).
   Answer: The surgeons might be advised to use the trunnion only with compatible components (e.g., stems and femoral heads) to avoid grinding and release of cobalt particles. Care should be taken in revision surgery where catastrophic failure of the original implants might leave debris that grind the trunnion. The surgeons also might be advised to use adhesives and cements that are compatible. They may be warned that patients with a history or family history of metal allergies, or susceptibility to potential cobalt toxicities (e.g., rheumatic disease, thyroid conditions, cardiac disease), might be prone to device failure and metal-induced disease. Patch testing for metal allergies might be useful in identifying patients who should not receive the material or should be monitored for symptoms of metal disease. In addition to device failure, postmarket testing might include monitoring for cobalt levels in the blood, muscle and joint pain, neurological symptoms (ataxia, confusion), cardiac abnormalities, thyroid deficiency, and dermatological rashes.
3. Name four ways that metals like cobalt or nickel can cause systemic toxicity and identify the form of the metal that would likely result in toxicity.
   Answer: Trace amounts of cobalt are essential cofactors for vitamin B12. However, above trace levels, cobalt can bind to proteins to generate allergenic haptens, can bind inappropriately to regulatory signaling molecules to cause cardiac tissue damage, and can cause electrical disturbance in the heart and brain by competing with ion uptake essential for normal electrical conduction and transduction. Nickel is a nonessential metal and, in addition to forming allergenic haptens and blocking calcium channels, can displace essential metals from their effector sites.

   It is the free concentration of the elemental ionic form of the metal that is important.
4. What is required for an element like nickel to elicit sensitization that would result in an allergy to a nickel-based implant? When would a Nitinol implant elicit an allergic reaction?
   Answer: Elemental nickel is a weak but highly prevalent allergen. For nickel allergy to occur, the patient must be genetically susceptible and exposed to elemental nickel ions (Ni^{2+}). The nickel ions must bind to proteins to form hapten complexes that are taken into antigen-processing cells and incorporated into major histocompatibility complexes (MHCs) on the surface of antigen-presenting cells. Reexposure results in T cells interacting with the Ni–hapten in the MHC, which stimulates differentiation into cytotoxic T cells and an allergenic reaction promoting B cells. The Nitinol (nickel–titanium) alloys are not allergenic. However, if the implanted device corrodes or generates wear debris, nickel ions might be released and be available to elicit an allergic reaction in a susceptible individual.
5. Zinc is an essential metal, but can produce local and systemic toxicity when in excess and when depleted. What would be necessary for zinc from an implant to be toxic and what would cause another metal leached from an implant to cause zinc toxicity?
   Answer: The levels of essential metals like zinc in the circulation and in cells are tightly controlled. The level of free zinc available for toxicity is very low and toxicity occurs only when the levels of zinc overwhelm the capacity of cellular compartments to maintain homeostatic zinc levels or when zinc levels are depleted. Other metals can promote zinc toxicity by displacing zinc from storage or protein-binding sites resulting in an excess of free zinc concentration. Toxicity can also result from the

metal preventing zinc access to essential sites of action, which simulates zinc deficiency. Finally, the metal may substitute for zinc in essential structural sites and disrupt protein function by changing the zinc-dependent protein structure.

6. You have designed and perfected a metal/ceramic/plastic composite dental implant and proven that each constituent, as well as the final manufactured implant, is biocompatible and safe. The FDA approves a clinical trial and several patients have severe allergic reactions to the implant. What would be the probable cause for these allergic reactions when your premarket testing showed the implant was completely nonallergenic?
Answer: The most likely culprit would be that an allergenic adhesive or cement was used for the implantation. A suggestion might be to market the implant with adhesives and cements that have been tested not to generate an allergic reaction to your implant. A secondary culprit would be that mice are not men and all of the premarket testing in animals failed to reveal a human-specific response.

2.2.6

Blood Coagulation and Blood–Material Interactions

STEPHEN R. HANSON[1], ERIK I. TUCKER[1], ROBERT A. LATOUR[2]

[1]Division of Biomedical Engineering, School of Medicine, Oregon Health & Science University, Portland, OR, United States

[2]Bioengineering Department, Clemson University, Clemson, SC, United States

Introduction

The hemostatic mechanism is designed to arrest bleeding from injured blood vessels. The same process may produce adverse consequences when artificial surfaces are placed in contact with blood. These events involve a complex set of interdependent reactions between: (1) the surface; (2) platelets; and (3) coagulation proteins, resulting in the formation of a clot or thrombus, which may subsequently undergo removal by (4) fibrinolysis. The process is localized at the surface by opposing activation and inhibition systems, which combine to maintain the fluidity of blood in the circulation. In this chapter, an overview of hemostatic mechanisms is first presented in Section Platelet Adhesion and the Blood Coagulation Cascade—An Overview to provide a general understanding of blood and blood coagulation processes. Following these generalized section, more specific content addressing blood–material interactions is presented in Section Blood–Material Interactions. Although a great deal is known about blood responses to injured arteries and blood-contacting devices, important relationships remain to be defined in many instances. More detailed discussions of hemostasis, thrombosis, and blood–material interactions have been provided elsewhere (Thompson et al., 2017; Reviakine et al., 2017; Jung and Braune, 2016; Liu et al., 2015; Jaffer et al., 2015; Xu et al., 2014; Li and Henry, 2011; Ratner, 1993, 2007; Colman et al., 2005; Gorbet and Sefton, 2004; Esmon, 2003; Gresle et al., 2002; Stamatoyannopoulos et al., 1994; Forbes and Courtney, 1987).

Platelet Adhesion and the Blood Coagulation Cascade—An Overview

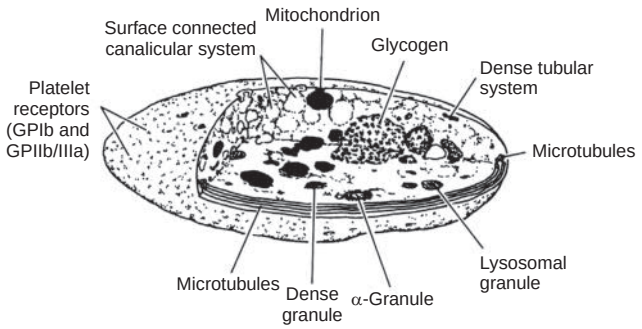
Cellular Composition of Blood

Erythrocytes (Red Cells)

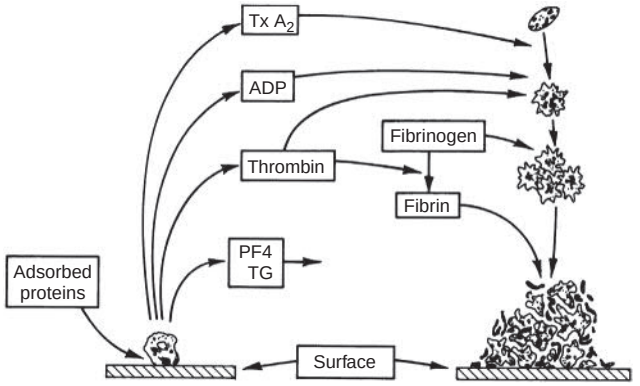
Red cells are usually considered as passive participants in processes of hemostasis and thrombosis, although under some conditions (low shear or venous flows) red cells may comprise a large proportion of the total thrombus mass. The concentration and motion of red cells have important mechanical effects on the diffusive transport of blood elements. For example, in flowing blood through small blood vessels, red cells tend to be concentrated in the middle of the blood vessel and displace a layer of plasma along with platelets toward the wall of the blood vessels, which is referred to as the marginal zone effect (Fournier, 2007). This phenomenon substantially increases the concentration of the platelets along the wall of the blood vessel. Under some conditions, red cells may also contribute chemical factors that influence platelet reactivity (Turitto and Weiss, 1980).

Leukocytes (White Cells)

The various classes of white cells perform many functions in inflammation, infection, wound healing, and the blood response to foreign materials. White cell interactions with artificial surfaces may proceed through as yet poorly defined mechanisms related to activation of the complement, coagulation, fibrinolytic, and other enzyme systems, resulting in the expression by white cells of procoagulant, fibrinolytic, and inflammatory activities. For example, stimulated



• **Figure 2.2.6.1** Platelet structure.



• **Figure 2.2.6.2** Platelet reactions to artificial surfaces. Following protein adsorption to surfaces, platelets adhere and release α-granule contents, including platelet factor 4 (PF-4) and β-thromboglobulin (β-TG), and dense granule contents, including ADP. Thrombin is generated locally through coagulation reactions catalyzed by procoagulant platelet surface phospholipids. Thromboxane A_2 (TxA_2) is synthesized. ADP, TxA_2, and thrombin recruit additional circulating platelets into an enlarging platelet aggregate. Thrombin-generated fibrin stabilizes the platelet mass.

monocytes express tissue factor, which can initiate thrombus formation by the extrinsic coagulation cascade. Neutrophils may contribute to clot dissolution by releasing potent fibrinolytic enzymes (e.g., neutrophil elastase). White cell interactions with devices having large surface areas may be extensive (especially with surfaces that activate complement), resulting in their marked depletion from circulating blood. Activated white cells, through their enzymatic and other activities, may produce organ dysfunction in other parts of the body. In general, the role of white cell mechanisms of thrombosis and thrombolysis, in relation to other pathways, remains an area of considerable interest.

Platelets

Platelets ("little plates") are nonnucleated, disk-shaped cells having a diameter of 2–3 μm, and an average volume of 10×10^{-9} mm^3 (Haley et al., 2011). Platelets are produced in the bone marrow, circulate at an average concentration of about 250,000 cells per microliter of whole blood, and occupy approximately 0.3% of the total blood volume. In contrast, red cells (erythrocytes) normally circulate at about 5×10^6 cells per microliter, and comprise 40%–50% of the total blood volume. Platelet functions are designed to: (1) initially arrest bleeding through the formation of platelet plugs; and (2) stabilize the initial platelet plugs by catalyzing coagulation reactions leading to the formation of fibrin.

Platelet structure provides a basis for understanding platelet function. In the normal (nonstimulated) state, the platelet discoid shape is maintained by a circumferential bundle (cytoskeleton) of microtubules (Fig. 2.2.6.1). The external surface coat of the platelet contains membrane-bound receptors [e.g., glycoproteins (GP) Ib, and IIb/IIIa] that mediate the contact reactions of adhesion (platelet–surface interactions) and aggregation (platelet–platelet interactions). The membrane also provides a phospholipid surface that accelerates important coagulation reactions and forms a spongy, canal-like (canalicular) open network that represents an expanded reactive surface to which plasma factors are selectively adsorbed. Platelets contain substantial quantities of muscle protein (e.g., actin, myosin) which allow for internal contraction when platelets are activated. Platelets also contain three types of cytoplasmic storage granules: (1) α-granules, which are numerous and contain the platelet-specific proteins platelet factor 4 (PF-4) and β-thromboglobulin (β-TG), and proteins found in plasma (including fibrinogen, albumin, fibronectin, coagulation factors V and VIII); (2) dense granules which contain adenosine diphosphate (ADP), calcium ions (Ca^{2+}), and serotonin; and (3) lysosomal granules containing enzymes (acid hydrolases).

Platelets are extremely sensitive cells that may respond to minimal stimulation. Activation causes platelets to become sticky and change in shape to irregular spheres with spiny pseudopods. Activation is accompanied by internal contraction and extrusion of the storage granule contents into the extracellular environment. Secreted platelet products such as ADP stimulate other platelets, leading to irreversible platelet aggregation and the formation of a fused platelet thrombus (Fig. 2.2.6.2).

Platelet Adhesion

Platelets adhere to artificial surfaces and injured blood vessels. At sites of vessel injury, the adhesion process involves the interaction of platelet glycoprotein Ib (GP Ib) and connective tissue elements, which become exposed (e.g., collagen) and require plasma von Willebrand factor (vWF) as an essential cofactor. GP Ib (about 25,000 molecules per platelet) acts as the surface receptor for vWF (Colman et al., 2005). The hereditary absence of GP Ib or vWF results in defective platelet adhesion and serious abnormal bleeding.

Platelet adhesion to artificial surfaces, which is mediated by adsorbed proteins (see Chapter 2.1.2), may also be mediated through platelet glycoprotein IIb/IIIa (integrin $\alpha_{IIb}\beta_3$), as well as through the GP Ib–vWF interaction. GP IIb/IIIa (about 80,000 copies per resting platelet) is the platelet receptor for adhesive plasma proteins that support cell attachment, including fibrinogen, vWF, fibronectin, and vitronectin (Gresle et al., 2002). Resting platelets do not bind these adhesive glycoproteins in circulation, an event

TABLE 2.2.6.1 Properties of Human Clotting Factors

Clotting Factor	Apparent Molecular Weight (Number of Chains)	Approximate Normal Plasma Concentration (μg/mL)	Active Form
Intrinsic Clotting System			
Prekallikrein	86,000 (1)	50	Serine protease
High-molecular-weight kininogen	120,000 (1)	70–90	Cofactor
Factor XII	80,000 (1)	30–40	Serine protease
Factor XI	160,000 (2)	3–6	Serine protease
Factor IX	55,000 (1)	3–5	Serine protease
Factor VIII[a]	330,000 (1)	0.1–0.2	Cofactor
Von Willebrand factor[a]	250,000 (1)	10	Cofactor for platelet adhesion
Extrinsic Clotting System			
Tissue factor	47,000 (1)	0[b]	Cofactor
Factor VII	50,000 (1)	0.5	Serine protease
Common Pathway			
Factor X	59,000 (2)	8–10	Serine protease
Factor V	330,000 (1)	5–12	Cofactor
Prothrombin	72,000 (1)	100–150	Serine protease
Fibrinogen	340,000 (6)	1500–4500	Fibrin polymer
Factor XIII	320,000 (4)	10	Transglutaminase

[a]In plasma, factor VIII is complexed with von Willebrand factor, which circulates as a series of multimers ranging in molecular weight from about 600,000 to 2×10^7.
[b]The tissue factor concentration in cell-free plasma is absent or minimal since tissue factor is an integral cell membrane-associated protein expressed by vascular and inflammatory cells.

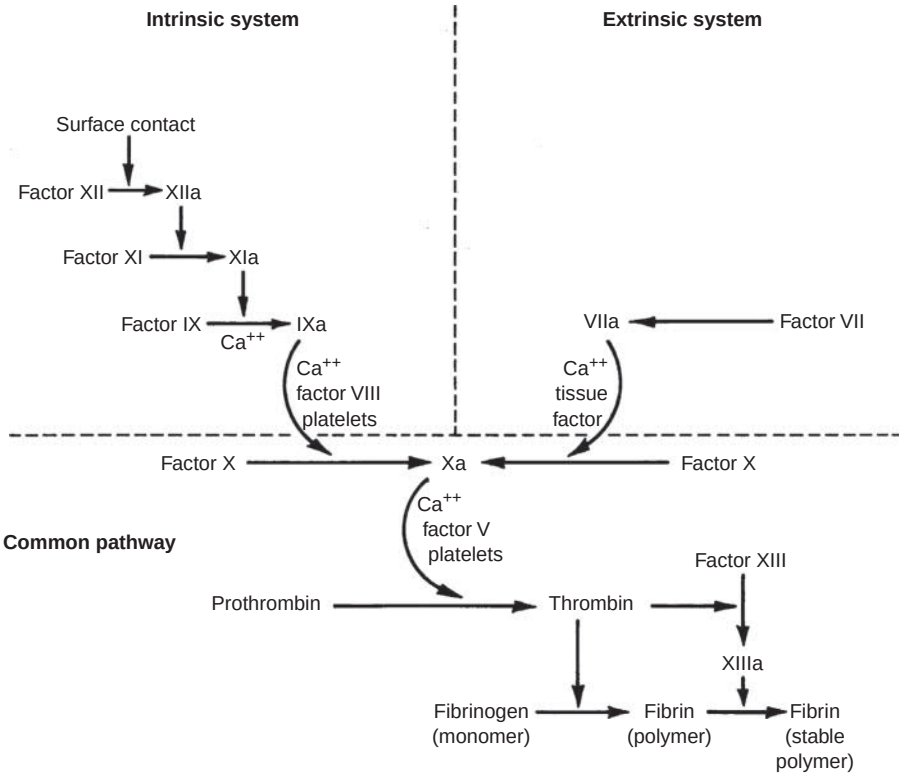
which normally occurs only after platelet activation causes a conformational change in GP IIb/IIIa. Platelets which have become activated near artificial surfaces (for example, by exposure to factors released from already adherent cells) adhere directly to surfaces through this mechanism (e.g., via GP IIb/IIIa binding to surface-adsorbed fibrinogen). Also, normally unactivated GP IIb/IIIa receptors can react with surface proteins that have undergone conformational changes as a result of the adsorption process (Savage and Ruggeri, 1991) (see Chapter 2.1.2). The enhanced adhesiveness of platelets toward surfaces preadsorbed with fibrinogen supports this view. Following adhesion, activation, and release reactions, the expression of functionally competent GP IIb/IIIa receptors may also support tight binding and platelet spreading through multiple focal contacts with fibrinogen and other surface-adsorbed adhesive proteins.

Platelet Aggregation

Following platelet adhesion, a complex series of reactions is initiated involving: (1) the release of dense granule ADP; (2) the formation of small amounts of thrombin (Fig. 2.2.6.2); and (3) the activation of platelet biochemical processes leading to the generation of thromboxane A_2. The release of ADP, thrombin formation, and generation of thromboxanes all act in concert to recruit platelets into the growing platelet aggregate (Fig. 2.2.6.2). Platelet stimulation by these agonists causes the expression on the platelet surface of activated GP IIb/IIIa, which then binds plasma proteins that support platelet aggregation. In normal blood, fibrinogen, owing to its relatively high concentration (Table 2.2.6.1), is the most important protein supporting platelet aggregation. The platelet–platelet interaction involves Ca^{2+}-dependent bridging of adjacent platelets by fibrinogen molecules (platelets will not aggregate in the absence of fibrinogen, GP IIb/IIIa, or Ca^{2+}). Thrombin binds directly to platelet thrombin receptors, and plays a key role in platelet aggregate formation by: (1) activating platelets, which then catalyze the production of more thrombin; (2) stimulating ADP release and thromboxane A_2 formation; and (3) stimulating the formation of fibrin, which stabilizes the platelet thrombus.

Platelet Release Reaction

The platelet release reaction is the secretory process by which substances stored in platelet granules are extruded from the platelet. ADP, collagen, epinephrine, and thrombin are physiologically important release-inducing agents, and interact



• **Figure 2.2.6.3** Mechanisms of clotting factor interactions. Clotting factors (proenzymes), identified by Roman numerals, interact in a sequential series of enzymatic activation reactions (coagulation cascade) leading to the amplified production of the enzyme thrombin, which in turn cleaves fibrinogen to form a fibrin polymer that stabilizes the clot or thrombus. Clotting is initiated by either an intrinsic or extrinsic pathway with subsequent factor interactions which converge upon a final, common path. The underlined factors are all activatable by the enzyme thrombin. The dotted lines indicate the divisions between the intrinsic, extrinsic, and common pathways.

with the platelet through specific receptors on the platelet surface. Alpha-granule contents (PF-4, β-TG, and other proteins) are readily released by relatively weak agonists such as ADP. Release of the dense granule contents (ADP, Ca^{2+}, and serotonin) requires platelet stimulation by a stronger agonist, such as thrombin. Agonist binding to platelets also initiates the formation of intermediates that cause activation of the contractile–secretory apparatus, production of thromboxane A_2, and mobilization of calcium from intracellular storage sites. Elevated cytoplasmic calcium is probably the final mediator of platelet aggregation and release. As noted, substances which are released (ADP), synthesized [thromboxane A_2 (TxA_2)], and generated (thrombin), as a result of platelet stimulation and release, affect other platelets and actively promote their incorporation into growing platelet aggregates. In vivo, measurements of plasma levels of platelet-specific proteins (PF-4, β-TG) have been widely used as indirect measures of platelet activation and release.

Platelet Coagulant Activity

When platelets aggregate, platelet coagulant activity is initiated, including the expression of negatively charged membrane phospholipids (phosphatidyl serine) which accelerate two critical steps of the blood coagulation sequence: factor X activation and the conversion of prothrombin to thrombin (Fig. 2.2.6.3). Platelets may also promote the proteolytic activation of factors XII and XI. The surface of the aggregated platelet mass thus serves as a site where thrombin can form rapidly in excess of the neutralizing capacity of blood anticoagulant mechanisms. Thrombin also activates platelets directly and generates polymerizing fibrin, which adheres to the surface of the platelet thrombus.

Platelet Consumption

Platelet consumption refers to the removal of platelets from the bloodstream by the liver and spleen, with the consumed platelets then normally replaced by new platelets freshly released from the bone marrow. As shown by radioisotope-labeling studies in humans, platelets are cleared from circulating blood in an approximately linear fashion over time, with an apparent lifespan of approximately 10 days. With ongoing or chronic thrombosis, which may be produced by cardiovascular devices, platelets may be removed from circulating blood at a more rapid rate. Thus steady-state elevations in the rate of platelet destruction, as reflected in a shortening of platelet lifespan, have been used as a measure of the thrombogenicity of artificial surfaces and prosthetic devices (Hanson et al., 1980, 1990).

Coagulation

In the test tube, at least 12 plasma proteins interact in a series of reactions leading to blood clotting. Their designation as Roman numerals was made in order of discovery, often before their role in the clotting scheme was fully understood. Their biochemical properties are summarized in Table 2.2.6.1. Initiation of clotting occurs either intrinsically by surface-mediated reactions that occur within a blood vessel, or extrinsically due to blood contacting tissue external to the vasculature due to a disrupted blood vessel wall through factors derived from tissues (i.e., tissue factor). The two systems converge upon a final common pathway, which leads to the formation of thrombin and an insoluble fibrin gel when thrombin acts on fibrinogen.

Coagulation proceeds through a "cascade" of reactions by which normally inactive factors (e.g., factor XII) become enzymatically active following surface contact, or after proteolytic cleavage by other enzymes (e.g., surface contact activates factor XII to factor XIIa). The newly activated enzymes in turn activate other normally inactive precursor molecules (e.g., factor XIIa converts factor XI to factor XIa). Because this sequence involves a series of steps, and because one enzyme molecule can activate many substrate molecules, the reactions are quickly amplified so that significant amounts of thrombin are produced, resulting in platelet activation, fibrin formation, and the arrest of bleeding. The process is localized (i.e., widespread clotting does not occur) owing to dilution of activated factors by blood flow, the actions of inhibitors that are present or are generated in clotting blood, and because several reaction steps proceed at an effective rate only when catalyzed on the surface of activated platelets or at sites of tissue injury.

Fig. 2.2.6.3 presents a scheme of the clotting factor interactions involved in both the intrinsic and extrinsic systems, and their common path. Except for the contact phase, calcium is required for most reactions and is the reason why chelators of calcium (e.g., citrate) are effective anticoagulants. It is also clear that the in vitro interactions of clotting factors, i.e., clotting, are not necessarily identical with coagulation in vivo, which may be triggered by artificial surfaces and by exposure of the cell-associated protein, tissue factor. There are also interrelationships between the intrinsic and extrinsic systems, such that under some conditions "crossover" or reciprocal activation reactions may be important (Bennett et al., 1987; Colman et al., 2005).

Mechanisms of Coagulation

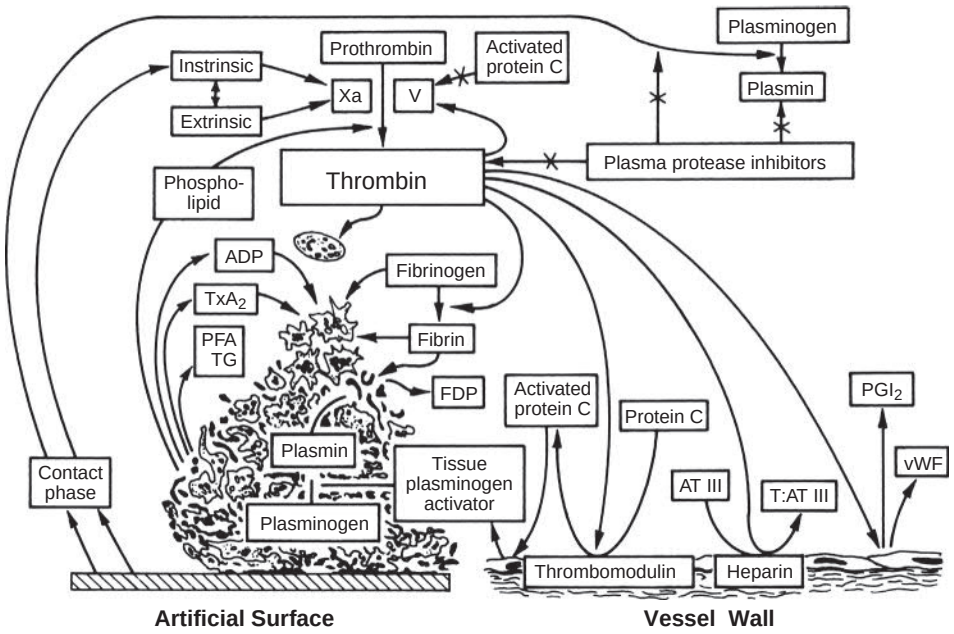
In the intrinsic clotting system, contact activation refers to reactions following the adsorption of contact factors to a material surface. These interactions are addressed in detail in Section Contact Activation of the Blood Coagulation Cascade. All of these contact reactions take place in the absence of calcium. Although extremely important for blood–material interactions, their pathologic significance in the absence of a biomaterial remains uncertain. For example, in hereditary disorders, a deficiency of factor XII, which is the initiating factor in the intrinsic coagulation cascade, is not associated with an increased bleeding tendency, and only a marked deficiency of factor XI produces abnormal bleeding.

A middle phase of intrinsic clotting begins with the first calcium-dependent step, the activation of factor IX by factor XIa. Factor IXa subsequently activates factor X. Factor VIII is an essential cofactor in the intrinsic activation of factor X, and factor VIII first requires modification by an enzyme, such as thrombin, to exert its cofactor activity. In the presence of calcium, factors IXa and VIIIa form a complex (the "tenase" complex) on phospholipid surfaces (expressed on the surface of activated platelets) to activate factor X. This reaction proceeds slowly in the absence of an appropriate phospholipid surface, and serves to localize the clotting reactions to the surface (vs. bulk fluid) phase. The extrinsic system is initiated by the activation of factor VII. When factor VII interacts with tissue factor, a cell membrane protein that may also circulate in a soluble form, factor VIIa becomes an active enzyme which is the extrinsic factor X activator. Tissue factor is present in many body tissues, is expressed by stimulated white cells and endothelial cells, and becomes available when underlying vascular structures are exposed to flowing blood upon vessel injury.

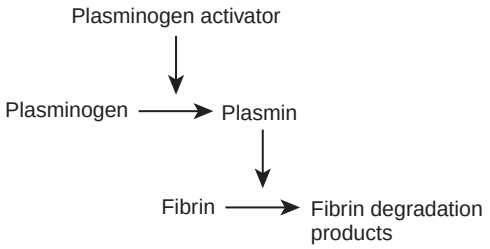
The common path begins when factor X is activated by either factor VIIa–tissue factor by or the factor IXa–VIIIa complex. After formation of factor Xa, the next step involves factor V, a cofactor, which (like factor VIII) has activity after modification by another enzyme, such as thrombin. Factor Xa–Va, in the presence of calcium and platelet phospholipids, forms a complex ("prothrombinase" complex) that converts prothrombin (factor II) to thrombin. Like the conversion of factor X, prothrombin activation is effectively surface catalyzed. The higher plasma concentration of prothrombin (Table 2.2.6.1), as well as the biological amplification of the clotting system, allows a few molecules of activated initiator to generate a large burst of thrombin activity. Thrombin, in addition to its ability to activate factors V and VIII and also platelets, acts on two substrates: fibrinogen and factor XIII. The action of thrombin on fibrinogen releases small peptides from fibrinogen (e.g., fibrinopeptide A), which can be assayed in plasma as evidence of thrombin activity. The fibrin monomers so formed polymerize to become a gel. Factor XIII is either trapped within the clot or provided by platelets, and is activated directly by thrombin. A tough, insoluble fibrin polymer is then formed by interaction of the fibrin polymer with factor XIIIa.

Control Mechanisms

Obviously, the blood and vasculature must have mechanisms for avoiding massive thrombus formation once coagulation is initiated. At least four types of mechanisms may be considered. First, blood flow may reduce the localized concentration of precursors and remove activated materials by dilution into a larger volume, with subsequent removal from the circulation following passage through the liver.



• **Figure 2.2.6.4** Integrated hemostatic reactions between a foreign surface and platelets, coagulation factors, the vessel endothelium, and the fibrinolytic system.



• **Figure 2.2.6.5** Fibrinolytic sequence. Plasminogen activators, such as tissue plasminogen activator (tPA) or urokinase, activate plasminogen to form plasmin. Plasmin enzymatically cleaves insoluble fibrin polymers into soluble degradation products (FDPs), thereby effecting the removal of unnecessary fibrin clot.

Second, the rate of several clotting reactions is fast only when the reaction is catalyzed by a surface. These reactions include the contact reactions, the activation of factor X by factor VII tissue factor at sites of tissue injury, and reactions which are accelerated by locally deposited platelet masses (activation of factor X and prothrombin). Third, there are naturally occurring inhibitors of coagulation enzymes, such as antithrombin III that are potent inhibitors of thrombin and other coagulation enzymes (plasma levels of thrombin–antithrombin III complex can also be assayed as a measure of thrombin production in vivo). Another example of a naturally occurring inhibitor is tissue factor pathway inhibitor (TFPI), a protein that, in association with factor Xa, inhibits the tissue factor–factor VII complex. Fourth, during the process of coagulation, enzymes are generated that not only activate coagulation factors, but also degrade cofactors. For example, the fibrinolytic enzyme plasmin (Figs. 2.2.6.4 and 2.2.6.5) degrades fibrinogen and fibrin monomers, and can inactivate cofactors V and VIII. Thrombin is also removed when it binds to thrombomodulin, a protein found on the surface of blood vessel endothelial cells. The thrombin–thrombomodulin complex then converts another plasma protein, protein C, to an active form that can also degrade factors V and VIII. In vivo, the protein C pathway is a key physiologic anticoagulant mechanism (Esmon, 2003; Colman et al., 2005). In short, the platelet, coagulation, and endothelial systems interact in a number of ways that promote localized hemostasis while preventing generalized thrombosis. Fig. 2.2.6.4 depicts some of the relationships and inhibitory pathways that apply to blood reactions following contact with both natural and artificial surfaces.

Fibrinolysis

The fibrinolytic system removes unwanted fibrin deposits to improve blood flow following thrombus formation, and to facilitate the healing process after injury and inflammation. It is a multicomponent system composed of precursors, activators, cofactors, and inhibitors, and has been studied extensively (Forbes and Courtney, 1987; Colman et al., 2005). The fibrinolytic system also interacts with the coagulation system at the level of contact activation (Bennett et al., 1987). A simplified scheme of the fibrinolytic pathway is shown in Fig. 2.2.6.5.

The most well-studied fibrinolytic enzyme is plasmin, which circulates in an inactive form as the protein plasminogen. Plasminogen adheres to a fibrin clot, being incorporated into the mesh during polymerization. Plasminogen is activated to plasmin by the actions of plasminogen activators, which may be present in blood or released from tissues, or which may be administered therapeutically. Important plasminogen activators occurring naturally in humans include tissue plasminogen activator (tPA) and urokinase. Following activation, plasmin digests the fibrin clot,

releasing soluble fibrin-fibrinogen digestion products (FDP) into circulating blood, which may be assayed as markers of in vivo fibrinolysis (e.g., the fibrin D-D dimer fragment). Fibrinolysis is inhibited by plasminogen activator inhibitors (PAIs), and by a thrombin-activated fibrinolysis inhibitor (TAFI), which promotes the stabilization of fibrin and fibrin clots (Colman et al., 2005).

Complement

The complement system is primarily designed to induce a biological response to antigen–antibody reactions. Like the coagulation and fibrinolytic systems, complement proteins are activated enzymatically through a complex series of reaction steps (Bennett et al., 1987). Several proteins in the complement cascade function as inflammatory mediators. The end result of these activation steps is the generation of an enzymatic complex that causes irreversible damage (by lytic mechanisms) to the membrane of the antigen-carrying cell (e.g., bacteria).

Since there are a number of interactions between the complement, coagulation, and fibrinolytic systems, there has been considerable interest in the problem of complement activation by artificial surfaces, prompted in part by observations that devices having large surface areas (e.g., hemodialyzers) may cause: (1) reciprocal activation reactions between complement enzymes and white cells; and (2) complement activation, which may mediate both white cell and platelet adhesion to artificial surfaces. Further observations regarding the complement activation pathways involved in blood–materials interactions are likely to be of interest.

Blood–Material Interactions

Overview

The medical treatment of cardiovascular disease today incorporates the use of a wide range of devices that involve direct contact between blood and artificial materials. These devices include catheters, stents, vascular grafts, and cardiac-support systems such as artificial heart valves, ventricular assist devices, and the total artificial heart. In addition, blood undergoes contact with large surface areas of artificial materials in extracorporeal blood-treatment devices, such as the blood oxygenator, tubing, and blood pump that are used during heart–lung-bypass surgery; blood filtration systems used for hemodialysis; and blood component separation processes used during apheresis.

Unfortunately, while these applications are obviously intended to benefit the patient, the inherent response of blood when it comes in contact with an artificial material surface is to activate the body's natural defense systems (Reviakine et al., 2017; Liu et al., 2015; Jaffer et al., 2015). These responses lead to blood coagulation as well as the activation of the inflammation and complement systems—all of which, if unchecked, lead to the formation of thrombus and thromboemboli, with potentially life-threatening consequences. In order to prevent or at least substantially suppress these natural responses for patients undergoing procedures involving blood–material interactions, the current approach implemented in medical practice relies on the use of anticoagulant and/or antiplatelet drugs in an attempt to inhibit the generation of material-contact-induced thrombus and thromboemboli (Reviakine et al., 2017; Liu et al., 2015; Jaffer et al., 2015). Despite these pharmacological treatments, thrombus formation is still a significant problem in essentially every device that is used for blood-contacting applications (Reviakine et al., 2017; Liu et al., 2015; Ratner, 2007). Furthermore, the use of these drugs, which cause the systemic suppression of blood coagulation, can lead to serious complications due to uncontrolled hemorrhaging, thus establishing the need for blood-compatible materials to minimize the use of these pharmacological agents. Although advances have been made over the past several decades of research in an attempt to develop materials that inhibit blood coagulation, thrombosis remains an unsolved problem for all synthetic materials used in blood-contact applications.

There are two primary mechanisms through which thrombus formation is initiated from contact between blood and artificial materials: (1) interaction between platelets with the material surface, which is mediated by adsorbed proteins, leading to platelet activation, and (2) contact-activation of the intrinsic clotting cascade directly by the material surface. These mechanisms are addressed in Section Platelet–Material Interactions and Section Approaches to Improve the Blood Compatibility of Artificial Materials. Section Platelet–Material Interactions addresses the topic of platelet–material interactions and Section Contact Activation of the Blood Coagulation Cascade addresses contact activation. Section Approaches to Improve the Blood Compatibility of Artificial Materials then summarizes approaches that are currently being explored in an attempt to improve the blood compatibility of artificial materials that are used in blood-contact applications.

Platelet–Material Interactions

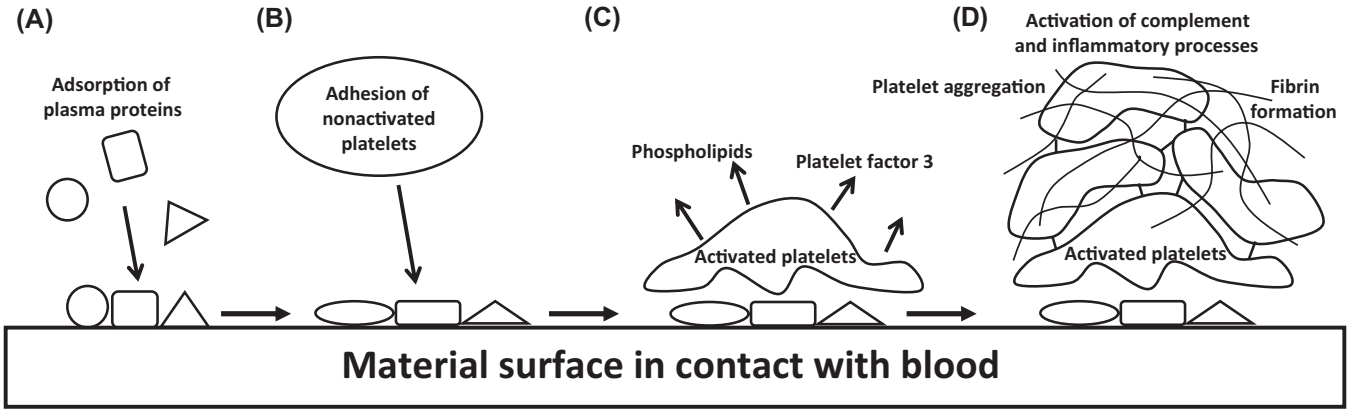
When an artificial material comes in contact with blood, the surface of the material is coated with an adsorbed layer of blood-plasma proteins within a matter of seconds (Horbett, 1993; Latour, 2008). This topic is covered in detail in Chapter 2.1.2. This process is initially kinetically driven, which results in the surface being first coated with the fastest diffusing proteins, such as albumin, which is the protein with the highest concentration in blood plasma (about 40 mg/mL) in addition to being relatively low molecular weight (about 67 kDa). Depending on how strongly these proteins are adsorbed, the initially adsorbed layer of protein may subsequently be displaced by more strongly adsorbing proteins, such as fibrinogen, through the Vroman effect, which is controlled by thermodynamics (i.e., processes driven by lowering the free-energy state of the system) (Dee et al., 2002).

Although still not yet fully understood, nonactivated platelets in blood have the ability to detect this adsorbed layer of proteins as something abnormal, which causes platelets to adhere to the adsorbed proteins, leading to platelet activation (Savage and Ruggeri, 1991). Once activated, platelets release factors including various phospholipids and platelet factor 3 that directly activate the blood coagulation cascade and nearby circulating platelets, as well as complement and inflammatory processes. Platelet activation also results in greatly increased expression of the fibrinogen-binding integrin receptor, GP IIb/IIIa (also known as $\alpha_{IIb}\beta_3$), which strongly binds to fibrinogen. The bifunctionality of fibrinogen enables each fibrinogen protein to bind to two different platelets, resulting in platelet aggregation (Dee et al., 2002). Fig. 2.2.6.6 provides a schematic illustrating thrombus formation induced by platelet adhesion on a synthetic material surface.

Platelets remaining adherent to the protein-coated surface result in the growth of thrombus on the material surface, leading to the reduction or possible complete blockage of blood flow, or the possible loss of function of the implanted prosthesis, such as has occurred with artificial heart valves and ventricular assist devices (Jaffer et al., 2015; Affeld et al., 2016). Alternatively, if the activated platelets release from the surface, thromboemboli may be generated, which will travel downstream in the vasculature to become lodged in subsequent capillary beds of downstream organs (Affeld et al., 2016; Liu et al., 2015; Li and Henry, 2011; Cannegieter et al., 1994). If the thromboemboli occur in the venous system, they may result in pulmonary embolism. Or, if they occur in the arterial system, they may result in stroke, myocardial infarction, or the blockage of blood flow to other organs in the body leading to organ failure.

The fact that nonactivated platelets will adhere and activate against adsorbed proteins such as fibrinogen, but not undergo activation in flowing blood when they are constantly interacting with these same proteins in the blood plasma, indicates that the adsorption of proteins to material surfaces must somehow alter their conformation in a manner for platelets to recognize them as something abnormal. Evidence of adsorption-induced conformational changes in adsorbed fibrinogen has been found through in vitro studies involving changes in the elutability of adsorbed fibrinogen with time (Bohnert and Horbett, 1986), changes in monoclonal antibody binding with time (Lindon et al., 1986; Horbett and Lew, 1994), and atomic force spectroscopy (Agnihotri and Siedlecki, 2004). Using circular dichroism spectropolarimetry to determine the secondary structure of fibrinogen before and after adsorption under a broad range of conditions, Sivaraman and Latour more recently directly showed that platelet adhesion to adsorbed fibrinogen is strongly correlated with the degree of adsorption-induced unfolding of the protein (Sivaraman and Latour, 2010a). Surprisingly, Sivaraman and Latour then also showed that platelets will even adhere to adsorbed albumin, which does not contain platelet-binding sites in its native structure, once the albumin unfolds beyond a critical degree (measured to be a loss of more than about 33% of albumin's α-helical structure) (Sivaraman and Latour, 2010b). Platelet adhesion to both of these proteins was found to be mediated by the GP IIb/IIIa platelet receptors (Sivaraman and Latour, 2011). Furthermore, an irreversibly adsorbed layer of albumin, which is initially resistant to platelet adhesion, may subsequently induce platelet adhesion and activation after undergoing aging-induced unfolding (Sivaraman and Latour, 2012), thus potentially providing an explanation for the occurrence of late thrombus formation on drug-eluting cardiovascular stents (McFadden et al., 2004; Virmani et al., 2004).

The adhesion and activation of platelets to adsorbed proteins has also been found to be influenced by the shear strain rate at the material surface (Affeld et al., 2016; Goto et al., 1998). Under wall shear strain rates above about $1000\,s^{-1}$, the adsorption of von Willebrand factor (vWf) is required for platelets to bind to the surface in a manner that is sufficiently strong to hold the platelets on the surface and



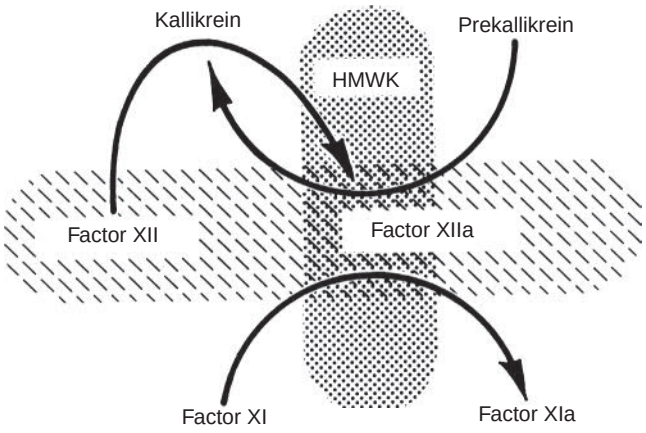
• **Figure 2.2.6.6** (A) Adsorption of plasma proteins to material surface. (B) Conformational changes in adsorbed proteins followed by the adhesion of nonactivated platelets from the blood stream. (C) Platelet activation leading to the release of activating factors. (D) Platelet aggregation and the activation of the blood coagulation cascade leading to thrombus formation, along with the subsequent activation of complement and inflammatory processes.

resist the tendency of the high shear stress along the wall to sweep the platelets downstream along with the flowing blood (Tronic et al., 2016; Goto et al., 1998). When vWf adsorbs to a material surface under these conditions, the high shear strain rate causes the protein to unfurl on the surface to expose otherwise hidden domains within the protein structure that bind to GP Ib receptors that are expressed by nonactivated platelets. Although this binding event does not tend to activate the adherent platelets, once the platelets bind securely to the adsorbed vWf, they are able to be activated through interactions of the platelet GP IIb/IIIa receptors to neighboring adsorbed adhesive proteins, such as fibrinogen, leading to the formation of thrombus and/or thromboemboli.

Contact Activation of the Blood Coagulation Cascade

The other primary mechanism that mediates thrombus formation against biomaterial surfaces that are used in blood-contact applications is referred to as contact activation. This pathway of thrombus formation was discovered by Margolius and Ratnoff in the 1950s (Margolius and Ratnoff, 1956). Margolius and Ratnoff observed that the blood from a patient named Hageman tended to clot unusually slowly in glass tubes. Further investigation determined that this patient lacked a certain factor that was involved with the initial stages of blood coagulation in response to material contact. The factor was initially called Hageman factor. Hageman factor was subsequently termed coagulation factor XII (FXII) and determined to be the first step of the intrinsic blood coagulation cascade.

As with platelet adhesion and activation, contact activation is mediated by the adsorption of plasma proteins on a material surface. This process primarily involves four plasma proteins that interact with material surfaces to activate the intrinsic blood coagulation cascade: FXII (Hageman factor), coagulation factor XI (FXI), prekallikrein (PKK), and high-molecular-weight kininogen (HMWK), which complexes with both FXI and PKK (Xu et al., 2014).



• **Figure 2.2.6.7** Contact activation. The initial event in vitro is the adsorption of factor XII to a negatively charged material surface (hatched, horizontal ovoid) where it is activated to form factor XIIa. Factor XIIa converts prekallikrein to kallikrein. Additional factor XIIa and kallikrein are then generated by reciprocal activation. Factor XIIa also activates factor XIa. Both prekallikrein and factor XI bind to a cofactor, high-molecular-weight kininogen (HMWK), which anchors them to the charged surface. Kallikrein is also responsible for the liberation of the vasoactive peptide bradykinin for HMWK, linking coagulation and inflammation.

Although the specific mechanism has not yet been fully understood, the adsorption of FXII to material surfaces is believed to induce a conformational change that activates this protein to its enzymatic form of FXIIa, which is referred to as autoactivation (Griffin, 1978). Once activated, FXIIa interacts with adsorbed HMWK-PKK to cause the PKK to convert to kallikrein (KK), which subsequently acts to induce further conversion of FXII to FXIIa (Meier et al., 1977). This process is referred to as reciprocal activation. FXIIa then also activates HMWK-bound FXI to FXIa, which then continues to propagate the intrinsic blood coagulation cascade leading to thrombus generation (Vogler and Siedlecki, 2009; Miller et al., 1980). This overall process is illustrated in Fig. 2.2.6.7.

Numerous studies investigating the contact activation pathway have shown that it is influenced by the surface chemistry, surface energy, surface area, and surface topology of the contacting material (Bauer et al., 2017; Xu et al., 2014; Chatterjee et al., 2009; Sperling et al., 2009; Vogler et al., 1995). In particular, contact activation is induced most strongly on negatively charged hydrophilic surfaces (Griep et al., 1986; Mitropoulos, 1999) while essentially being suppressed on highly hydrophobic surfaces (Xu et al., 2014; Sperling et al., 2009). Siedlecki, Vogler, and coworkers have shown that both negatively charged hydrophilic and hydrophobic surfaces will actually induce the autoactivation of FXII to FXIIa in simple buffer solution, while only negatively charged hydrophilic surfaces appear to induce this reaction in blood plasma (Xu et al., 2014). The reason for this difference is believed to be that the much stronger adsorption of plasma proteins to hydrophobic surfaces compared to hydrophilic surfaces results in the strong adsorption of numerous other proteins that effectively interfere with the adsorption of FXII, thus limiting the autoactivation of FXII to FXIIa.

As shown by Sperling et al. (2009), the opposite response is found with platelet adhesion and activation on material surfaces, with greater platelet response typically occurring on hydrophobic versus hydrophilic materials. Interestingly, in their study they found that heterogeneous surfaces that combine both negatively charged hydrophilic groups and hydrophobic groups, thus inducing both platelet adhesion and contact activation, exhibit the greatest degree of thrombogenicity. These results indicate that a synergistic interaction occurs between platelet responses and contact activation, with the surface of the activated platelets also inducing the conversion of FXII to FXIIa to further amplify the contact activation pathway.

Recognition of the important role of the contact activation pathway to induce thrombus formation against biomaterial surfaces has led to attempts to use pharmaceutical

agents to block the activation of FXII to FXIIa or FXI to FXIa, thus inhibiting the initiation of the intrinsic blood coagulation cascade through these processes (Muller et al., 2011; Montfoort and Meijers, 2013; Kenna and Renne, 2014; Bane and Gailani, 2014).

Approaches to Improve the Blood Compatibility of Artificial Materials

Because thrombus formation against artificial surfaces by both platelet adhesion and contact activation is mediated by adsorbed proteins, one of the primary approaches in attempts to prevent thrombus formation has been the development of surface coatings that are strongly resistant to protein adsorption (Thompson et al., 2017; Liu et al., 2015; Jaffer et al., 2015; Li and Henry, 2011). These surface chemistries include polyHEMA, polyethylene glycol (PEG), phosphatidyl choline, and, more recently, zwitterionic molecules such as betaines [poly(carboxybetaine) (PCB) and poly(sulfobetaine) (PSB)]. However, while demonstrated to be highly effective in vitro, these surface chemistries have not been shown to be fully effective in eliminating protein adsorption and subsequent thrombus formation in vivo (Liu et al., 2015). Thus the development of protein-resistant surfaces continues as an ongoing area of research.

Other approaches to develop artificial materials that are resistant to thrombus formation include surface functionalization with bioactive molecules that inhibit thrombus formation and the coating of surfaces with endothelial cells in attempts to provide surfaces that resemble that of natural blood vessels (Thompson et al., 2017; Liu et al., 2015; Jaffer et al., 2015; Li and Henry, 2011).

Attempts to provide surface functionalization with biomolecules to inhibit thrombus formation have included the use of heparin and hirudin (Liu et al., 2015; Jaffer et al., 2015; Li and Henry, 2011), both of which are potent inhibitors of thrombin. Heparin is a natural polysaccharide, which, in combination with antithrombin III (ATIII), strongly binds and deactivates thrombin. Heparin–ATIII complexes can also inhibit other blood coagulation factors including XIa, Xa, and IXa (Holmer et al., 1981). Hirudin is a small protein composed of only 65 amino acids, which is derived from the medicinal leech. These types of strategies have been explored in in vivo studies as coatings for mechanical heart valves, stents, and artificial vascular grafts with varied levels of success, with the use of such bioactive coatings still representing an active area of research (Liu et al., 2015; Li and Henry, 2011).

Other approaches include polymer coatings that release nitric oxide (NO), which are strong inhibitors of thrombin formation (Goudie et al., 2017; Naghavi et al., 2013). One of the inherent limitations of this approach, however, is that once the NO release is diminished, prevention of thrombus formation is lost, thus potentially limiting this approach to short-term blood-contact applications. Another more recent approach is to apply coatings designed to bind to plasminogen, which upon activation by circulating plasminogen-activating factor may result in the rapid breakdown of thrombus if it begins to form on the material surface (Liu et al., 2015).

The blood-contacting surface of the natural vasculature is lined with a layer of endothelial cells, which is, of course, nonthrombogenic. Thus the coating of blood-contacting artificial material surfaces with a layer of viable endothelial cells holds promise for providing long-term blood compatibility (Liu et al., 2015; Jaffer et al., 2015; Li and Henry, 2011). Unfortunately, thus far, this approach has proven to be extremely difficult to achieve. As a biological cell, endothelial cells used for surface coatings must be of autologous origin to prevent immunological reactions against these cells. Early attempts to accomplish the endothelialization of artificial vascular grafts have thus tried seeding the surfaces with autologous endothelial cells. However, under in vivo flow conditions, the cells tended to wash off from the surface, indicating a need for approaches to increase the strength of cell attachment to maintain complete coverage of the surface and cell viability. Attempts to overcome this problem have included preconditioning the endothelial cell-coated surfaces in vitro under moderate flow conditions or precoating the material surfaces with adhesive peptides to provide stronger focal adhesions between the endothelial cells and the underlying material surface.

Another approach to coat artificial material surfaces with endothelial cells that has been tried is by in situ endothelialization (Liu et al., 2015; Li and Henry, 2011). This approach requires functionalizing the surface with bioactive molecules designed to stimulate the migration and proliferation of endothelial cells from the adjacent vasculature, or to capture endothelial progenitor cells from the circulation and stimulate their maturation to form a firmly attached endothelial cell layer to completely cover the material surface. Attempts to accomplish this for vascular grafts and stents, however, have thus far also been unsuccessful and efforts to achieve this capability continue.

At this time, the development of a truly blood-compatible material remains an unreached goal. As summarized above, this capability requires material surfaces that are resistant to thrombus formation induced by both platelet adhesion and the contact-activation pathway. While successful treatments have been demonstrated in vitro, these same methods have not been proven to be as effective in vivo. It is thus apparent that the in vitro tests conducted thus far are not adequately representative of in vivo conditions. One of the possible explanations for these shortcomings is the "cross-talk" that occurs between blood coagulation and the activation of inflammation and complement processes, with the in vitro tests that have been performed thus far not being sufficiently complex to capture these types of interactions. The solution to this problem may thus require the implementation of more complex multifaceted in vitro test methods combined with in vitro test-method standardization (Braune et al., 2013) (see Chapter 2.3.5—Evaluation of Blood–Material Interactions).

While significant progress has been made over the past several decades of research, the development of blood-compatible materials still remains an unsolved issue and research continues toward the attainment of this long-sought-after goal.

Conclusions

Interrelated blood systems respond to tissue injury in order to rapidly minimize blood loss, and later to remove unneeded deposits after healing has occurred. When artificial surfaces are exposed, an imbalance between the processes of activation and inhibition of these systems can lead to excessive thrombus formation, and an exaggerated inflammatory response. While many of the key blood cells, proteins, and reaction steps have been identified, their reactions in association with artificial material surfaces have not been well defined in many instances. Therefore, blood reactions which might cause thrombosis continue to limit the potential usefulness of many cardiovascular devices for applications in humans (Reviakine et al., 2017; Liu et al., 2015; Jaffer et al., 2015; Li and Henry, 2011; Ratner, 2007; Gorbet and Sefton, 2004). Consequently, these devices still require anticoagulant and/or antiplatelet drugs to be used, which present an inherent bleeding risk due to the resulting systemic suppression of blood coagulation processes.

Chapter Exercise Questions

Question 1

Cardiovascular stents are positioned at a site of arterial stenosis by inserting a catheter containing an undeployed stent at its tip into an artery in the arm or groin area, with the tip of the catheter then guided to the site of the stenosis for deployment of the stent under real-time imaging. Once the stent is deployed, the catheter is then removed with the stent remaining at the site of stenosis to hold the artery open at that location.

Part A. When a catheter is inserted into the artery, will the blood coagulation cascade primarily be activated via the extrinsic or intrinsic pathway at the site of catheter insertion?

Answer: At the site of insertion, the blood vessel wall will be cut, causing blood to be exposed to tissue external to the vasculature, with the blood then exposed to tissue factor. Exposure of the blood to tissue factor will initiate blood coagulation via the extrinsic pathway.

Part B. As the catheter is slid within the artery away from the insertion site, will the blood coagulation cascade primarily be activated by the catheter via the extrinsic or intrinsic pathway?

Answer: Away from the insertion site, the catheter will be exposed to blood within intact arteries without exposure to tissue outside of the vasculature, thus tending to activate the intrinsic blood coagulation pathway.

Question 2

Which blood protein is polymerized and cross-linked at the end of the common pathway of the blood coagulation cascade to form a stable insoluble blood clot?

Answer: Fibrinogen polymerization and cross-linking is the final phase of the common pathway of the blood coagulation cascade to form a stable insoluble fibrin blood clot.

Question 3

To prevent or at least minimize blood coagulation against medical devices that are used during cardiovascular procedures, patients are given either anticoagulant or antiplatelet drugs, or a combination of both. What are the differences in the physiological activities in these two different types of antithrombotic drugs?

Answer: Anticoagulant drugs inhibit the contact activation of the coagulation factors of the blood clotting cascade while antiplatelet drugs suppress platelet activation.

2.2.7

Tumorigenesis and Biomaterials

VICKIE Y. JO, FREDERICK J. SCHOEN

Department of Pathology, Brigham and Women's Hospital and Harvard Medical School, Boston, MA, United States

The possibility that implant materials could cause tumors or promote tumor growth has long been a concern of surgeons and biomaterials researchers. This chapter describes general concepts in neoplasia, the association of tumors with implants in human and animals, and the pathobiology of tumor formation adjacent to biomaterials. As therapies utilizing biomaterial stem cells are in brisk development and have begun to be investigated in clinical trials, the current understanding of stem cell-related tumorigenesis is also discussed.

General Concepts

Neoplasia, which literally means "new growth," is the process of excessive and uncontrolled cell proliferation (Kumar et al., 2015). The new growth is called a *neoplasm* or *tumor* (i.e., a swelling), since most neoplasms are expansile, solid masses of abnormal tissue. Tumors are either *benign* (when their pathologic characteristics and clinical behavior are relatively innocent) or *malignant* (harmful, often deadly). Malignant tumors are collectively referred to as *cancers* (derived from the Latin word for crab, to emphasize their obstinate ability to adhere to adjacent structures and spread in many directions simultaneously). The characteristics of benign and malignant tumors are summarized in Table 2.2.7.1. Examples of malignant tumors are depicted in Fig. 2.2.7.1. Benign tumors do not penetrate (invade) adjacent tissues, nor do they spread to distant sites. They remain localized and surgical excision is curative in many cases. In contrast, malignant tumors show aggressive growth and have a propensity to invade contiguous tissues. Moreover, owing to their ability to gain entrance into blood and lymph vessels, cells from a malignant neoplasm can spread to distant sites, where subpopulations of malignant cells take up residence, grow, and again invade as satellite tumors (called *metastases*).

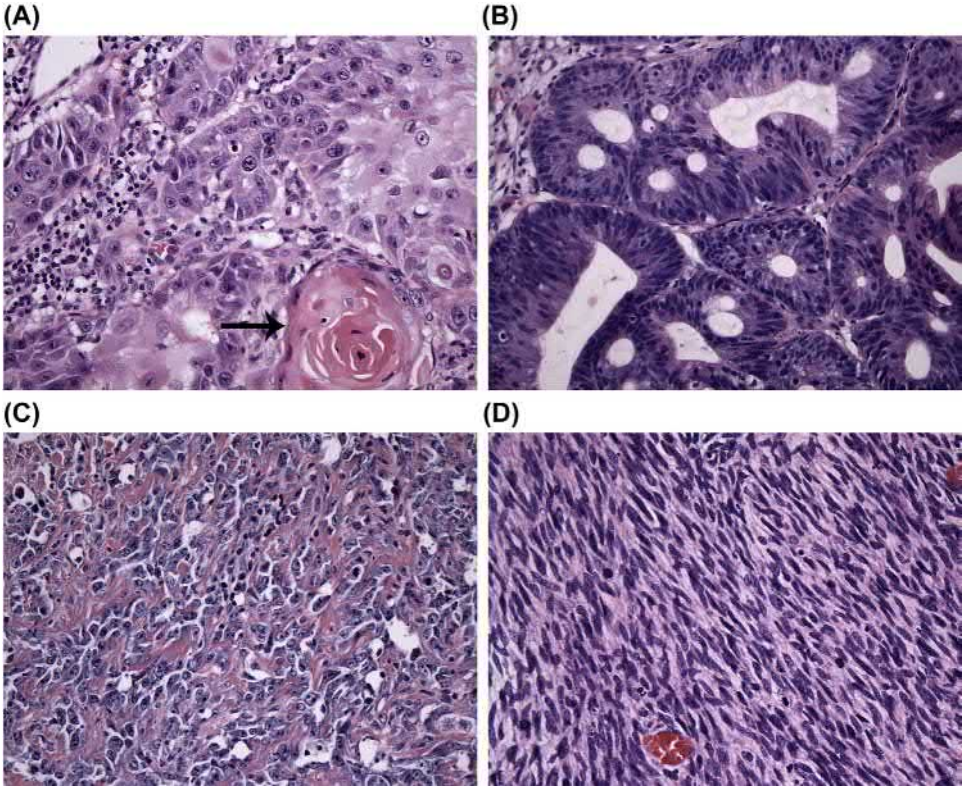
The primary descriptor of any tumor is the site of origin and the normal cell or tissue/organ that it recapitulates. For malignant tumors arising in epithelium, the suffix "carcinoma" is applied (e.g., squamous cell or adenocarcinoma, referring to protective and glandular epithelia, respectively), while the suffix "sarcoma" is used for mesenchymal malignancies (e.g., osteo- or chondrosarcoma, producing bone and cartilage, respectively). Malignant neoplasms of the hematopoietic system, in which the cancerous cells circulate in blood, are called leukemias; solid tumors arising from lymphoid tissue are called lymphomas. Neoplastic growth entails both abnormal cellular proliferation and modification of the structural and functional characteristics of the cell types involved. Tumor *grade* or differentiation refers to the degree to which a tumor resembles its counterpart normal cell or tissue type. Malignant cells are generally less differentiated than normal cells. The morphologic similarity of cancer cells to their normal counterparts enables specific *diagnosis* (source organ and cell type); moreover, the grade also predicts the *prognosis* of the patient (i.e., expected outcome based on biologic behavior of the cancer). Therefore, poorly differentiated tumors generally are more aggressive (i.e., display more malignant behavior) than those that are better differentiated. The extent of spread and other effects on the patient determine its *stage*. Both *grade* and *stage* are clinically useful indicators of prognosis.

Neoplastic growth occurs by evasion of normal regulatory cell and tissue functions. Neoplastic cell proliferation is therefore unrelated to the physiological requirements of the tissue, and once initiated is unaffected by removal of the stimulus which initially caused it. These characteristics differentiate neoplasms from (1) normal proliferations of cells during fetal development or postnatal growth, (2) normal wound healing following an injury, and (3) hyperplastic growth which adapts to a physiological need, but which ceases when the stimulus is removed.

All tumors, benign and malignant, have two basic components: (1) proliferating neoplastic cells that constitute their *parenchyma*, and (2) supportive *stroma* comprised of connective tissue and blood vessels. The parenchymal component is more readily recognizable as neoplasia (resembling normal cell and tissue counterparts). Tumor growth and evolution are critically dependent on the nonspecific stromal elements and inflammatory cells.

TABLE 2.2.7.1 Characteristics of Benign and Malignant Tumors

Characteristics	Benign	Malignant
Differentiation	Well defined; structure may closely resemble normal cell or tissue/organ counterpart	Less differentiated with pleomorphism and bizarre (anaplastic) cells; often atypical structure
Rate of growth	Usually progressive and slow; may come to a standstill or regress; cells in mitosis are rare	Erratic, and may be slow to rapid; mitoses may be absent to numerous with abnormal forms
Local invasion	Usually cohesive, expansile, well-demarcated masses that neither invade nor infiltrate the surrounding normal tissues	Locally invasive, infiltrating adjacent normal tissues
Metastasis	Absent	Frequently present; larger and more undifferentiated primary tumors are more likely to metastasize

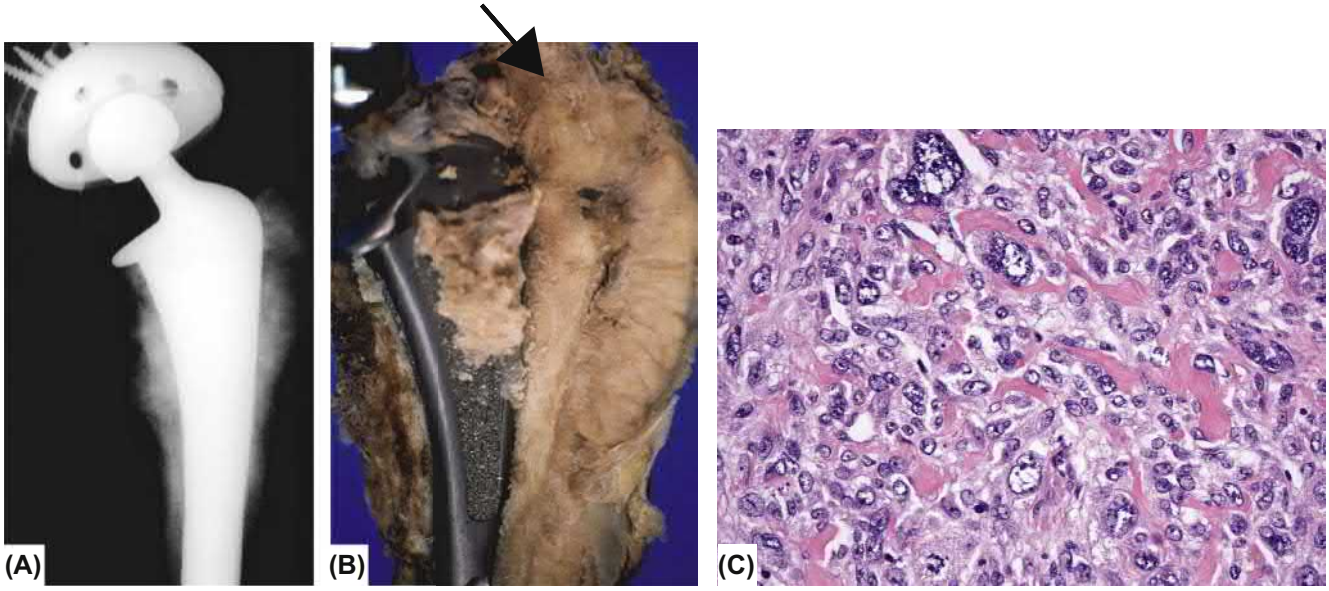


• **Figure 2.2.7.1** Examples of malignant tumor types. (A) Squamous cell carcinoma, with characteristic keratinization (*arrow*). (B) Adenocarcinoma, showing abnormal proliferation of back-to-back glands. (C) Angiosarcoma, with tumor cells forming vague slitlike spaces mimicking vascular channels. (D) Malignant peripheral nerve sheath tumor, an example of a high-grade spindle cell sarcoma. (All slides stained with hematoxylin and eosin.)

Association of Implants With Human and Animal Tumors

Neoplasms occurring at the site of implanted medical devices are rare, despite the large numbers of implants used clinically over an extended period of time. Nevertheless, cases of both human and veterinary implant-associated tumors have been reported (Balzer and Weiss, 2009; Black, 1988; Jennings et al., 1988; Pedley et al., 1981; Schoen, 1987; Visuri et al., 2006a,b). In all, approximately 100 cases of tumors associated with surgical implants have been reported, as well as other cases of tumors related to nontherapeutic foreign materials (e.g., bullets, shrapnel, other metal fragments, sutures, bone wax, and surgical sponges) (Ebrahimzadeh et al., 2013). One comprehensive review cites 46 cases of reported malignant tumors at the site of total hip arthroplasty from 1974 to 2002 (Visuri et al., 2006a).

Implant-related tumors have been reported to arise in settings of both short- and long-term implantation. Over 25% of tumors associated with foreign material develop within 15 years, while over 50% arise within 25 years (Brand and Brand, 1980). The vast majority of malignant neoplasms associated with clinical fracture fixation devices, total joint replacements, mechanical heart valves, vascular grafts, breast implants and



• **Figure 2.2.7.2** Orthopedic implant-related osteosarcoma in a 68-year-old man, arising 3 years following total hip replacement. (A) Radiograph demonstrating the osteoblastic (i.e., bone-making) tumor surrounding the implant. (B) Resected tumor, showing its relationship to the implant and partially destroyed proximal femur. (C) Photomicrograph of tumor, demonstrating high-grade osteosarcoma. The cytologically malignant cells surround coarse lacelike neoplastic bone. ((A) and (B) reproduced and modified with permission from Keel, S.B. et al., 2001. Orthopedic implant-related sarcoma: a study of 12 cases. Mod. Pathol. 14, 969–977. (C) Courtesy of Rosenberg, A.E., Department of Pathology, University of Miami, Laser Institute of America, Miami, FL, United States of America.)

experimental foreign bodies in both animals and humans are sarcomas (i.e., mesenchymal tumors), and are characterized by rapid and locally infiltrative growth. While various histologic subtypes have been reported, including osteosarcoma, chondrosarcoma, and angiosarcoma, most of these sarcomas are unclassified (i.e., lacking evidence of a specific line of differentiation) (Keel et al., 2001). An osteosarcoma forming adjacent to a hip joint prosthesis is illustrated in Fig. 2.2.7.2. Carcinomas, reported in association with foreign bodies far less frequently, have usually been restricted to situations where an implant has been placed in the lumen of an epithelium-lined organ. Illustrative reported cases are noted in Table 2.2.7.2; descriptions of others are available (Goodfellow, 1992; Jacobs et al., 1992; Jennings et al., 1988). Lymphomas have been reported most commonly in association with the capsules surrounding breast implants (Balzer and Weiss, 2009; Gaudet et al., 2002; Keech and Creech, 1997; Mallick et al., 2009; Sahoo et al., 2003; Visuri et al., 2006a, de Jong et al., 2008; Miranda et al., 2014). Occasional cases of nonimplant-related primary tumors (i.e., a metastasis to an implant site) exist in the literature, such as a report of gastric cancer with a metastasis to a total knee replacement (Kolstad and Hgstorp, 1990).

Whether there is a causal role for implanted medical devices in local or distant malignancy remains controversial and a general association is unproven. In an individual case, caution is necessary in implicating the implant in the formation of a neoplasm; clearly, demonstration of a tumor occurring adjacent to an implant does not necessarily prove that the implant caused the tumor (Morgan and Elcock, 1995). Large-scale epidemiological studies and reviews of available data have concluded that there is no evidence in humans for increased tumorigenicity of nonmetallic and metallic surgical implants (McGregor et al., 2000). Indeed, the risk in populations appears low, as exemplified by cohorts of patients with both total hip replacement and breast implants that demonstrated no detectable increases in tumors at the implant site (Berkel et al., 1992; Deapen and Brody, 1991; Mathiesen et al., 1995; Brinton and Brown, 1997; Visuri et al., 2006a). Although cancers at most other organ sites seem not to be increased, some studies suggest that there may be a slightly increased risk of hematopoietic cancers (i.e., leukemias and lymphomas). Such cancers occur in organs where exogenous elements and particles may accumulate; in this regard, one study suggests enhanced surveillance in total hip recipients with metal-on-metal articulations, in which the number of metallic particles is estimated to be much higher than with metal-on-plastic bearings (Visuri et al., 2006a), and the size of the particles smaller, with a correspondingly high reactive surface area. However, one population-based study of patients showed no overall differences in risk of cancer development between patients with metallic and nonmetallic hip replacements over a 4-year follow-up period (Mäkelä et al., 2012). Another clinical and experimental study suggested that the incidence of breast carcinoma may be decreased in women with breast implants (Su et al., 1995). Interestingly, breast implant-associated anaplastic large-cell lymphoma has been established as a distinct T-cell lymphoproliferative disorder that is postulated to evolve from malignant transformation of the normal, indolent chronic inflammatory response to the implant and local infection (Miranda et al., 2014; Leberfinger et al., 2017). This is the first observed robust association between a clinical implant and development of neoplasia, although the pathogenetic mechanism has yet to be established. Fig. 2.2.7.3 illustrates an example of an anaplastic large-cell lymphoma that arose in association with a breast implant. Most cases arise

secondary to a "textured" implant, presenting as an effusion or mass confined to the textured capsule, with a mean time to presentation of 9-10 years after placement (Quesada et al., 2019). To date the United States Food and Drug Administration (FDA) has received reports of approximately 400 cases of breast implant-associated anaplastic large-cell lymphoma (U.S. FDA, 2018, https://www.fda.gov/medicaldevices/productsandmedicalprocedures/implantsandprosthetics/breastimplants/ucm239995.htm). While the relative risk of developing breast implant-associated anaplastic large-cell lymphoma is increased

in women with breast implants, the absolute risk remains extremely low (de Boer et al., 2018). Currently, the FDA recommends routine care for patients with breast implants, with special attention to patients who develop late-onset (greater than 7 years after implantation) periimplant seromas or masses. Based on available data, most cases have an excellent prognosis with explantation and complete surgical resection of disease, and do not require chemotherapy, although more aggressive behavior may be seen for mass-forming disease compared to effusions confined to the capsule (Quesada et al., 2019).

Moreover, some neoplasms are common in both humans and animals and can occur independently at the sites at which biomaterials are implanted. Sporadic human benign and malignant neoplasms in musculoskeletal sites are not unusual. Most clinical veterinary cases have been observed in dogs, a species with a relatively high natural frequency of osteosarcoma and other tumors at sites where orthopedic devices are implanted. However, since sarcomas arising in the aorta and other large arteries are rare, the association of primary vascular malignancies with clinical polymeric grafts may be stronger than that with orthopedic devices.

Clinically, benign but exuberant foreign body reactions may simulate neoplasms. For example, fibrohistiocytic proliferations resembling malignant tumors may occur as a reaction to silica, previously injected as a soft-tissue sclerosing agent (Weiss et al., 1978), and these exuberant fibrohistiocytic lesions have been observed in association with the capsules that form around breast implants (Balzer and Weiss, 2009) and a type of polytetraethylene sleeve used for lung cancer resections (Fernandez et al., 2008). Moreover, regional lymphadenopathy (i.e., enlargement of lymph nodes) may result from an exuberant foreign body reaction to material that has migrated from a prosthesis. This has been documented in cases of silicone emanating from both finger joints (Christie et al.,1977) and breast prostheses (Hausner et al., 1978), as well as with polymeric replacements of the temporomandibular joint and with conventional metallic, ceramic, and polymeric total replacements of large joints (Jacobs et al., 1995). Reactive fibrous lesions can arise secondarily to a foreign body reaction and simulate a neoplasm, often referred to as a *pseudotumor*; *gossypibomas* (derived from Latin "gossypium" for cotton), or *textilomas*, refer to large mass-forming foreign body reactions to inadvertently retained materials during surgery, such as surgical sponges (Malot and Meena, 2012). Interestingly, nodular fasciitis, a benign myofibroblastic entity that arises rapidly but spontaneously regresses, often mimics sarcoma but is known as a "transient neoplasm," harboring recurrent *USP6-MYH9* fusion gene (Erickson-Johnson et al., 2011).

Pathobiology of Foreign Body Tumorigenesis

Considerable progress has been made over the last several decades in the understanding of the molecular basis of cancer (Kumar et al., 2015). These fundamental principles are well accepted: (1) Neoplasia is associated with and often results from nonlethal genetic damage (or mutation), either inherited or acquired by the action of environmental agents such as physical effects [e.g., radiation, fibers or foreign bodies (Fry, 1989)], chemicals, or viruses. (2) The principal targets of the genetic damage are cellular regulatory genes (normally present and necessary for physiologic cell function, inducing cellular replication, growth and repair of damaged DNA). (3) The tumor mass evolves from the clonal expansion of a single progenitor cell which has incurred the genetic damage. (4) Tumorigenesis is a multistep process, generally owing to accumulation of successive genetic lesions. Once tumorigenesis has been initiated, the most important factors in tumor growth are the kinetics (i.e., balance of replication or loss) of cell number change and its blood supply. The formation of new vessels (*angiogenesis*) is also essential for enlargement of tumors and for their access to the vasculature and hence, metastasis (Carmeliet and Jain, 2000).

The pathogenesis of implant-induced tumors is not well understood, yet most experimental data indicate that there is an interplay of physical effects of the implant and subsequent tissue response (i.e., microenvironment). Most data indicate that the physical effects rather than the chemical characteristics of the foreign body are the principal determinants of tumorigenicity (Brand et al., 1975). Tumors can be induced experimentally by a wide array of materials of diverse composition, including those that could be considered essentially nonreactive, such as certain glasses, gold, or platinum, and other relatively pure metals and polymers. Indeed, one surgeon performed a much-maligned experiment in which dimes inserted in rats led to the development of sarcomas in 60% within 16 months (prompting the suggestion that dimes and probably all metallic coins were carcinogenic and should be discontinued!) (Moore and Palmer, 1997). Solid materials implanted in a configuration that maximizes surface area are most tumorigenic. Materials lose their tumorigenicity when implanted in pulverized, finely shredded, or woven form, or when surface continuity is interrupted by multiple perforations. This trend is often called the *Oppenheimer effect*. Thus, foreign body neoplasia is generally considered to be a transformation process mediated by the physical state of implants; it is largely independent of the composition of the materials, unless specific carcinogens are present.

Nanotechnology is an active area of research and has gained many applications in medicine, including disease diagnosis, molecular imaging, and target-specific drug delivery. Recent evidence suggests that tumor formation induced by nanoparticles is dependent on both the physical properties and chemical properties in a particle-dependent preneoplasia–neoplasia model (Hansen et al., 2006). In vivo studies in a rat model comparing bulk versus nanoparticulate implants have demonstrated that secondary sarcomas arose secondary to both nickel and cobalt nanoparticles; however, only bulk nickel implants were associated with sarcomas, while no malignancies developed with cobalt bulk implants (Hansen et al., 2006). Nanoparticles may accumulate both at the site of injection and easily translocate to

other organs and through cell walls; their migratory capability depends on their size, shape, and physical and chemical properties (Kumar and Dhawan, 2013). While nanoparticles may accumulate in organs and cells, their clearance from the body is slower. Solid-state tumorigenesis depends in part on the development of a fibrous capsule around the implant. Tumorigenicity corresponds directly to the extent and maturity of tissue encapsulation of a foreign body and inversely with the degree of active cellular inflammation. Thus, an active, persistent inflammatory response inhibits tumor formation in experimental systems. Host (especially genetic) factors also affect the propensity to form tumors as a response to foreign bodies. Humans are less susceptible to foreign body tumorigenesis than are rodents, the usual experimental model. In rodent systems, tumor frequency and latency depend on species, strain, sex, and age. Concern was initially raised over the possibility that foreign body neoplasia can be induced by the release of wear debris or needlelike elements from composites in a mechanism that is analogous to that of asbestos-related mesothelioma (Brown et al., 1990; Jurand, 1991)—see below. However, animal experiments suggest that only particles with very high length-to-diameter ratios (>100) produce this effect. Particles with this high aspect ratio are highly unlikely to arise as wear debris from orthopedic implants.

Nevertheless, cancer at foreign body sites may be mechanistically related diseases in which tissue fibrosis is a prominent feature, including asbestosis (i.e., lung damage caused by chronic inhalation of asbestos), lung or liver scarring, or chronic bone infections (Brand, 1982). Asbestos is well known as having a causal relationship with mesothelioma, and occurs with pulmonary ingestion specific to fiber shape. Interestingly, most cancers associated with tissue damage and scarring are epithelial, in contrast to the fact that most implant-related tumors are mesenchymal malignancies. Indeed, tissue and matrix stiffness has a role in cancer development. Cells engage in "tensional homeostasis" and increased tissue stiffness results in adaptations in cell behavior, leading to sustained changes in biochemical signaling and ultimately gene expression pathways that can induce malignant transformation (Butcher et al., 2009). Ex vivo studies have also implicated viscoelasticity of tissue and tissue porosity as additional physical properties that may promote neoplasia, which can led to nuclear deformation and damage and aberrant DNA repair (Singh et al., 2018).

Chemical induction effects are also possible. With orthopedic implants, the stimulus for tumorigenesis could be metal particulates released by wear of the implant (Harris, 1994). Indeed, implants of chromium, nickel, cobalt, and some of their compounds, either as foils or debris, are carcinogenic in rodents (Swierenza et al., 1987), and the clearly demonstrated widespread dissemination of metal debris from implants (to lymph nodes, bone marrow, liver, and spleen, particularly in subjects with loose, worn joint prostheses) could cause both damage to distant organs and be associated with the induction of neoplasia (Case et al.,1994). Although unequivocal cases of metal particles or elemental metals provoking the formation of malignant tumors are not available, continued vigilance and further study of the problem in animal models is warranted (Lewis and Sunderman, 1996).

TABLE 2.2.7.3 Steps in Implant-Associated Tumorigenesis: A Hypothesis[a]

1. Cellular foreign body reaction
2. Fibrous capsule formation
3. Preneoplastic cells contact implant surface during quiescent tissue reaction
4. Preneoplastic cell maturation and proliferation within a sequestered microenvironment
5. Tumor growth

[a]Adapted from K. G. Brand and colleagues.

"Nonbiodegradable" and "inert" implants have been shown to contain and/or release trace amounts of substances such as remnant monomers, catalysts, plasticizers, and antioxidants. Nevertheless, such substances injected in experimental animals at appropriate test sites (without implants) in quantities comparable to those found adjacent to implants, are generally not tumorigenic. Moreover, chemical carcinogens such as nitrosamines or those contained in tobacco smoke may potentiate scar-associated cancers.

A chemical effect has been considered in the potential carcinogenicity of polyurethane biomaterials (Pinchuk, 1994). Under certain conditions (i.e., high temperatures in the presence of strong bases), diamines called 2,4-toluene diamine (TDA) and 4,4′-methylene dianiline (MDA) can be produced from the aromatic isocyanates used in the synthesis of polyurethanes. TDA and MDA are carcinogenic in rodents. However, it is uncertain whether (1) TDA and MDA are formed in vivo, and (2) these compounds are indeed carcinogenic in humans, especially in the low dose rate provided by medical devices. Although attention has been focused on polyurethane foam-coated silicone gel-filled breast implants, one type of which contained the precursor to TDA, the risk is considered zero to negligible (Expert Panel, 1991).

Foreign body tumorigenesis is typically characterized by a long latency period, during which chronic exposure to the implant instigates tumor formation. Available data suggest the following sequence of essential developmental stages in foreign body tumorigenesis (summarized in Table 2.2.7.3): (1) cellular proliferation in conjunction with tissue inflammation associated with the foreign body reaction (specific susceptible preneoplastic cells may be present at this stage); (2) progressive formation of a well-demarcated fibrotic tissue capsule surrounding the implant; (3) quiescence of the surrounding tissue reaction (i.e., dormancy and phagocytic inactivity of macrophages attached to the foreign body), but direct contact of clonal preneoplastic cells with the foreign body surface and progression of tumor microenvironment; (4) final maturation of preneoplastic cells; and (5) sarcomatous proliferation. Primary support for this multistep hypothesis for foreign body tumorigenesis comes from an

experimental study by Kirkpatrick et al. (2000) in which premalignant lesions were frequently found in implant capsules. A spectrum of lesions was observed, from proliferative lesions without atypical cells to atypical proliferation to incipient sarcoma.

The essential hypothesis is that initial acquisition of neoplastic potential and the determination of specific tumor characteristics do not depend on direct physical or chemical interaction between susceptible cells and the foreign body, and, thus, the intrinsic properties of the foreign body itself probably do not initiate the tumor. However, although the critical initial event occurs early during the foreign body reaction, the final step to neoplastic autonomy (presumably a genetic event) is accomplished only when preneoplastic cells attach themselves to the foreign body surface. Subsequently, there is proliferation of abnormal mesenchymal cells in this sequestered microenvironment by the fibrous capsule, a situation not permitted with the prolonged active inflammation associated with less inert implants. The fibrous capsule acts to sequester the tumor microenvironment, creating an "immune-privileged microenvironment" that can selectively impart the immune system from recognizing tumor antigens that would normally lead to destruction of the cancerous cells (Kitamura et al., 2015). Interestingly one study using a model of biomaterial-induced sarcoma formation in which preneoplastic changes in both tumors and the foreign-body-induced fibrous capsule can be studied by contemporary histologic and molecular techniques (Kirkpatrick et al., 2000), suggested that biomaterial-associated tumorigenesis does not occur by a specific genetic insult, and thereby is different to spontaneous tumorigenesis (Weber et al., 2009). There is increased evidence supporting inflammatory mechanisms in carcinogenesis, with a role for the formation of reactive oxygen and nitrogen species in malignant progression; this is likely the basis for carcinogenesis by nanoparticles (Okada, 2007; Onuma et al., 2009). In vitro and in vivo experiments have shown that nanoparticles can induce DNA damage and mutations due to excessive oxidative stress and generation of free radicals having mutagenic potential (Kumar and Dhawan, 2013). Rodent studies of multiwalled carbon nanotubes have shown widespread development of mesotheliomas, both at the site of injection and elsewhere (Takagi et al., 2008; Sakamoto et al., 2009). Further research is necessary to clarify the malignancy risks in patients.

Thus, the critical factors in sarcomas induced by foreign bodies include implant configuration, fibrous capsule development and remodeling, and a period of latency long enough to allow progression to neoplasia in a susceptible host. The major role of the foreign body itself seems to be that of stimulating the formation of a fibrous capsule conducive to neoplastic cell maturation and proliferation by yet poorly understood mechanisms. The rarity of human foreign body-associated tumors suggests that cancer-prone cells are infrequent in the foreign body reactions to implanted human medical devices.

Stem Cell Therapies and Tumorigenesis

There have been many recent advances in stem cell-based regenerative therapies, which also raise specific considerations for tumorigenesis in these settings (among other controversies). Currently, stem cell therapies in most countries are in the stages of preclinical research and clinical trials, and one major obstacle to clinical implementation is the potential for tumorigenesis. Stem cells are pluripotent, meaning they have the potential to differentiate and mature into any kind of cell type (Kumar et al., 2015). Preclinical research has focused on human embryonic stem cells (collected from embryonic and fetal tissues) (hESC) and human-induced pluripotent stem cells (hiPSCs), which are engineered from adult cells using viral transfection to "genetically reprogram" pluripotent potential. Adult stem cells are normally present in certain tissues and divide to replenish damaged tissue, and are the basis for bone marrow transplants. While stem cells are an attractive source for tissue regeneration, hESCs and hiPSCs have the potential for unregulated growth after implantation, and in vivo animal studies show frequent development of teratomas (i.e., tumors comprised of varied and haphazard primitive tissues recapitulating fetal development) (Cooke et al., 2006; Shih et al., 2007; Blum and Benvenisty, 2008; Knoepfler, 2009; Cunningham et al., 2012). The tumorigenic potential between hESCs and hiPSCs varies; however, because adult stem cells are typically restricted and can only differentiate into certain lineages, they are rarely implicated in tumorigenesis. Research has indicated that the development of these malignancies occurs secondary to unique gene expression profiles that are permissive to tumorigenesis, as well as the acquisition of genetic mutations in culture (Blum et al., 2009). Furthermore, the behavior of stem cells is somewhat unpredictable outside of the intricate regulatory mechanisms of embryogenesis, which dictate specific patterns of differentiation and migration.

The issue of teratoma development has been a major barrier to clinical implementation of stem cell therapy and an area of active research. Ongoing clinical trials are investigating methods for treatment standardization and reducing the risk of tumorigenesis, including measured dosage administration and preimplantation induction of "partial" differentiation of stem cells (Fox et al., 2014; Mazzini et al., 2015). Studies in a macaque monkey model have shown that grafts of hESCs that are induced to differentiate into cardiomyocytes can enhance cardiac function (Liu et al., 2018). The residual "undifferentiated" pluripotent stem cells within a stem cell preparation are considered to be the source of tumorigenesis, and in vivo mouse studies have shown that selective inhibition of undifferentiated stem cells by a variety of methods mitigates against teratoma and tumor formation, such as targeting antiapoptotic pathways by small molecules (Lee et al., 2013), treatment by high-concentration L-alanine medium (Nagashima et al., 2018), and induced phototoxicity (Cho et al., 2015).

Currently, the U.S. FDA encourages patients to enroll only in regulated, approved clinical trials. Worldwide, several commercial exploitative stem cell operations with

limited or no regulation, employing unproven therapies, and reports of unusual, unclassifiable malignancies have been reported in these patients (Amariglio et al., 2009; Thirabanjasak et al., 2010; Berkowitz et al., 2016).

Conclusions

Neoplasms associated with therapeutic clinical implants in humans are rare, and causality is difficult to demonstrate in any individual case. Experimental implant-related tumors are induced by a large spectrum of materials and biomaterials, dependent primarily on the physical and not the chemical configuration of the implant. However, specific considerations for tumorigenesis exist for the newer technologies of nanomedicine and stem cell therapy. The mechanism of experimental tumor formation, yet incompletely understood, appears related to the implant fibrous capsule, which sequesters an inflammatory response and immune-privileged tumor microenvironment. Although the mechanism is yet uncertain, the pattern of lymphomas occurring in the context of a breast implant appears to be the first established clinical situation of tumor clearly associated with, and likely directly causal to, a surgical implant.
