Typical in vivo studies of bone metastasis involve intracardiac injection of human tumor cells into immunocompromised mice as metastases in mice do not form spontaneously (Esposito et al., 2018). Interestingly, the regions that tumor cells target during bone metastasis are not only characterized by distinct cellular composition, but also contain less mature mineral that further changes during premetastatic remodeling (Fig. 2.5.11.3Ci) (He et al., 2017). Given that mineral properties can directly influence tumor cell behavior, studies of bone metastasis should not only consider tumor-associated changes of bone organic ECM components and the related cellular and molecular changes, but also the role of minerals in these processes (Choi et al., 2015; Pathi et al., 2011). To more closely mimic the importance of human microenvironmental components in driving bone metastasis, humanized mouse models of bone metastasis have been engineered. For example, humanized bone can be developed using polycaprolactone (PCL) scaffolds coated with calcium phosphate and cultured with primary human osteoblastic cells in the presence of recombinant human bone morphogenic protein (BMP)-7 (Holzapfel et al., 2014; Martine et al., 2017) (Fig. 2.5.11.3Cii). Following implantation into immunocompromised mice, the cell-seeded constructs develop into humanized ossicles complete with many structural and biochemical features of native bone including mineralized collagen I and II and a bone marrow space containing osteoclasts, osteoblasts, and hematopoietic cells. When breast cancer cells were injected intracardially, bone metastases developed in the implant regions. The benefits of such systems are the reproducible formation of bone metastasis with similarities to those in humans (Dondossola et al., 2018; Tatosian and Shuler, 2009). However, these studies depend on the use of immunocompromised mice, which cannot recapitulate the full immunologic responses that are known to play a role in bone metastasis. Indeed, scaffold-based premetastatic niches implanted into immunocompetent mice have helped reveal the importance of specific immune cell populations in driving tumor cell dissemination (Fig. 2.5.11.3Ciii) (Azarin et al., 2015; Rao et al., 2016). More specifically, implantation of microporous PLGA or PCL scaffolds leads to the recruitment of different immune cell types generating a microenvironment that promotes recruitment of metastatic cells relative to neighboring sites with scaffold degradation kinetics appearing to play a role in this process. Hence, complementary in vivo approaches will be needed to elucidate the independent and combined effects of human conditions and the immune system in bone metastasis.

Conclusions

Biomaterials-based models of the tumor microenvironment contribute to a better understanding of cancer development, progression, and treatment. While previous and current approaches primarily focus on local phenomena, systemic effects broadly impact many aspects of tumor growth and therapeutic response. As such, more integrated approaches will be needed. In particular, microphysiological systems platforms in which models of varied tissues and organs are interconnected using fluidic conduits allow for mimicry of systemic interactions and can be used for analyzing treatment responses (Bhatia and Ingber, 2014; Tatosian and Shuler, 2009). Such systems are particularly useful in cancer drug screenings because a drug can be tested simultaneously for efficacy in killing the cancer cells and for side effects on other cell types. Furthermore, using such platforms in combination with patient-derived cells or organoids as well as in vivo studies will be critical to enable precision medicine applications that are poised to greatly improve clinical outcomes for patients in the future (DelNero et al., 2018).

Chapter Exercises With (Guided) Solutions

Question 1: List four important biological design considerations for engineered tumor models.

Answer:

1. Tissue dimensionality
2. Mass and fluid transport/transport phenomena
3. ECM physicochemical properties/changes to stiffness, structure, chemical composition in malignancy, e.g., remodeling by stromal cells
4. Immunological considerations such as incorporation of immune cell types or immunocompetent animal models

Question 2: Describe three model systems that serve to replicate changes in tissue dimensionality during tumorigenesis. Explain how they are manufactured and which specific aspects of the tumor microenvironment they can recapitulate.

Answer:

1. Spheroids
   (i) Formed via hanging drop, agarose-coated plates, or specialized plates (pyramidal microwells or plates with vertical channels)
   (ii) Promote cell–cell contacts in three dimensions, provide mass transport dynamics seen in tissues, and tissue-like structural features
2. Scaffolds
   (i) Encapsulation in polymeric scaffolds, hydrogels (both natural and synthetic)
   (ii) Cells get cues from their surroundings, adopt morphology different from 2D, changes to signaling and gene expression due to a variety of mechanisms including differential integrin engagement, cell–cell contact, as well as responses to tumor-intrinsic microenvironmental cues including hypoxia
3. Patterned hydrogels
   (i) Covalently couple adhesion molecules normally expressed on a cell's membrane onto a PDMS stamped micropatterned PEG hydrogel; examples include N-cadherin, VE-cadherin, I-CAM, V-CAM, P-Sel, and Jag-1
   (ii) This system allows for isolation and direct study of cell–cell contacts via interaction of specific protein binding pairs. These are also mechanically tunable allowing to compare effects of cell–cell adhesion in the presence and absence of varied substrate mechanical properties. This has identified how single cell division kinetics are impacted by intercellular adhesion proteins and how these correlate to in vivo function

Question 3: Describe how changes in ECM dynamics can be recapitulated with hydrogel systems using examples from the text and explain the benefit of such systems to cancer research.

Answer: The tumor microenvironment is not static, but constantly changing. For example, spatial and temporal changes of ECM mechanical properties can be modulated by cell-mediated degradation. Studying the impact of such changes can be achieved by incorporating specifically engineered cross-links into hydrogel systems. For example, covalent coupling of MMP degradable sequences enables cell-mediated degradation of the material and consequential changes in cell behavior. Additional chemistry can be incorporated to cause a secondary cross-linking reaction later during the culture period that inhibits additional enzymatic degradation. Mechanical properties can also be changed in a reversible manner through light-dependent stiffening or softening of materials. For example, reversible stiffening/softening of hyaluronic acid-based hydrogels can be achieved though incorporation of supramolecular cross-links formed via azobenzene bound to β-cyclodextrin where exposure to 365 nm light will soften and 400–500 nm light will stiffen the gels. PEG gels can also undergo delayed secondary cross-link reactions via thiol-ene polymerization. Such dynamic systems allow for cell-mediated remodeling, isolation of initial stiffness from another value, and separating the effect of morphology changes from those mediated by varied substrate mechanical properties.

Question 4: Which experimental technique is routinely used to measure the adhesive forces of cells on materials-based ECM mimics? Explain how this technique is performed.

Answer: Traction force microscopy. Fluorescent beads are embedded into polyacrylamide hydrogels. Cells are seeded on top and images are acquired of the cells as they exert a force on the underlying substrate. An enzyme called trypsin is then added to detach the cells from the gel. More images are taken in the same field of view of the gel in the relaxed state. The difference in the positions of the fluorescent beads is used to computationally determine the forces the cells were exerting.

Question 5: What are some immune-related changes that happen in cancer? To create a tumor model with functional immune response, what types of immune cells would you incorporate?

Answer:

A. Changes:
   (1) Hijack inflammatory and immunomodulatory signals to enhance tumorigenesis
   (2) Suppressed cytotoxic activity of other immune cells
   (3) Increased remodeling due to upregulation of enzymes to degrade matrix
   (4) Changes to matrix mechanics and structure (intratumoral pressure, ECM density, fiber alignment).

B. Cell types:

Dendritic cells, T cells (CD4+ and/or CD8+), macrophages (M1,M2), natural killer cells, lymphocytes. Other stromal cells such as endothelial cells or fibroblasts could also be useful.

Question 6: Many cancers metastasize to the brain and much is still unknown about what happens when they arrive there. Explain how model systems for the study of brain metastases will differ from the models in the case study on bone metastasis. Consider the properties of brain tissue that

would differ from bone and how these would affect your choice of materials.

Answer: Differences include mechanical properties, cell types, and ECM proteins present. Brain tissue is much softer than bone and thus, the materials used to model brain must have a lower Young's modulus than those used for bone. There are also compositional differences between the bone and brain ECM. Whereas the bone is composed predominantly of mineralized collagen, the brain contains fibronectin, vitronectin, tenascin C, laminin, and HA. The cellular composition of the brain and bone also vary and cocultures of brain cells with cancer cells would be very different from those used in bone. Finally, the interstitial pressure developing within the brain is significantly different given the space constraints mediated by the skull.

Question 7: What role does vasculature play in cancer? List four materials and methods that could be used to model vasculature. What could be improved on existing models to more accurately model tumor vasculature?

Answer: Vasculature transports oxygen, nutrients, metabolic waste products, cells (e.g., metastatic cancer cells, immune cells), and drugs. Tumors must develop new vasculature as they grow to support the increased number of cells and the oxygen and nutrients they require. Often tumors outgrow the blood supply and develop a hypoxic necrotic core. When new vessels are created, they are often dysfunctional and leaky leading to impaired mass transport kinetics and the development of interstitial pressure.

A. Example model systems include:
   - Laser ablation of channels into PEGDA gels
   - Patterning vascular structures into hydrogel scaffolds using photolithography-based coupling of cell-adhesion peptides
   - Creating microfluidic networks within natural hydrogel matrices using soft lithography approaches
   - Using sacrificial materials to pattern channels into hydrogels
   - Performing vasculogenesis (i.e., individual endothelial cells forming vascular networks within hydrogel) within a microfluidic device
   - 3D printing in GelMA

B. Improvements: Answers may vary, examples include: simulating leaky vessels, incorporating spheroid models with vascular models etc.

Question 8: A drug company has developed a new candidate drug that appears to target cellular adhesion mechanisms of cancer cells in solid tumors. When they tested the drug on prostate cancer cells seeded on a Petri dish, it was remarkably effective, but did not harm normal cells. However, investors are concerned that this experiment is not enough to justify the cost of preclinical animal testing. Outline and justify a series of experimental systems to test the drug's efficacy, first in a precisely controlled environment, then in a more biologically complex system. Consider the advantages of natural and synthetic materials as well as the clarity of the data produced by different systems. Consider also additional factors that may impact or confound your data.

Answer:

1. Controlled environments could utilize a synthetic hydrogel material like PEG conjugated with one or more specific adhesion sequences that are thought to play a role in the drug's mechanism of action (e.g., RGD from fibronectin). The lack of biological complexity will help focus the experiment on adhesion while still enabling 3D culture that is more faithful to tumor characteristics.
2. A more complex system could be a synthetic material that contains multiple peptide sequences, a composite material containing collagen or fibronectin, or a natural material. An experiment utilizing multiple cell types would be a closer approximation of a tumor. Embedding individual cells in a 3D gel or matrix would make the system less cumbersome to use, while embedding a spheroid into a hydrogel adds more complexity and cost.
3. Confounding factors: material porosity, pH, stiffness, viscoelasticity, fiber alignment, and/or size. For gels: mass transfer and diffusion from culture medium.

Question 9: Researchers are studying cancer progression in two groups of mice. One group of mice forms large aggressive tumors while the other group does not. The researchers hypothesize that it may have something to do with differences in the ECM properties between the two groups.

a. Describe how this hypothesis could be studied using a cell-derived matrix model.
b. Additional testing shows that the group of mice with larger tumors has stiffer ECM to start with. Design a model using synthetic biomaterials to test whether differences in ECM mechanics could be responsible for differences in tumor growth between the two groups of mice. Explain why you chose the material you did.

Answer:

1. Stromal cells can be isolated from each group of mice and cultured to produce matrices. The cultures can be decellularized to produce CDMs with unique properties to each group of mice. Cancer cells can be seeded on top of the matrices and analyzed for proliferation, morphology, migration, cluster formation, etc.
2. Many answers are possible. The main focus is on a material that has tunable mechanical properties. Other considerations include 2D versus 3D ability (PA versus PEG), the inclusion of cell-adhesive ligands (RGD), and degradable properties of the material

Question 10: Several immune cell types have previously been grown in coculture systems with cancer cells, but model systems that accurately model the role of the immune system in systemic regulation of cancer progression are still needed. Define the design criteria for a body-on-a-chip system that is comprised of three or more organoid systems relevant to cancer development, control, or metastasis. Your system should contain multiple cell types and consider physiological conditions necessary for cells to function normally (as in the lung-on-a-chip and endothelialized microvessel devices from the text).

Answer:

Possible design features—a primary tumor compartment with stromal cells of the primary site connected to other compartments by microfluidics or vascularized microvessels. Possible other compartments include common metastatic sites (liver, lung, brain, bone) as well as a lymphoid compartment (lymph node, lymph vessels, skin, bone marrow, thymus, spleen, and liver). Physical design features will depend on the organs modeled, but mechanics, diffusion, and flow as well as multiple cell types relevant to the model designed should be considered.

2.5.12

Drug Delivery Systems

Biomaterials are outstanding platforms to ensure controlled, reproducible drug delivery. Furthermore, biomaterials play a critical role in enhancing or enabling drug efficacy for both traditional small molecule drugs and new classes of drugs, such as nucleic acids and proteins, that suffer from delivery challenges associated with instability and poor tissue localization. This chapter overviews drug delivery challenges as well as subsequent design and use of biomaterial drug delivery systems (DDSs) to overcome these hurdles. Fig. 2.5.12.1 summarizes the key aspects of DDS development from basic research to clinical applications that are discussed in this chapter. Although highly sophisticated, targeted, bioresponsive DDSs have only recently started delivering on ambitious promises, the concepts and approaches being developed are rooted in longstanding historical motivations. Therefore a brief overview of DDS history from its origins to today is first presented to provide a framework for understanding current biomaterial DDS design. For additional information on drug formulation and DDSs, please see these excellent in-depth reviews (Bader et al., 2014; Galaev and Mattiasson, 2010; Hilery et al., 2001; Hillery et al., 2002; Holowka and Bhatia, 2016; Mahato and Narang, 2018; Saltzman, 2001; Sinko, 2017).

History of DDS Development

Routine, periodic drug administration to achieve therapeutic efficacy has been used for more than 150 years. In the 1850s, John Snow documented how periodic chloroform inhalation maintained anesthetizing effects throughout surgical procedures (Snow, 1858). In the early 1920s, Frederick Banting, Charles Best, and John Macleod identified that well-controlled, routine administration of insulin was necessary to treat diabetes (Herring, 1924; Banting and Best, 1922). These findings led to an early understanding of the typical "peak and trough" pharmacokinetics (PK) curve of drugs (see the section "DDSs to Improve Drug Pharmacokinetics"), which preceded the great advances in DDS development during the 20th century.

Pharmaceutical formulations capable of prolonging drug activity and reducing dosing frequency entered the market in the early 1950s (Fig. 2.5.12.2). In 1952, Smith Kline & French introduced the first commercial controlled-release formulation product, known as Dexedrine Spansules (Park, 2014). This product consisted of macrospheres coated with a "wax-fat" layer (e.g., a mixture of glyceryl monostearate and bees wax), a formulation now commonly known as a reservoir, of varying thickness to control capsule dissolution and drug release (Blythe, 1956). However, the PK of such products varied greatly from patient to patient. In 1956, Riker Laboratories, Inc. introduced the first Food and Drug Administration (FDA)-approved pulmonary DDS, the pressurized metered dose inhaler, and dramatically advanced the therapeutic aerosol industry (Stein and Thiel, 2017; Anselmo and Mitragotri, 2014). These events marked the beginning of what has been defined as the first

generation of drug delivery (i.e., 1950–80) (Fig. 2.5.12.2) (Park, 2014).

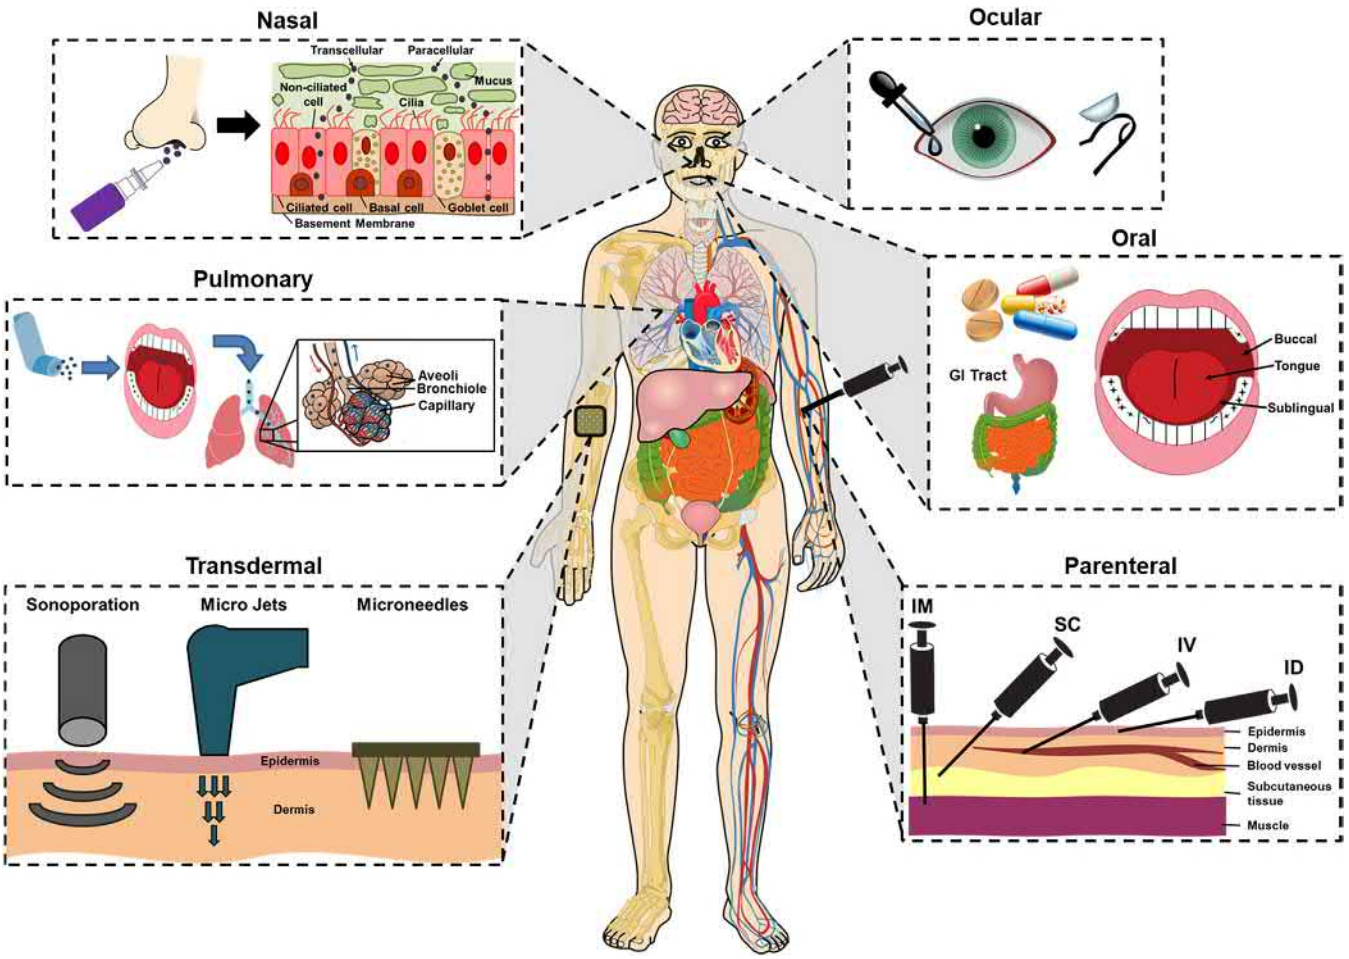
In the mid-1960s, Alejandro Zaffaroni, inspired by his biochemistry and endocrinology training, envisioned DDSs that would release drugs with reproducible and predictable kinetics, independent of the patient (Hoffman, 2008; Urquhart, 2000; Zaffaroni, 1991). Simultaneously, Judah Folkman showed that a capsule made of silicone rubber (later termed "Silastic") filled with drug, e.g., a reservoir, enabled sustained release (Folkman and Long, 1964). This concept led to the first zero-order reservoir DDS (Hoffman, 2008). Zaffaroni founded the first company dedicated to the concept of controlled drug delivery in 1968, Alza Corp., and Folkman was enlisted to head the Scientific Advisory Board (Hoffman, 2008). In 1971, Alza Corp. defined the key components of a DDS as "a drug delivery module comprising the drug, rate controller, and energy source" that were housed in a "platform" (Zaffaroni, 1991). The first controlled DDS products based on this definition were macroscopic designs with reservoirs of constant drug concentration enclosed in rate-controlling membranes made of polymers, such as Silastic or poly(ethylene-*co*-vinyl acetate) (Table 2.5.12.1). These first-generation DDSs employed different release mechanisms, including dissolution-, diffusion-, osmosis-, and ion exchange-based mechanisms, to produce devices that exhibited zero-order release rates to maintain constant drug plasma concentrations (Park, 2014). As such, this period established the basic understanding of DDSs and is characterized by the macroscopic size scale of DDSs developed (Fig. 2.5.12.2) (Park, 2014; Hoffman, 2008).

The second generation of drug delivery (1980–2010) included both micro- (~1980s) and nano- (~1990–2000s) sized DDS as well as "smart" DDS technologies (Fig. 2.5.12.2) (Park, 2014; Hoffman, 2008). The new technologies included depot DDSs using polymer microparticles, hydrogels, or phase-separated formulations (Park, 2014; Binauld and Stenzel, 2013). Many of these DDSs, such as the first FDA-approved matrix/monolithic depot DDS, Zoladex and Lupron introduced in 1989 (Park, 2014; Anselmo and Mitragotri, 2014; Zhang et al., 2013), were based on polyesters, such as poly(lactic acid) and poly(lactic-*co*-glycolic acid) (PLGA) that had been used previously in degradable sutures (Hoffman, 2008; Ulery et al., 2011). These degradable DDSs exhibited first-order release kinetics and were micron-sized particles. Furthermore, "smart" or environmentally triggered chemistries were developed to enable drug delivery in response to an external stimulus, such as pH or temperature (Park, 2014; Binauld and Stenzel, 2013).

During the late 1980s and 1990s, interest and activity rapidly grew in the development of injectable nanocarriers, which are discussed in the section "DDSs to Enhance Stability." This interest stemmed largely from two advances. First, the concept of poly(ethylene glycol) (PEG) conjugation to proteins to increase drug circulation times and decrease immunogenicity was spearheaded by Enzon Pharmaceuticals, Inc. in 1981 (Hoffman, 2016). Second, the discovery of the enhanced permeability and retention (EPR) effect in 1984 (Matsumura and Maeda, 1986; Maeda et al., 1985) provided strong rationale and motivation for the development of nanocarriers that passively target solid tumors, leading to the development of Doxil, a PEGylated lipososmal doxorubicin approved in 1995 (Hoffman, 2008; Barenholz, 2012). Both PEGylation and the EPR effect contributed to the idea of passive targeting discussed further in the section "DDS Targeting." Altogether, these advances aided in the development of site-specific and smart DDSs during the second generation of drug delivery (Fig. 2.5.12.2).

The third generation of drug delivery (i.e., 2010–present) (Fig. 2.5.12.2) has sought to modulate DDSs and understand how they behave in vivo to streamline development for licensure. Active targeting has also become a major focus in the field during this period and is discussed in more detail in the section "DDS Targeting." Global nanoscale DDS research and development has increased steadily since the United States pioneered the use of national funds for such efforts with the announcement of the National Nanotechnology Initiative in 2000 and the passage of the 21st Century Nanotechnology Research and Development Act in 2003 (Bobo et al., 2016; Jia, 2005). For example, the number of FDA investigational new drug approvals for nanoscale DDS products has increased since 2003 despite increasingly stringent FDA regulations and escalating costs for new drug formulation licenses to more than US$2.6 billion per drug (DiMasi et al., 2016). However, translation of actively targeted DDSs into the clinic has been slow and no targeted DDS has been approved to date.

Although many of the early DDS developments were focused on small molecule delivery, another recent focus has been on DDSs for macromolecular drug candidates, including peptides, proteins, and nucleic acids (e.g., DNA and siRNA). Onpattro (e.g., patisiran), which was developed by Alnylam Pharmaceuticals, Inc. as a lipid nanoparticle DDS,



• **Figure 2.5.12.3** Summary of typical drug delivery routes. Additional drug delivery routes include topical, rectal, vaginal, and intrathecal (not shown). *GI*, Gastrointestinal tract; *ID*, intradermal; *IM*, intramuscular; *IV*, intravenous; *SC*, subcutaneous.

became the first FDA-approved RNAi drug in 2018 (Mullard, 2018). Ultimately, the third generation will be defined by the success of these innovative modulated and targeted DDSs in clinical applications (Abdelwahed et al., 2006).

The remainder of this chapter focuses on the biomaterials used in DDSs as well as the design challenges and approaches to overcome these hurdles, including pertinent examples in use and under development. For a more detailed overview of the interesting history of the DDS field from its origins until today, the reader is referred to several review articles (Park, 2014; Hoffman, 2008; Urquhart, 2000; Zaffaroni, 1991; Zhang et al., 2013; Bobo et al., 2016).

General Considerations in DDS Design

Routes of Drug Delivery

Common routes of drug delivery for conventional drugs are oral, parenteral, transdermal, nasal, ocular, pulmonary, rectal, vaginal, and intrathecal (Fig. 2.5.12.3). Oral administration has excellent patient compliance and ~90% of current conventional drugs are administered via this route. In fact, tens of billions of pills are annually consumed worldwide for aspirin alone (Anselmo and Mitragotri, 2014). However, oral delivery suffers from challenges associated with the harsh environments of the oral cavity, stomach, and intestines, as well as poor transport across the epithelial mucosal layer of the intestine, which is discussed further in this chapter (see the section "DDS Design to Overcome Biological Barriers"). Moreover, after systemic adsorption, orally delivered drugs are subject to first-pass metabolism by intestinal and liver enzymes, which results in drug degradation upon initial administration, thereby reducing unaltered drug concentration in the blood. Parenteral administration, accounting for more than 10 billion annual drug administrations worldwide (Kermode, 2004), includes intravenous, subcutaneous, and intramuscular injections. The parenteral route ensures that effective drug concentrations are rapidly achieved but suffers from poor patient compliance due to injection site pain (Spain et al., 2016; Rubin et al., 2009; Zambanini et al., 1999; Deacon and Abramowitz, 2006). Transdermal delivery has excellent patient compliance but has traditionally been limited to drugs that are small and lipophilic. Nasal, pulmonary, and vaginal routes are also of interest due to high epithelial surface area, leading to rapid drug efficacy; however, due to challenges associated with delivery across the epithelial mucosa,

these routes are also limited to small, lipophilic compounds. DDS designs seek to enhance drug efficacy and/or enable new routes of administration that avoid adverse side effects, address low patient compliance, or overcome biological barriers as discussed in the section "DDS to Overcome Biological Barriers."

DDS Biomaterials Design Considerations

As highlighted previously in Chapter 1.1.1, a biomaterial is "a material intended to interface with biological systems to evaluate, treat, augment, or replace any tissue, organ or function in the body," with a focus on "treat" for DDSs. All biomaterials, including DDSs, must be biocompatible, that is, perform as designed without adverse effects. Thus DDSs should deliver drugs at the intended concentration, with appropriate kinetics, and to the target tissue. Behavior deviating from this expectation could result in adverse events or even death. Therefore understanding how biomaterials interact with the body is critical for DDS design. DDS biomaterials have the potential to interact with target and off-target tissues, adsorb proteins, and potentiate immune reactions. Biocompatibility is highly dependent upon DDS route of delivery; systemic introduction has significantly different expected interactions than transdermal, oral, or even depot-based delivery systems. Although many biomaterial properties are already highlighted in this textbook (see Section 1.2), this section will focus on the important aspects of biomaterials design with respect to DDS development.

Biomaterials Used in DDSs

Of the three main classes of biomaterials (metals, ceramics, and polymers), polymers are the most common platform for DDSs. Polymers have many advantages over other classes. Polymers can be fabricated into complex shapes and structures with a wide range of bulk compositions and physical properties. Furthermore, polymers have tunable chemistries, including controllable, responsive properties (e.g., stimuli responsive), yet allow for robust and flexible conjugation or incorporation of various drug classes. Synthetic rather than natural materials are often utilized as they are amenable to formation by controlled processes, which lead to highly reproducible structure–function relationships. The reader is encouraged to review Chapter 1.3.2 for details about synthesis and characterization of polymeric biomaterials (Cabral et al., 2018).

DDS Biomaterial Properties

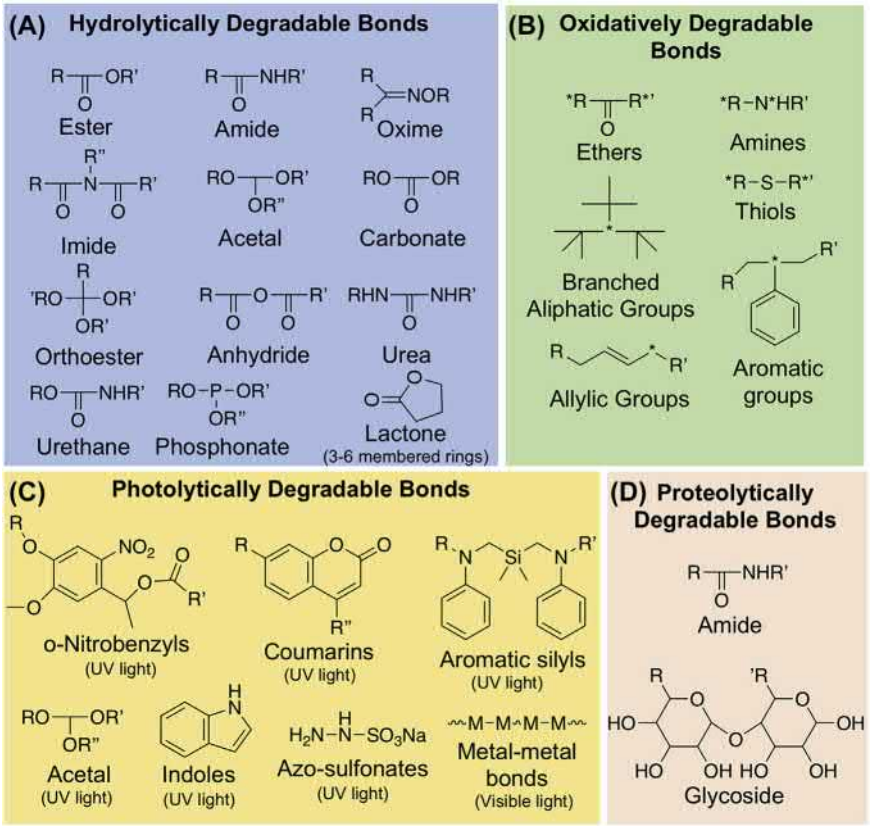
Degradation

DDSs can be designed from both nondegradable and degradable materials to align with the intended application. For implanted DDSs, degradable materials can be used to control drug release, which is discussed in greater detail within the section "DDSs to Improve Drug Pharmacokinetics," and avoid secondary retrieval surgeries and outcomes associated with long-term biomaterial persistence. As discussed in Chapter 1.3.2, degradation can be controlled or uncontrolled (unintended) but falls into one of four classes: hydrolysis, oxidation, photolysis, and proteolysis. Briefly, hydrolytic degradation requires electrophiles susceptible to nucleophilic attack by the hydroxyl oxygen of water. Hydrolytically degradable groups include esters, amides, oximes, urethanes, urea, carbonate, acetal, phosphonate, anhydride, lactones, and imides (Fig. 2.5.12.4A). Oxidation is an inherently uncontrolled degradation mechanism that occurs when free radicals, resulting from inflammatory reactions, abstract hydrogens from branched aliphatic hydrocarbons, phenols, or other aromatic groups, thiols, amines, ethers, and carbon–carbon double bonds, causing polymer chain scission (Fig. 2.5.12.4B). Although photolysis or photodegradation is common for drugs, only recently has it been exploited to controllably degrade/alter biomaterials (Pasparakis et al., 2012; Watanabe and Ohtsuki, 2016). Light-sensitive functional groups include nitrobenzyl derivatives, coumarins, azo sulfonates, metal–metal bonds, indoles, vinyl ketones, and aromatic silyl derivatives (Pasparakis et al., 2012; Watanabe and Ohtsuki, 2016). Chemical structures and requisite wavelength ranges mediating photoreaction of these chemical moieties are shown in Fig. 2.5.12.4C. Finally, proteolysis of natural materials, including carbohydrate, glycoprotein, protein, and proteoglycans, occurs when enzymes attack amides and glycosidic linkages (Fig. 2.5.12.4D).

DDS degradation depends on the relative rates of degradation and diffusion by the reactant (e.g., water, radicals, photons, or enzymes). This rate is a function of biomaterial hydrophilicity, crystallinity, surface area to volume, and pore size, as discussed in Chapter 1.3.2. For example, the highly crystalline anhydride-based polymers that comprise the biodegradable polymer Gliadel undergo surface degradation, while less crystalline PLGA-based polymers typically bulk degrade (Shoichet, 2009). Both nondegradable and degradable materials may succumb to biological responses, such as inflammation, that can cause either unexpected or expedited degradation. If the biological environment deviates significantly due to atypical inflammatory responses (e.g., excessively acidic pH or increased reactive oxygen/nitrogen species generation), degradation, and therefore drug release rates, may be increased (Helle et al., 2002; Heller, 1990; Heller et al., 2000, 2002).

Surface Properties

As with any biomaterial, surface properties are a key design parameter for DDSs. Surface properties are particularly important for systemically delivered DDSs and implantable systems since surface interactions will control cell–material behaviors that affect drug delivery. Surface properties, such as hydrophilicity, roughness/curvature, and surface chemistry, lead to different levels of protein adsorption (as discussed in Chapter 1.2.4). If a permanent implant or depot is used, the repertoire of cells at the implant site can interact directly with the biomaterial or adsorbed proteins, leading to acute and possibly chronic inflammation or a foreign body reaction (FBR) (see Chapter 2.2.2). These reactions may



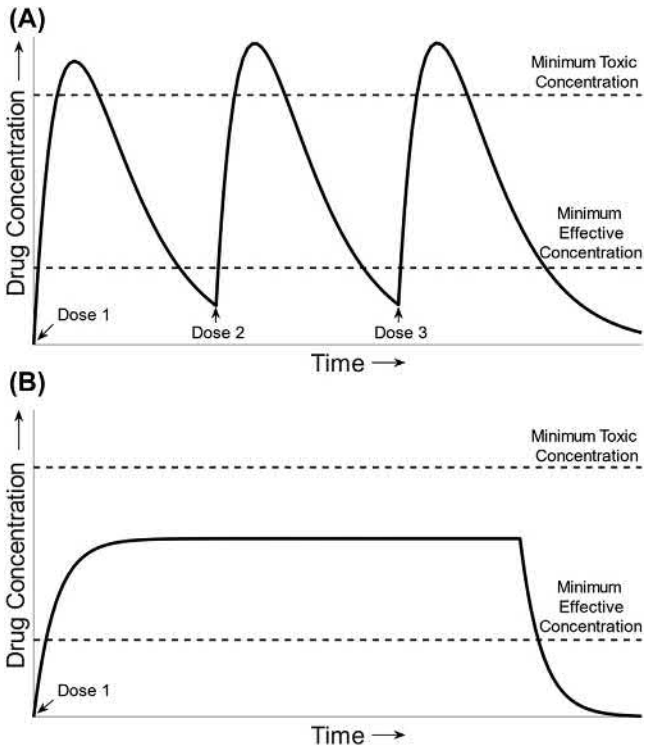
• **Figure 2.5.12.4** (A) Hydrolytically, (B) oxidatively, (C) photolytically, and (D) proteolytically degradable groups found within biomaterials and drugs that are susceptible to controlled or uncontrolled degradation. *Indicates group susceptible to radical attack during oxidation, R, R′, R″ are generic hydrocarbon groups (Mahato and Narang, 2018; Pasparakis et al., 2012; Temenoff and Mikos, 2009). *UV*, Ultraviolet.

compromise controlled drug release. For example, inflammatory responses include reactive oxygen and nitrogen species and enzyme production. These reactants can expedite material degradation or cause uncontrolled degradation, which will lead to dramatic changes in drug release kinetics. Note, uncontrolled degradation of polymers is discussed in depth within Chapter 1.3.2. The FBR is characterized by collagenous capsule formation around foreign materials that is a diffusional hindrance to drug release. This effect can be seen even with inert, unreactive biomaterials commonly used in DDSs, such as poly(tetrafluoroethylene) (Teflon), poly(urethanes), and poly(dimethylsiloxanes) (PDMSs), where capsules of ~100 μm thick have been described (Ratner, 2002). Fibrous encapsulation due to FBR has been credited for inadequate control over steroid release from Norplant, an implantable device formed from PDMS-based Silastic (Ratner, 2002). Furthermore, FBR-related inconsistencies with drug delivery may also underpin the predominance of implantable depot applications within immune privileged tissues, such as the eye, brain, and prostate (e.g., eye: Ocusert, Vitrasert, Restisert, Ozurdex; brain: Gliadel; prostate: Vantas, Viadur).

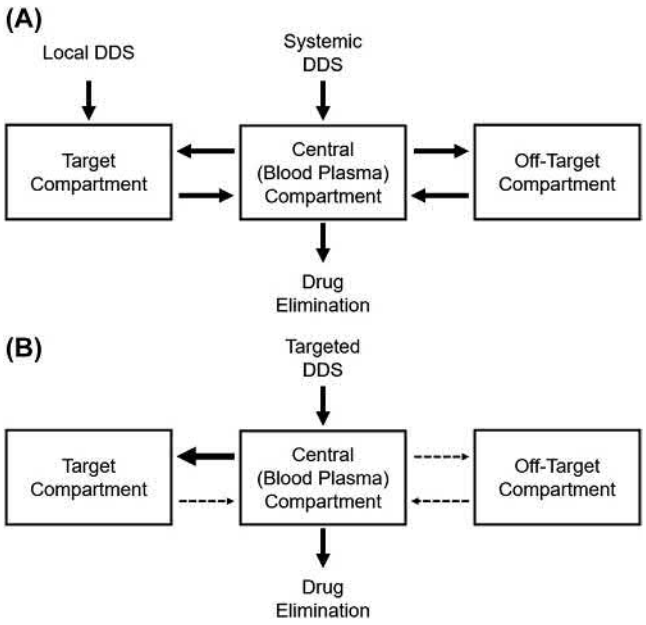
For parenteral DDS, protein adsorption can also occur (Cedervall et al., 2007; Monopoli et al., 2012) and dramatically change naïve biomaterial surface properties, which may impact circulation time and/or biodistribution. Biomaterial geometry, size, charge, and surface chemistry influence the protein–corona composition and adsorbed protein structure, and as many as 300 different proteins have been shown to be bound to nanoparticle surfaces irrespective of material class, charge, or hydrophilicity after 30-s incubations in serum (Tenzer et al., 2013; Huhn et al., 2013; Lundqvist et al., 2008; Fleischer and Payne, 2014; Parveen et al., 2017). Protein adsorption can then result in nonspecific cellular uptake by immune cells in the mononuclear phagocytic system (MPS) residing in the liver, spleen, and lymph nodes (Blanco et al., 2015).

Mechanics

The mechanical properties of implantable or transdermal DDSs can also impact drug delivery success. The relative crystallinity and elastomeric nature of polymeric systems (see Chapter 1.3.2) can affect resistance to mechanical forces exerted during placement (Temenoff and Mikos, 2009). If the material cracks or breaks during placement or duration of use, the increased surface area can lead to significant alterations in drug release due to a greater surface area-to-volume ratio and decreased biocompatibility due to an amplified FBR (Temenoff and Mikos, 2009). Altered inflammatory and/or FBR reactions can also result from tissue mechanical damage due to mismatched biomaterial depot and tissue properties (Temenoff and Mikos, 2009).



• **Figure 2.5.12.5** Pharmacokinetics (PK) curves of plasma concentration of a drug versus time for two types of delivery systems: (A) typical bolus PK for multiple dosing with oral tablets or injections; (B) zero-order PK for one dose of controlled drug delivery from a specific formulation or device.



• **Figure 2.5.12.6** A basic pharmacokinetics compartment model showing the interactions between blood plasma, target tissues, and off-target tissues. (A) Typical systemic drug delivery delivers to blood plasma either directly (i.e., intravenous injection) or indirectly (i.e., oral pills), which is transported to the target and off-target tissue. Accumulation in other compartments occurs through transport processes that typically follow first-order kinetics. Elimination of most drugs ultimately occurs by excretion by the kidneys, and hence is dependent on drug plasma concentration. Local delivery in the target tissue bypasses compartmental transport into the target but does not affect transport kinetics out of the target compartment and into others. (B) Targeted drug delivery systems (DDSs) alter the transport kinetics by increasing the affinity for the target compartment, which is described in the section "DDS Targeting".

DDSs to Improve Drug Pharmacokinetics

Pharmacokinetics

One of the primary motivations for the development of DDSs is to improve the therapeutic window (TW) of drug-based therapies. The TW is the range of drug concentrations that produce therapeutic benefit without causing intolerable harm. This concept is related to the therapeutic index (TI), which is the ratio of the minimum toxic concentration divided by the minimum effective concentration. Drugs with a narrow TI are more difficult to use clinically and correlate with increased complication rates compared with wider TI drugs (Blix et al., 2010). Typically, TI is intrinsic to a drug; however, DDSs can be used to dramatically improve its apparent TW. The effects of DDSs on TI are generally PK and consist of release rate modulation, dosage control, and localization.

The relationship between PK, the TW, and drug delivery is demonstrated in Fig. 2.5.12.5. Administration of a single large dose follows typical first-order PK (e.g., oral delivery) producing a spike in blood plasma drug concentration where the desired therapeutic concentration is achieved only for a short period of the time postadministration. This rise and fall follows the *LADME* sequence. *LADME* stands for *Liberation* of the drug from the formulation, *Absorption* of the drug into the blood, *Distribution* of the drug throughout the body, including action of the drug at various sites—especially at and within cells, *Metabolism* of the drug, usually in the liver, and finally *Elimination* of the drug from the body, usually by excretion through the kidneys in the urine. Elimination rate is typically described in terms of a first-order half-life ($t_{1/2}$), which is the time required for maximal blood plasma drug concentration to decrease by half. Note that in the absence of a drug delivery vehicle or excipients in a formulation, the "L" can be disregarded. Zero-order release maintains constant drug concentration in the blood plasma, ideally within the TW, after an initial equilibration period. The area under the PK curve (AUC) of drug concentration is used to quantify drug exposure. Higher AUC indicates greater drug exposure over time and is a useful comparison for different DDS systems. Additionally, the DDS can be used to localize drug concentrations to specific PK compartments, concentrating drug in target tissues rather than off-target tissues (Fig. 2.5.12.6). DDSs can also improve bioavailability, defined as the proportion of unaltered drug after administration, by reducing drug–serum protein binding and premature enzymatic degradation.

Many DDS strategies improve AUC by reducing elimination rate to increase $t_{1/2}$. Conjugation of drugs, including proteins and small molecules, and DDSs to hydrophilic

PEG ("PEGylation") improve the circulation time by reducing elimination in the kidneys through increased solubility and physical size (Veronese and Pasut, 2005). PEGylation is particularly useful for drugs that are rapidly eliminated and has been shown to enhance therapeutic utility of antibody therapeutics and chemotherapy agents, such as Taxol and doxorubicin (Pasut and Veronese, 2009). Albumin-functionalized conjugates, such as paclitaxel-based Abraxane, have similar circulatory PK effects to PEGylation with benefits that include reduced drug chemistry modification and improved bioavailability (Green et al., 2006). However, albumin conjugates suffer from preferential liver and tumor biodistribution (Kratz, 2008). Nanocarrier systems, such as liposomes, polymeric nanoparticles, and others (see the section "DDSs to Improve Drug Solubility") increase circulation time of drugs as they are too large (>4–6 nm) to pass through the glomeruli of the kidneys (Wilhelm et al., 2016). In cases where drug elimination is similar to or faster than absorption or pharmacodynamic effects, a DDS can be critical for the clinical application of a drug candidate.

Dosage and Distribution Control

DDSs allow better control of dosage to match the TI. Control can come via feedback (i.e., electrical control via sensors or from physical interactions with the body) or simple rate-limited release to improve convenience or better match the therapeutic concentration of a drug with a narrow TI. As an example, insulin is a hormone with a narrow and rapidly changing therapeutic concentration that is dependent upon food intake and composition, activity level, and blood glucose concentration. A fully integrated glucose sensor coupled with insulin release could act as an artificial pancreas and remove the burden of constant monitoring and calculation of insulin dosages, providing improved quality of life and reduced risk of hypo- or hyperglycemia. Current insulin delivery pumps, such as wearable modules that deliver insulin through a persistent subcutaneous injection site, offer excellent control over blood glucose levels and improve patient compliance, but still require user input despite attempts at automation (Bergenstal et al., 2010). One biomaterial DDS solution under development is the use of phenylboronic acid, a glucose-responsive moiety, as a sensor for insulin release from systemically delivered mesoporous silica nanoparticles (Zhao et al., 2009). DDSs designed for convenience include extended-release oral capsules, transdermal delivery patches, and implanted depots, which are covered in the section "DDSs to Overcome Biological Barriers."

Controlling Drug Release Kinetics

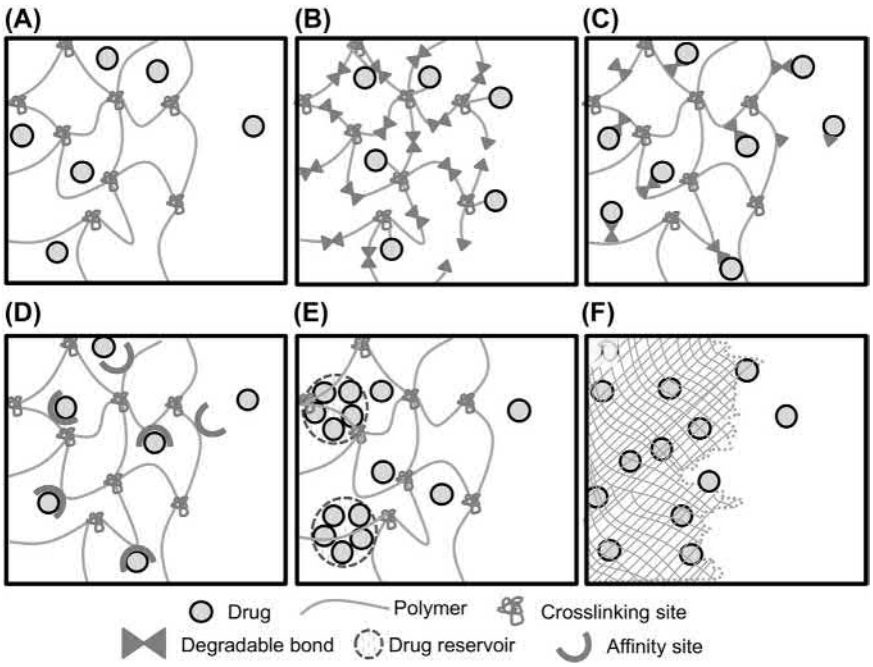
Modifying drug delivery rate can be sufficient to ensure maintenance of the TW. Drug release rate from a DDS can be controlled via several mechanisms, including diffusion, dissolution, affinity, swelling, and ion exchange (Fig. 2.5.12.7). Table 2.5.12.2 lists examples of FDA-approved DDSs that exploit these delivery mechanisms. Diffusion from DDSs is common and driven by concentration gradients. The general categories for these DDSs are matrix or reservoir-type systems. Matrix-based systems, which are also known as monoliths, contain drug uniformly dispersed within the material and are commonly accompanied by an initial "burst" release of drug upon placement due to rapid diffusion of surface-localized drug. If the material is hydrophilic, swelling mediates diffusion-controlled release. If the material is hydrophobic, drug releases after water penetration enables a diffusive path. In addition to "burst" release, diffusive release from matrix devices inherently follows first-order kinetics and requires coupling with degradable DDS materials to modify the release profile. Reservoir systems contain drug within an inner core surrounded by a permeable membrane layer that controls release and can achieve zero-order release with appropriately designed membrane–drug combinations.

Dissolution is liberation of matrix-entrapped drug as a function of matrix degradation or dissolution rate (Fig. 2.5.12.7). The kinetics of drug delivery by dissolution is controlled by DDS properties, including pore size, degradable bonds, and hydrophobicity, rather than drug solubility and mobility, as in diffusion. However, drug release is often dependent upon both drug diffusion and dissolution, as dissolution or degradation alters the DDS pore size, thus liberating greater amounts of drug over time.

Affinity-based systems exploit noncovalent interactions, including electrostatic, van der Waals, hydrophobic, and hydrogen-bonding interactions between drug and DDS to control drug release rate (Fig. 2.5.12.7). Affinity-based DDS release rates are tunable and based on the association constant of drug–ligand interactions, which allow for release of multiple drugs with various kinetics. However, a priori identification of affinity ligands is necessary for affinity-based release. Several ligands have been identified; these include cyclodextrin, heparin, albumin, and various cationic DDSs to release a variety of drugs, including small molecule antibiotics, proteins, and nucleic acids (Bader et al., 2014; Fu et al., 2011; Oss-Ronen and Seliktar, 2011; Rivera-Delgado et al., 2016; Vulic and Shoichet, 2014; Wang and von Recum, 2011).

Charged drug molecules can be loaded into an ion exchange resin to provide control over release rate as a function of the ionic environment. Ion exchange is particularly suitable for enteral delivery routes, as ion exchange resins are typically inert, functionalized poly(styrene) derivatives formed into micron- or millimeter-scale beads that pass through the digestive tract safely (Guo et al., 2009). These resins have found commercial success in many over-the-counter extended release formulations (Table 2.5.12.2).

Swelling of osmotic pumps can control mechanical dispensing systems to achieve variable drug release (Table 2.5.12.2). An osmotic pump is a compartment surrounded by a semipermeable membrane typically composed of cellulose acetate. The membrane controls diffusion of water into the osmogen: a material with high osmotic pressure, such as sugars or salts, embedded into a carrier such as poly(ethylene oxide) or poly(hydroxypropyl methylcellulose). The influx



• **Figure 2.5.12.7** Mechanisms of drug release from drug delivery systems (DDSs). Release of drugs from DDSs can be controlled by a number of mechanisms. (A) Drug is encapsulated within a DDS with mesh/pore size to allow for diffusive release of the encapsulated drug with optional diffusional membrane barrier. (B) Drug is tethered to a DDS that degrades hydrolytically, oxidatively, photolytically, or proteolytically to control release. (C) Drug is tethered to the DDS by a degradable tether, and released upon linker cleavage via hydrolysis, oxidation, photolysis, or proteolysis. (D) Diffusive release of encapsulated drug is controlled by affinity interactions between the DDS and the drug. (E) Diffusive release of encapsulated drug is prolonged by delayed release of the drug from a matrix or reservoir. (F) Drug is encapsulated within a degradable DDS and released by dissolution as the material degrades. Not to scale. (Adapted from Van Hove, A.H., Benoit, D.S., 2015. Depot-based delivery systems for pro-angiogenic peptides: a review. Front. Bioeng. Biotechnol. 3, 102.)

of water to the osmogen increases the pressure inside the container, forcing the drug or drug carrier through microdrilled pores within the membrane. There are many variations of osmotic pumps, from the single-component elementary osmotic pump (Theeuwes, 1975) to multistage, multichamber systems, all of which can range from ingestible pills to implantable devices. Release kinetics can be tuned from zero-order to complex profiles simulating multiple separate doses (Malaterre et al., 2009). More detailed reviews of osmotic pumps can be found within Malaterre et al. (2009) and Herrlich et al. (2012).

DDSs to Improve Drug Solubility

Drug solubility is vital for successful delivery. Dose variations, poor and unknown absorption profiles, low bioavailability, and subpar therapeutic efficacy are limitations associated with systemically delivered, poorly soluble, small molecule drugs. The intrinsic link between solubility and drug efficacy is described by Lipinski's rule of 5, which predicts that compounds with molecular weight <500 Da, H-bond donors ≤5, H-bond acceptors ≤10, and octanol–water partition coefficient (log P) <5 are more likely to succeed clinically due to better absorption and distribution (Choy and Prausnitz, 2011). However, approximately 40% of approved small molecule drugs and 70%–90% of pipeline agents are poorly soluble (<100 μg/mL) (e.g., do not follow Lipinski's rule of 5) (Kalepu and Nekkanti, 2015). Conventional approaches to improve drug solubility include salt formation, pH adjustments, and prodrug formulations. Unfortunately, these conventional strategies are not applicable for all drug candidates. Therefore colloidal and noncolloidal DDSs have been developed to enhance drug solubility. Many of these approaches also have the added benefit of improving drug stability, biodistribution, and cell uptake. However, for simplicity this section will focus only on improved solubility. Drugs can be dissolved, entrapped, encapsulated, chemically bonded, or adsorbed on DDSs and released by diffusion, dissolution, or swelling (Fig. 2.5.12.8). A brief introduction to these DDSs follows and highlights examples of solubility-enhancing DDSs with their routes of delivery, advantages and disadvantages, and the biomaterials employed (Table 2.5.12.3). While this section only focuses on nanoscale DDSs due to space constraints, there are similar approaches to enhance drug solubility using both micro- and macroscale formulations, such as tablets and capsules. For more comprehensive reviews, the interested reader may reference Chapter 1.3.8 and Cabral et al. (2018), Cerpnjak et al. (2013), Callender et al. (2017), Prasad et al. (2018), Date et al. (2010), Narvekar et al. (2014), Stegemann et al. (2007), and Letchford and Burt (2007).

TABLE 2.5.12.2 Sample of Clinically Approved Drug Delivery Systems (DDSs) With Various Release Mechanisms

Clinically Approved DDS	Release Mechanism	Polymer	Degradable Bond	Drug(s)	References
Gliadel	Dissolution	Bis(*p*-carboxyphenoxy) propane-*co*-sebacic acid	Anhydride	Carmustine, temozolomide	Zhang et al. (2013); Bock et al. (2010); Lawson et al. (2007)
Zoladex, Lupron Depot, Sandostatin LAR, Neutropin depot, Trelstar, Eligard, Risperdal Consta, Vivitrol, Somatuline, Ozurdex	Diffusion and Dissolution	Poly(lactic-*co*-glycolic acid)	Ester	Goserelin acetate, Leuprolide acetate, polifeprosan 20/ carmustine, glucose/ octreotide acetate, recombinant human growth hormone, triptorelin pamoate, minocycline, Leuprolide acetate, risperidone, naltrexone lanreotide, dexamethasone	Zhang et al. (2013)
Atridox	Diffusion and Dissolution	Poly(lactic acid)	Ester	Doxycycline hyclate	Zhang et al. (2013)
Capronor	Diffusion and Dissolution	Poly(caprolactone)	Ester	Levonorgestrel	Ulery et al. (2011)

• **Figure 2.5.12.8** Schematic showing different drug delivery system platforms discussed herein.

Colloidal DDSs

Colloidal DDSs include a variety of nanoscale carriers that improve drug solubility by incorporating drug within a reservoir or matrix. Emulsions are early examples of colloidal DDSs. Because of their long-standing use in a variety of industries, including cosmetics, food, and agriculture, emulsions inevitably evolved into DDSs. Emulsions (Fig. 2.5.12.8) are heterogeneous dispersions of oil and water that improve drug solubility by increasing the surface area of the drug. The idea that increasing drug surface area improves drug solubility subsequently propelled the development of more advanced nanocarriers, including nanospheres, solid-lipid nanoparticles (SLNs), nanocapsules, micelles, polymersomes, and liposomes.

Nanospheres and SLNs are composed of a solid lipid or polymer matrix core that loads a variety of hydrophobic drugs (Fig. 2.5.12.8). Despite being formulated with different materials (i.e., lipids, polymers), drug loading in nanospheres and SLNs is achieved by selecting a core material with excellent drug solubility. Additional information can be found in Table 2.5.12.3.

Nanocapsules, micelles, polymersomes, and liposomes (Fig. 2.5.12.8) can be broadly categorized as reservoir DDSs. Specifically, nanocapsules have hydrophobic liquid or solid cores surrounded by a single layer of polymer or lipid corona, while micelles form a hydrophobic core and hydrophilic corona through the self-assembly of amphiphilic polymers (Fig. 2.5.12.8) (Letchford and Burt, 2007). The core of nanocapsules and micelles may also serve as a reservoir for hydrophobic drugs that can also enhance drug stability. In these carriers, the size of the hydrophobic region and drug–core interactions control loading capacity. A major advantage of nanocapsules and micelles is their stable core, which reduces premature drug loss. Specifically, micelles are thermodynamically stable, and are associated with low critical micelle concentration, allowing for maintenance of loaded material for long periods of time.

Polymersomes (Fig. 2.5.12.8) are amphiphilic copolymers, while liposomes are amphiphilic lipids that self-assemble into bilayered structures (Fig. 2.5.12.8). Polymersome formulations are complex and depend on the weight fraction of the hydrophilic block to ensure uniform distribution (Letchford and Burt, 2007; Discher et al., 2007; Rideau et al., 2018). Both polymersomes and liposomes enable the delivery of various molecules, including small molecule hydrophobic drugs within the bilayer and, in contrast to other carriers, hydrophilic molecules (e.g., nucleic acids or proteins) within the core (Rideau et al., 2018). Similar to the other carriers, polymersome and liposome drug loading are highly dependent on drug interactions with the carrier's bilayer or core. To reduce rapid clearance of liposomes, PEG was introduced as a surface modification on Doxil, the first colloidal DDS approved by the FDA in 1995 (Lian and Ho, 2001). Since then, additional liposomal formulations have adapted PEG surface modifications resulting in various marketed DDSs, as listed in Table 2.5.12.3.

Colloidal DDSs range from core-based carriers to more complex bilayered structures. Regardless of the carrier type, drug loading and drug release kinetics are dictated by the lipid/polymer composition, drug–carrier interactions, and nanoparticle size (Prasad et al., 2018; Allen and Cullis, 2013; Kataoka et al., 2001; Mukherjee et al., 2009).

Noncolloidal DDSs

Dendrimers are highly branched polymer chains that are stable and easy to modify (Table 2.5.12.3) (Prasad et al., 2018; Marx, 2008; Boas and Heegaard, 2004; Morgan et al., 2006). Dendrimers have evolved over time from simple structures that enable covalent or electrostatic drug loading to more complex hydrophobic-to-hydrophilic structures that enable core encapsulation of hydrophobic drugs (Marx, 2008; Boas and Heegaard, 2004; Duncan and Izzo, 2005; Li et al., 2007). Examples of dendrimers, including the most prominent, poly(amidoamine) (PAMAM) (Duncan and Izzo, 2005; Esfand and Tomalia, 2001), are provided in Table 2.5.12.3, and information about the various biomaterials used for dendrimer formulations can be found in the following references (Buhleier et al., 1978; Hawker and Fréchet, 1990; Turnbull and Stoddart, 2002).

Polymer–drug conjugates (PDCs) are made of three components: the polymer, a linker, and the drug, as shown in Fig. 2.5.12.8. PDCs can achieve high drug loading via covalent linkages and exhibit tunable properties through

TABLE 2.5.12.3 Summary of Drug Delivery Systems (DDSs) That Address Poor Aqueous Solubility With Associated Advantages, Disadvantages, and Examples

DDS Type	Advantages	Disadvantages	Examples	Material	Delivery Routes	References
Emulsions	Liquid formulations facilitate faster absorption, adaptable for hydrophobic and hydrophilic drugs	Toxic excipients, phase separation over time, rapid clearance	TOCOSOL paclitaxel, Norvir, Restasis, cyclosporine A	Soybean, cottonseed, and safflower oils, Tween, Pluronics, etc.	Oral, parenteral, transdermal, ocular	Prasad et al. (2018); Narvekar et al. (2014)
Nanocapsules	Chemically stable, biocompatible, and reproducible	Delayed release of active drugs, loading capacity dictated by size of reservoir	SOLUDOTS-PTX	Poloxamer	Parenteral	Kothamasu et al. (2012)
Solid-Lipid Nanoparticle (SLN)	Easy scale-up, high lipid content, affordable, biocompatible lipids used	Limited drug loading potential, contains a mixture of colloidal structures, rapid clearance	Ciprofloxacin-loaded SLNs	Triglycerides, fatty acids, steroids, waxes, etc.	Oral, parenteral, topical	Zhang et al. (2013); Mukherjee et al. (2009)
Nanosphere	Flexibility in how drug is incorporated, tunable polymer	Rapid clearance, poor reproducibility	Eligard	MePEG-*b*-PLA, PEG-*b*-PDLLA, PEG-PCL, etc.	Parenteral	Ventola (2017)
Micelles	Thermodynamically stable, high drug loading, controllable release kinetics	Complex polymer chemistry	Estrasorb, Genexol-PM[a]	PLGA, MePEG-*b*-PDLLA, MePEG-*b*-PCL, MePEG-*b*-PLDA, etc.	Topical, parenteral	Yokoyama (2011)
Liposomes, polymersomes	Adaptable for hydrophobic and hydrophilic drugs (both), stable and less permeability (polymersomes)	Immunogenicity, toxicity, and cellular uptake, poor circulation time (liposomes)	Doxil/Caelyx, Marqibo, Onivyde	Phospholipids, PEO-*b*-PBD, etc.	Parenteral	Discher et al. (2007); Lian and Ho (2001); Allen and Cullis (2013)
Dendrimer	Enables incorporation of diverse drugs, stable, size is controllable, easy to modify	Low yield, complex synthesis	VIvaGel[b]	PAMAM, PPI	Transdermal, oral, ocular, and pulmonary	Esfand and Tomalia (2001); Larson and Ghandehari (2012)
PDC	Selective delivery due to linker chemistry, can tune PK via conjugate molecular weight	Complex design, steric hindrance during drug incorporation	SMANCS, Oncaspar, Plegridy, Krystexxa	PEG, HPMA	Parenteral, topical	Larson Ghandehari (2012)

HPMA, Poly(*N*-(2-hydroxypropyl) methacrylamide); *MePEG*, methoxy(poly(ethylene glycol)); *MePEG-b-PLA*, methoxy(poly(ethylene glycol))-*block*-poly(D,L-lactic acid); *MePEG-b-PLDA,* methoxy(poly(ethylene glycol))-*block*-poly(ld–lactide); *PAMAM*, poly(amidoamine); *PDC*, polymer–drug conjugate; *PEG*, poly(ethylene glycol); *PEG-b-PDLLA*, poly(ethylene glycol)-block-poly(D,L-lactide); *PEG-PCL*, poly(ethylene glycol)-poly(ε-caprolactone); *PEO-b-PBD*, poly(ethylene oxide)-*b*-poly(butadiene); *PLGA*, poly lactic-*co*-glycolic acid; *PPI*, polypropylenimine; *SMANCS*, poly(styrene-*co*-maleic acid)-neocarzinostatin.

linker selection and molecular weight. However, PDCs can also diminish drug efficacy due to steric hindrance of conjugations close to or at drug active sites (Duncan, 2003; Ulbrich and Subr, 2010; Xu et al., 2015). Various biomaterials have been explored to develop PDCs, including PEG and poly(*N*-(2-hydroxypropyl) methacrylamide) (Table 2.5.12.3) (Ulbrich and Subr, 2010; Xu et al., 2015; Larson and Ghandehari, 2012).

Biomaterial DDSs Can Enhance Drug Stability

For various therapeutic compounds and biomaterial DDSs, instability can be a major hurdle to clinical success. The consequences of unexpected drug or DDS degradation—physically or chemically–are dire. These consequences include loss of potency, formation of toxic by-products, and for DDSs, loss of controlled delivery that may cause drug concentrations outside of the TW (subtherapeutic or toxic). Drug degradation mechanisms are similar to those discussed for DDSs (e.g., hydrolysis, oxidation, photolysis, and proteolysis), which can occur for all drug classes: small molecules, proteins/peptides, or nucleic acids. Use of DDSs has been shown to protect drugs from the various modes of degradation (Silva et al., 2018; Opanasopit et al., 2005), as detailed herein (Chono et al., 2008).

Small Molecule Drugs

Several small molecule drug candidates perceived to have excellent and selective therapeutic efficacy are unstable due to inclusive degradable groups. For example, esters and lactones are susceptible to hydrolysis and/or proteolysis by enzymes in the gastrointestinal (GI) (oral delivery) and serum proteins, such as albumin, in systemic circulation (Fig. 2.5.12.4) (Silva et al., 2018; Opanasopit et al., 2005; Dube et al., 2011; Di Martino et al., 2017; Ramezanli et al., 2017; Heredia et al., 2016; Montanari et al., 2016). For example, camptothecin and topotecan are potent chemotherapeutic drugs but include lactone rings making them susceptible to hydrolysis (Fig. 2.5.12.4A). Various approaches to protect these drugs include pH-responsive nanospheres of poly(2-hydroxyethyl methacrylate), liposomes, and SLNs (Silva et al., 2018; Iglesias et al., 2018). Another example is vitamin D3, which is a steroid that can undergo oxidation (Fig. 2.5.12.4B) or photolysis-mediated isomerization (Fig. 2.5.12.4C), thus hindering its biological efficacy (Ramezanli et al., 2017). Micelles comprised of PEG, desaminotyrosyl-tyrosine octyl ester, and suberic acid triblock copolymers have been exploited to protect vitamin D3 (Ramezanli et al., 2017).

Protein/Peptide Drugs

Protein and peptide therapeutics are a growing category of drug entities and have special requirements for stability. Protein therapeutics, such as antibodies and cytokines, as well as peptide therapeutics, can suffer from sequence-specific enzymatic degradation of amide bonds as well as nonspecific enzymatic activity. Additionally, the amino acid functional groups of histidine, tryptophan, methionine, and cysteine are subject to oxidation (Fig. 2.5.12.4B) and tryptophan can photodegrade (Fig. 2.5.12.4C). Various DDSs (i.e., PLGA microspheres, amphiphilic anhydrides, silicone elastomer reservoirs, hydrogel-based systems, and ethylene-*co*-vinyl acetate polymer matrices, etc.) have been explored to protect and controllably delivery proteins/peptides (Van Hove and Benoit, 2015; Patel et al., 2014). Hydrogel-based depot systems are the most commonly used DDSs for protein and peptide delivery with mechanisms of release summarized in Fig. 2.5.12.7.

Nucleic Acid Drugs

Effective delivery of nucleic acid drugs, including DNA, small RNAs, ribozymes, aptamers, and even CRISPR-Cas9, is of immense interest due to their ability to drug the "undruggable." Through mechanisms subverted from biology, nucleic acid drugs can inhibit, degrade, or alter DNA and/or RNA in ways not possible through traditional low molecular weight drugs or antibodies. However, nucleic acid drugs have significant stability challenges. While some nucleic acid base chemical modifications are protective (Behlke, 2008), generally, nucleic acids are susceptible to degradation by extracellular nucleases and exhibit short half-lives due to renal clearance. For this reason, the majority of nucleic acid-based drugs to undergo clinical trials have only been successfully developed for local delivery (Ozcan et al., 2015), and the development of DDSs to enable systemic delivery for nucleic acid drugs is of high priority (Giang et al., 2014).

Cationic DDSs are predominately used for nucleic acid delivery. Electrostatic interactions of cationic DDSs with anionic nucleic acids protect against enzymatic degradation and achieve nanoparticle formation, which triggers nonspecific intracellular uptake. After nanoparticle DDS uptake, intracellular trafficking through endolysosomes exposes the therapeutic to significant variations in pH (7.4–5) and degradative lysosomal enzymes. This pH gradient provides an environmental stimulus that can be exploited by DDS to escape lysosomal fate. Cationic polymers containing proton-accepting amine groups facilitate endosomal release by osmotic disruption through the "proton sponge" effect (Behr, 1996; Behr, 1997; Boussif et al., 1995; Lynn and Langer, 2000; Pack et al., 2000), which was first proposed by Behr and coworkers (Behr, 1996, 1997). By accepting protons during endosomal acidification, cationic polymers neutralize endosomes and inhibit the typical reduction in pH, resulting in a continued influx of protons and counterions (typically Cl^-). This proton influx causes the osmotic pressure inside the vesicle to increase, resulting in greater water influx, swelling, endosomal membrane disruption, and finally the release of the endocytosed cargo. There

are many examples of amine-containing "proton sponge" DDSs, including poly(dimethylaminoethyl methacrylate) (DMAEMA), poly(diethylaminoethyl methacrylate), poly(ethylenenimine), chitosan, poly(lysine), PAMAM, peptides, and cyclodextrin (Ozcan et al., 2015; Xiao et al., 2019; Sun et al., 2018; Smith, 2018; Li et al., 2018; Hong et al., 2018; Zhang and Wagner, 2017; Shi et al., 2017; Palmerston Mendes et al., 2017; Leiro et al., 2017; Ahmed, 2017; Pandey and Sawant, 2016; Miyata, 2016; Ho et al., 2016).

Polymers that are inert under physiological conditions and membrane disruptive at endolysosomal trafficking pH have also been used to prevent nucleic acid drug lysosomal degradation. Mechanistically, protonation of membrane-disruptive polymers causes a hydrophobic transition from an extended, soluble conformation into a compact, membrane interactive globule (Thomas and Tirrell, 1992; Thomas et al., 1994; Borden et al., 1987; Eum et al., 1989; Chen and Thomas, 1979). Membrane-disruptive DDSs include several polymeric and lipid-based formulations, including poly(propylacrylic acid) (PPAA), combinations of PPAA, butyl methacrylate, DMAEMA, and alkylamine-modified poly(styrene-alt-maleic anhydride) (Sun et al., 2018; Zhang and Wagner, 2017; Shi et al., 2017; Miyata, 2016; Buse and El-Aneed, 2010; Jabr-Milane et al., 2008; MacEwan et al., 2010; Sebiakin Iu and Budanova, 2006).

In a landmark achievement in drug delivery, Alnylam Pharmaceuticals' Onpattro (e.g., patisiran) received FDA approval in 2018, making it the first RNAi-based drug brought to market (Mullard, 2018; Hoy, 2018; Morrison, 2018). Developed to treat transthyretin-mediated liver amyloidosis, which is a rare but deadly genetic disease, patisiran is a particle formulation comprised of cholesterol and PEG-conjugated lipids. The lipid moieties contain ionizable amines that complex and protect the siRNA and trigger the proton sponge effect to escape lysosomal degradation upon cell uptake (Whitehead et al., 2014; Jayaraman et al., 2012; Akinc et al., 2008; Wolfrum et al., 2007). In addition to patisiran, numerous other nucleic acid drugs are currently in the developmental pipeline. Of the DDSs employed for systemic delivery of nucleic acids, nearly all are cationic and lipid-based nanocarriers (Ozcan et al., 2015). Continual improvements in rational design of DDSs, especially in controlled synthetic approaches enabling careful structure–function analyses, have the potential to ensure development of highly effective and safe nucleic acid-based therapeutics for clinical applications.

DDS Design to Overcome Biological Barriers

Many natural barriers exist to prevent free exchange of drugs within tissues and organs. The chemistry and function of these barriers vary among the protective outer epithelial layers, the water- and gas-permeable mucosal membranes, and the tightly interconnected phospholipid membranes of endothelial cells. This section briefly discusses these biological barriers and the ways in which DDSs have been designed to overcome them.

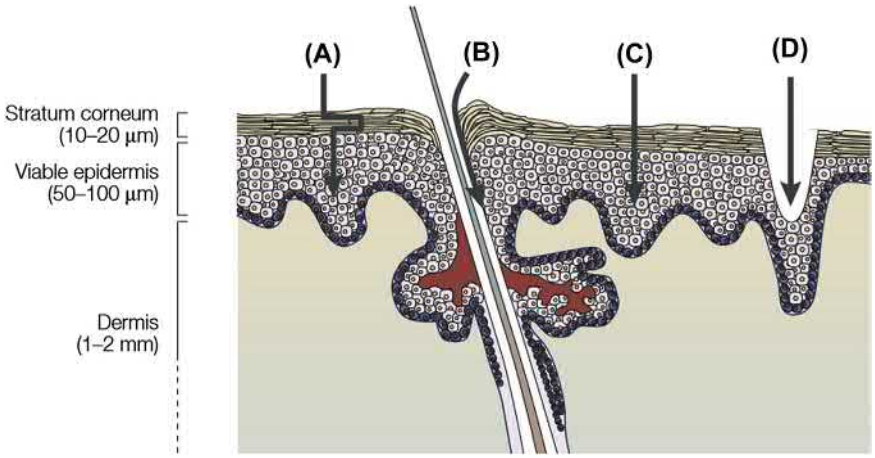
As already introduced in the section "General Considerations for DDS Design—Routes of Drug Delivery," drug delivery routes include oral (e.g., buccal, sublingual, gastric, enteric), parenteral injection (e.g., intradermal, intramuscular, intravenous, and subcutaneous), transdermal, nasal (e.g., insufflation), rectal, vaginal, and intrathecal (Fig. 2.5.12.3) (Vaidhya, 2013; Tiwari et al., 2012; Ensign et al., 2012; Prausnitz, 2004; Naik et al., 2000). The most commonly used methods are parenteral injections due to high drug absorption (i.e., bioavailability) and oral delivery due to patient convenience and compliance. However, all routes have limitations due to known anatomical, physiological, chemical, pharmacological, or psychological barriers. The primary limitations associated with parenteral drug delivery are trypanophobia (i.e., fear of needles) and the requirement of skilled expertise for proper administration. The key limitations of oral drug delivery include poor drug solubility, stability, and bioavailability due to "first-pass metabolism" effects (Ensign et al., 2012). Therefore interest in additional drug delivery routes, most notably transdermal and mucosal approaches, has grown rapidly in recent years. A closer examination of the various drug delivery routes with respect to the epithelial, mucosal, and endothelial barriers is presented next.

Epithelial Barriers

The epithelium is the outermost of the body's barriers and consists of the epidermis, various mucosal tissues (e.g., pulmonary, corneal, rectal, vaginal, etc.), and the alimentary canal (i.e., GI tract) tissues. These epithelia are the first barriers through which all drugs must pass before reaching target tissues. The primary drug delivery routes used to bypass epithelial barriers are parenteral and transdermal administration, as described next.

Parenteral Administration

The stratum corneum is the top layer of the epidermis and outermost skin layer that serves as the primary protective barrier to the body due to its unique mechanical and chemical protection (Fig. 2.5.12.9) (Landmann, 1988; Proksch et al., 2008). The stratum corneum consists of dead keratinocytes and intracellular spaces filled with continuous lipid layers (e.g., ceramides, free fatty acids, and cholesterol) measuring approximately 10–15 μm thick (Fig. 2.5.12.9) (Landmann, 1988). Although some small molecule drugs can penetrate the skin, the stratum corneum is impermeable to molecules larger than 500 Da (Bos and Meinardi, 2000), thus limiting drug delivery of higher molecular weight compounds. Mechanical penetration, such as intravenous (IV) injections using hypodermic needles, is a common option for bypassing this barrier and enabling maximal drug delivery to the bloodstream (Fig. 2.5.12.3). Additionally, subcutaneous and intramuscular administrations are the most



• **Figure 2.5.12.9** Schematic representation of a cross-section through human skin and potential routes for drug delivery. The stratum corneum provides nearly all of the barrier functions of the skin by keeping foreign substances out of the body while retaining moisture. Hair interrupts the stratum corneum, but lipid-containing sebum around the hair maintains barrier function. For transdermal DDSs, (A) diffusion, potentially with a chemical enhancer, (B) iontophoresis can enable transport through hair follicles or sweat glands, (C) electroporation can disrupt lipid bilayers, increasing transdermal transport, (D) microneedles puncture skin to enable delivery. (Used with permission from Prausnitz, M.R., Mitragotri, S., Langer, R., 2004. Current status and future potential of transdermal drug delivery. Nat. Rev. Drug Discov. 3 (2), 115–124.)

frequently used parenteral routes after IV (Fig. 2.5.12.3). Drugs delivered intramuscularly are absorbed faster than those delivered subcutaneously due to greater vascularity and volumetric capacity of muscle versus subcutaneous tissue (Guerra and Kitabchi, 1976; Turner et al., 2011). Parenteral administration is useful for any drugs or biologics that are sterile, fast acting, stable in serum, and not inherently suited for oral delivery without advanced DDSs. However, this delivery route is painful, typically requires trained personnel, and may cause difficult-to-control adverse events, including overdose.

Transdermal DDSs

Besides bypassing the skin through parenteral injection, various transdermal delivery systems provide direct drug administration through the epidermis. Transdermal DDSs are often considered more convenient than parenteral injections and improve patient compliance (Prausnitz and Langer, 2008). Some small molecule drugs can pass through the epidermis and typically follow a "Lipinksi-like" rule set: <500 Da, log P between 2 and 3, and measurable solubility in both oil and water (Wiedersberg and Guy, 2014). For these skin-penetrating drugs, a topical patch or cream can be sufficient for delivery and have gained widespread regulatory approval (Prausnitz and Langer, 2008). However, for drugs with hindered diffusion through the skin, several active delivery systems exist (Prausnitz, 2004; Naik et al., 2000). Active transdermal systems transport the drug across the stratum corneum via mechanical, electrostatic, or chemical means, allowing hydrophilic drugs or larger molecules such as proteins to be delivered. Table 2.5.12.4 provides an overview of these techniques.

Prominent transdermal DDSs include microneedle arrays (Prausnitz, 2004), transdermal jets (Prausnitz and Langer, 2008; McAllister et al., 2014), thermal ablation (Arora et al., 2008), and ultrasonic sonophoresis (Park et al., 2014). These DDSs function by physically transporting drug through the stratum corneum by penetration or electroporation of the lipid layers. Electrostatic techniques include iontophoresis, where charged drug molecules are electrophoretically transported through the stratum corneum, and electroporation, where the stratum corneum (i.e., lipid layers) is disrupted by alternating current. Chemical enhancers improve the transport of drugs across the stratum corneum by acting as a solvent or surfactant to disrupt epidermal cell membranes, increasing drug penetration depths and rates. Enhancers are often used in combination with other active and passive techniques. The reader is directed to reviews of transdermal DDSs for more information (Prausnitz and Langer, 2008; Arora et al., 2008).

Mucosal DDSs

Mucosal membranes are the other major external barrier tissue found in the body. Mucous membranes are present in the eyes, oral cavity, nasal passages, pulmonary tract, stomach, intestines, urethra, vagina, and anus. These tissues vary in structure and function, but all secrete mucus (Bansil and Turner, 2018). The composition of mucus varies by tissue, but it is an omnipresent hydrogel composed of various mucins expressed by goblet cells in the outer mucosal layers and is well distributed on mucosal *surfaces* due to its shear-thinning properties and constant production (Bansil and Turner, 2018). Mucus dramatically reduces the local diffusion rate of entrapped compounds through a combination of its hydrogel mesh and lipid-binding properties (Bansil and Turner, 2018). However, mucosal barriers can be overcome with careful DDS design.

Important DDS design parameters that affect the ability to cross mucosa include hydrophobicity, electrostatic interactions, van der Waals interactions, size, osmotic solution

TABLE 2.5.12.4 Summary of Transdermal Drug Delivery Systems (DDS)

Delivery Mechanism	Description	Materials	Drugs	References
Topical Delivery (passive)	Drug or DDS diffuses through intact skin while a carrier acts as a depot	Vinyl acetate, poly(acrylic acid), poly(vinyl alcohol), Cyclodextrins	Methylphenidate, nicotine, buprenorphine, scopolamine, nitroglycerin	Naik et al. (2000); Prausnitz and Langer (2008)
Chemical Enhancers	Solvent disrupts integrity of lipids in stratum corneum, improving drug diffusion	Sodium laurel sulfate, phenyl piperazine, Cell penetrating peptides, Liposomes, Dendrimers	Insulin, testosterone, triamcinolone acetonide	Prausnitz and Langer (2008); Mitragotri (2000); Alkilani et al. (2015)
Iontophoresis and electrophoresis	Electrophoretic transport of charged drug molecules or disruption of stratum corneum	Metals (electrodes), poly(vinyl alcohol), poly(vinyl pyrrolidone), poly(acrylic acid)	Lidocaine, fentanyl, acyclovir	Prausnitz and Langer (2008); Ariura et al. (1984)
Microneedles	Submillimeter needles penetrate stratum corneum to carry drug through	Silicon, polycarbonate, titanium, poly(lactic acid)	Vaccines, parathyroid hormone, naltrexone	Prausnitz Langer (2008)
Thermal Ablation	Heat creates micropores in stratum corneum to allow drug diffusion	Metals	Human growth hormone, interferon α-2b, Insulin	Arora et al. (2008)
Transdermal MicroJets	High-velocity jet of liquid or microparticles penetrates stratum corneum by momentum	N/A	Influenza Vaccines (FDA approved)	McAllister et al. (2014)
Sonophoresis	Ultrasonic transducer cavitates lipids in stratum corneum along with gel medium	Poly(ethylene glycol), isopropyl trioleate, glycerol trioleate, linoleic acid	Dexamethasone, Insulin, erythropoietin, Heparin	Mitragotri (2000); Prausnitz et al. (2004); Park et al. (2014)

FDA, Food and Drug Administration; *N/A*, not applicable.

conditions, and mucoadhesion (Ensign et al., 2012). These parameters directly affect mucosal contact time, permeability, enzyme inhibition, and uptake rate by specialized mucosal regions, such as Peyer's patches, as described for DDSs in Table 2.5.12.5 (Ensign et al., 2012; Kumar et al., 2016; Rathbone et al., 2015; Aungst, 2000; Shaji and Patole, 2008; Saini and Singh, 2015; Lam et al., 2014). Moreover, mucosal permeation enhancers, similar to transdermal systems, increase mucosa permeability to increase drug diffusion (Ensign et al., 2012; Kumar et al., 2016; Rathbone et al., 2015; Aungst, 2000). Together, increased mucosal contact time, permeability, and enzyme inhibition allow for DDS transport across the mucosal barrier via paracellular (i.e., around cells) or transcellular (i.e., through cells) pathways (Ensign et al., 2012; Kumar et al., 2016; Rathbone et al., 2015).

Oral DDSs

Oral drug delivery is the most common and most convenient delivery route. However, many drugs are difficult to formulate for oral delivery due to low solubility, poor stability, and low absorption within the GI tract (Ensign et al., 2012). As shown in Table 2.5.12.6, variations in epithelial cell type, mucus consistency, surface area, residence time, and pH within the GI tract make oral drug delivery particularly difficult. However, the development of smart DDS that can undergo relatively large and abrupt physical or chemical changes in response to small external changes in environmental conditions has overcome these challenges (Binauld and Stenzel, 2013; Perkins et al., 1999; Liu et al., 2016; Kumar et al., 2017). For example, enteric coatings are polymeric layers that protect drugs against the harsh acidic gastric environment, ensuring drug release in the small intestines. Additionally, DDSs have been designed to be responsive to environmental changes, such as fluctuations in temperature, pH, electric fields, magnetic fields, ultraviolet light exposure, and ionic strength (Binauld and Stenzel, 2013; Schmaljohann, 2006; Gao et al., 2010; Linsley and Wu, 2017; Bear et al., 2016; Mura et al., 2013; Zhao and Moore, 2001; Sood et al., 2016; Hoffman, 2013; Knipe and Peppas, 2014; Koetting et al., 2015), to deliver the right amount of drug to the right place within the GI tract at the right time. Some of these DDSs even release drugs

TABLE 2.5.12.5 Summary of Mucosal Drug Delivery System (DDS) Design Parameters

Mucosal Design Parameter	Description	Drug Delivery Mechanism	Examples	FDA-Approved DDS Examples	References
Mucosal Contact time	Maintains contact between drug or DDS and mucosal absorption surface for prolonged periods of time	Mucoadhesives, sustained Drug Release	Carrageenan, Chitosan, CMC, CP, Eudragit, HEC, HPC, HPMC, PIB, PIP, POE, pullulan, PVA, PVP, sodium alginate	Actiq (lozenge), NiQuitin (lozenge), Nitroguard (buccal tablet), Onsolis (buccal dissolvable film), Orabase (oral paste), Suboxone (sublingual tablet), Striant (buccal tablet)	Saini and Singh (2015); Lam et al. (2014); Hearnden et al. (2012); Shojaei (1998); Silva et al. (2015)
Permeability	The flux of drugs or DDS through the mucosa	Permeability Enhancers	Glyceryl monooleate, lauryl lactate, LCC, PCC, propylene glycol, sodium caprate, sodium caprylate, bile salts (e.g., sodium chenodeoxycholate, sodium glycodeoxycholate, sodium lauryl sulfate, sodium taurocholate, sodium taurodeoxycholate, sodium ursodeoxycholate)	Oral-lyn (oral spray containing bile salts to improve buccal permeability)	Aungst (2000); Shaji and Patole (2008); Hearnden et al. (2012); Shojaei (1998); McCartney et al. (2016)
Enzyme Inhibition	Prevents enzyme degradation of drug or DDS	Enzyme Inhibitors	Aprotinin, bestatin, Chitosan, CP, deoxycholic acid, glutathione, Isabgol, soybean trypsin inhibitor, PEG, poly(acrylates), polycarbophil, puromycin, thiomers	Trasylol (IV injection)	Hearnden et al. (2012); Shojaei (1998); Semwal et al. (2014); Karsdal et al. (2015)

CMC, Sodium carboxymethyl cellulose; *CP*, Carbopol 934P; *HEC*, poly(hydroxy ethyl cellulose); *HPC*, poly(hydroxypropyl cellulose); *HPMC*, poly(hydroxypropyl methylcellulose); *HPMC/PVP*, poly(hydroxypropyl methylcellulose)/poly(vinyl pyrrolidone); *IV*, intravenous; *LCC*, lauryl carnitine chloride; *PCC*, palmitoyl carnitine chloride; *PEG*, poly(ethylene glycol); *PIB*, poly(isobutylene); *PIP*, poly(isoprene); *POE*, poly(oxyethylene); *PVA*, poly(vinyl alcohol); *PVP*, poly(vinyl pyrrolidone).

according to circadian rhythms (Jain et al., 2011). However, as previously mentioned, poor drug bioavailability due to "first-pass metabolism" effects within the GI tract or liver markedly limits oral DDS effectiveness (Ensign et al., 2012; Lam et al., 2014). Therefore alternative drug delivery routes capable of reducing or bypassing "first-pass effects" altogether have been widely investigated.

Additional transmucosal drug delivery routes capable of bypassing "first-pass effects" include nasal, sublingual, buccal, ocular, rectal, and vaginal approaches. Sublingual and buccal DDS approaches are two examples that have gained interest recently and have been reviewed elsewhere (see Kumar et al., 2016; Lam et al., 2014; Shojaei, 1998; Silva et al., 2015; Boateng et al., 2015; Mrsny, 2009; Goswami et al., 2008).

Endothelial Barriers

Once a DDS has crossed the epithelia or mucosa and is absorbed into the bloodstream after administration, a host of new endothelial and cell-associated barriers must be overcome to reach most targets. Endothelial barriers consist of four main components: endothelial cell membranes, tight junctions between cells, the apical surface glycocalyx, and the basement membrane. The endothelial lumen glycocalyx is a thick layer of glycoproteins with embedded proteases. This glycoprotein network inhibits diffusion locally, serving as a barrier for nanoparticles and protein therapeutics (Frey et al., 1996; Aoki et al., 2005). Endothelial cell lipid bilayers prevent free diffusion of most water-soluble compounds over 500 Da due to robust tight junctions, composed of claudins, relegating transport of these molecules to endothelial transcytosis (Lipinski et al., 1997). The basement membrane consists of interconnected laminin and collagen fibers that restrict diffusion of particles greater than 10 nm (Vllasaliu et al., 2014). However, endothelial cell transcytosis can transport nanoparticles up to at least 100 nm in a charge-dependent manner (Bannunah et al., 2014). More detailed reviews of endothelial barriers and their transport mechanisms can be found in Lum et al. (1994), Minshall et al. (2002), and Abbott et al. (2010).

TABLE 2.5.12.6 Characteristics of Gastrointestinal (GI) Tract Segments

GI Tract Segment	Epithelial Cell Type	Mucus Type	Surface Area	Segment Length	Residence Time	pH	Temperature
Oral cavity	Stratified squamous	Dilute	100–220 cm^2	8–9 cm	Seconds to minutes	6.2–7.3	34–37°C
Esophagus	Stratified squamous	Salivary	200 cm^2	23–25 cm	4–8 s	~7.0	36–38°C
Stomach	Secretory columnar	Thick, adherent	3.5 m^2	0.25 m	90 min	1–2	36–38°C
Duodenum	Simple columnar	Thin, adherent	1.9 m^2	0.35 m	30–40 min	4–5.5	36–38°C
Jejunum	Simple columnar	Thin, adherent	184 m^2	2.8 m	1.5–2 h	5.5–7.0	36–38°C
Ileum	Simple columnar	Thin, adherent	276 m^2	4.2 m	5–7 h	7.0–7.5	36–38°C
Colon and rectum	Columnar dominated	Thick, Increasing	1.3 m^2	1.5 m	1–60 h (35–38 h avg)	7.0–7.5	34–37°C

Biomaterial DDSs for Drug Targeting

Tissue targeting of DDSs can ameliorate many side effects, including off-target tissue toxicity, by increasing the width of the TW. Tissue targeting is especially critical for delivery of cytotoxic cancer treatments; the chemotherapeutic drug doxorubicin is dose limited due to off-target cardiotoxicity (Barenholz, 2012). Nanoscale DDSs can be used to passively target tissues based on the carrier physicochemical properties or modified with active targeting ligands to enhance tissue accumulation (Fig. 2.5.12.10). Recent advances in both passive and active targeting are shown in Table 2.5.12.7 and additional information can be found in Chapter 1.3.8.

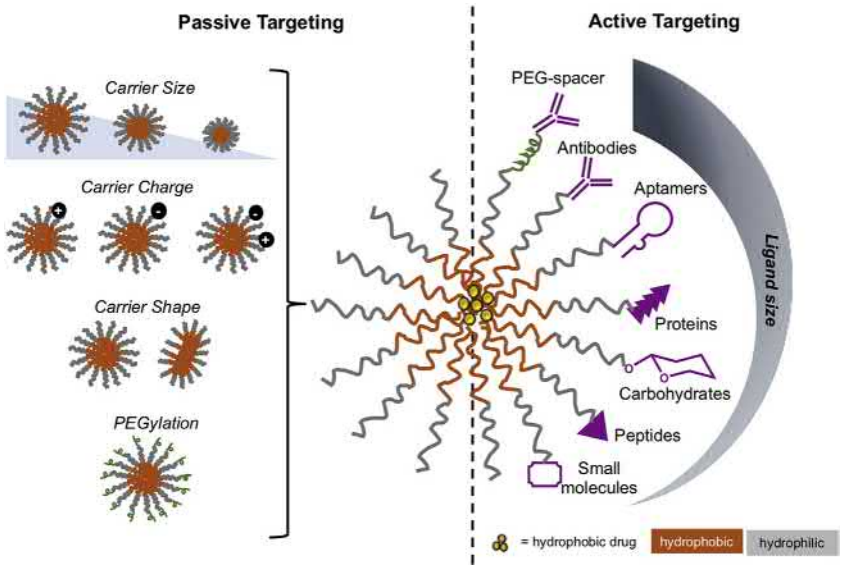
Passive Targeting

Passive targeting describes tissue accumulation of DDSs based on physicochemical properties and target tissue physiology (Fig. 2.5.12.10). In the 1980s, Maeda et al. observed preferential tumor accumulation of poly(styrene-*co*-maleic acid)-neocarzinostatin drug–polymer conjugates and coined the process as the enhanced permeability and retention (EPR) effect (Matsumura and Maeda, 1986; Maeda et al., 1985). The EPR effect describes the phenomena in which leaky vasculature of the tumor environment is coupled with poor lymphatic drainage, resulting in increased extravasation of macromolecular and nanoparticles into the interstitial space (Accardo and Morelli, 2015). EPR has been subsequently described as a consequence of tissue inflammation, including injury and infection. Passive targeting has evolved since the discovery of EPR, and the evolution has highlighted the importance of DDS physicochemical properties, including size, surface charge, shape, modulus, hydrophobicity, and PEGylation to achieve preferential targeting, as depicted in Fig. 2.5.12.10 (Blanco et al., 2015; Duncan, 2003; Chen et al., 2015; Perry et al., 2011; Merkel et al., 2011; Christian et al., 2009; Cai et al., 2007; Decuzzi et al., 2010; Kolhar et al., 2013; Barua et al., 2013; Banerjee et al., 2016; Beletskii et al., 2014).

A unique advantage of passive targeting is that it requires little to no DDS modification and therefore is relatively simple, which leads directly to lower costs and easier translation (Muro, 2012). Passive targeting is a straightforward approach to achieve tissue-specific accumulation; however, it relies upon EPR. Unfortunately, the EPR effect applies predominantly to inflamed tissues and is not guaranteed to widen the TW to sufficiently limit off-target toxicity for all drugs. In addition to the EPR effect, when a DDS is injected systemically, it undergoes interactions with plasma proteins and subsequent immune cell recognition and uptake within the liver, spleen, and lymph nodes, the MPS (Lucas et al., 2017; Petschauer et al., 2015). MPS can be taken advantage of for passive targeting by altering DDS size, shape, surface modification, surface charge, and particle dose to dramatically impact their distribution (Lucas et al., 2017). For more information regarding the effect of other physiochemical properties of carriers on passive targeting, please refer to the following publications (Blanco et al., 2015; Chen et al., 2015; Perry et al., 2011; Decuzzi et al., 2010; Muro, 2012).

Active Targeting

The concept of the "magic bullet" (e.g., target-specific drug delivery) was first proposed by Paul Ehrlich (Strebhardt and Ullrich, 2008; Ehrlich, 1900). Although still not a reality due to the body's inherent ability to recognize and clear foreign substances, active targeting has been attempted for a variety of DDSs, targets, and drugs to enhance tissue-specific accumulation (Hoffman, 2008). Active targeting involves direct coupling or adsorption of targeting groups to a DDS leading to greater drug accumulation versus off-target tissues (Fig. 2.5.12.10). The target can be on an organ/tissue, cellular, subcellular, or molecular level, thus requiring appropriate selectivity of the ligand. This section will



• **Figure 2.5.12.10** Schematic representation of passive and active targeting of drug delivery systems. Passive targeting relies on the physicochemical properties of the carrier, including size, charge, and shape. Additionally, surface modification with poly(ethylene glycol) (PEG) has been shown to enhance circulation time and improve targeting. Active targeting is shown displaying the different ligands and associated range in sizes.

briefly discuss the different types of targeting ligands, and the delivery systems that have been explored to further the quest for the "magic bullet."

Antibodies

Antibodies are promising targeting groups due to specificity toward their respective antigen. Antibodies that are directly conjugated to small molecule drugs are termed antibody–drug conjugates (ADCs). Although ADCs enjoy therapeutic success, they will not be further discussed here as they are outside the scope of biomaterial DDSs. Antibodies are excellent targeting groups due to high target affinity and specificity and myriad functional groups that allow simple and robust DDS conjugation. However, conjugation can lead to impaired antibody affinity due to uncontrolled conjugation in close proximity to antigen binding sites. Additionally, the large molecular weight of antibodies may also dramatically change DDS characteristics. To circumvent some of these challenges, antibody fragments (Fab and Fv or scFv) have been explored. Antibodies and antibody fragments have been conjugated to liposomes (Huang et al., 1980; Heath et al., 1980), polymeric carriers (Kabanov et al., 1989; Song et al., 2010; Seymour et al., 1991; Omelyanenko et al., 1996; Merdan et al., 2003; Song et al., 2005), and PDCs (Ulbrich and Subr, 2010; Xu et al., 2015; Kopecek and Kopeckova, 2010; Minko, 2010). Additional information of antibody-targeted DDSs can be found in Table 2.5.12.7 and in the following reviews (Xu et al., 2015; Bertrand et al., 2014; Friedman et al., 2013; Allen, 2002).

Proteins

Proteins, such as naturally occurring transferrin or synthetic proteins (e.g., ankyrin), can also be used as targeting moieties. Although typically smaller than antibodies, these proteins still may result in alterations in DDS characteristics and result in poorly controlled functional group conjugations. Currently, there are various transferrin targeted liposomes being developed and undergoing clinical trials, as highlighted in Table 2.5.12.7 and in the following reviews (Bertrand et al., 2014; Friedman et al., 2013; Allen, 2002).

Peptides

Peptides have excellent potential for targeted DDSs due to their small size, high stability, limited immunogenicity, and ease of conjugation. The development of phage display techniques has enabled identification of various peptide sequences with high specificity and affinity to cellular and microenvironmental targets. The most widely used targeting peptide is arginylglycylaspartic acid (RGD), which binds to integrins upregulated in tumor cells and endothelial cells during tumorigenesis. RGD and other peptides have since been conjugated to liposomes (Accardo and Morelli, 2015; Nishiya and Sloan, 1996; Schiffelers et al., 2002; Garg et al., 2009), polymeric carriers (Hart et al., 1995; Erbacher et al., 1999; Suk et al., 2006; Nasongkla et al., 2004), and PDC (Newman et al., 2018). Additional information of peptide-targeted DDSs can be found in Table 2.5.12.7 and in various reviews (Accardo and Morelli, 2015; Bertrand et al., 2014; Friedman et al., 2013).

Aptamers

Aptamers are single-stranded oligonucleotides developed with selective enrichment processes to have high affinity for protein targets (Bertrand et al., 2014; Liang et al., 2015; Catuogno et al., 2016). Prostate-specific membrane antigen (PSMA)-targeted aptamers for docetaxel have decreased tumor growth and increased survival (Farokhzad et al., 2006). Despite the potential of aptamer ligands, their

TABLE 2.5.12.7 Various Examples of Targeting Ligands

Ligand	Advantages	Disadvantages	Ligands	Targets	Carriers	References
Antibody	Highly specific and selective	Immunogenic, large size hinders conjugations and contributes to NP size increase, sensitive to environmental changes	Anti-CD44, trastuzumab, anti-HER2 Ab, anti-EGFR Ab#, ScFv-EGFR, etc.	CD44, HER2#, EGFR	Liposomes#, polymer NPs, PDC	Xu et al. (2015); Heath et al. (1980); Song et al. (2010); Merdan et al. (2003); Song et al. (2005); Friedman et al. (2013); Allen (2002); Park et al. (2002); Guo et al. (2018)
Aptamer	Easy to synthesize, high affinity and specificity, nonimmunogenic	Easily degraded by enzymes, conjugation stability is challenging, increases size of carriers, expensive to produce	Anti-PSMA aptamer (A9/A10), anti-HER2 aptamer (A6), CH6, etc.	PSMA, HER2, osteoblasts	Polymer NPs, Liposomes, PDC	Bertrand et al. (2014); Friedman et al. (2013); Liang et al. (2015); Catuogno et al. (2016); Powell et al. (2017); Jiang et al. (2015); Cheng et al. (2007)
Protein	High affinity	Immunogenic, conjugations are complicated due to presence of multiple functional sites	Transferrin#, affibodies, ankyrin repeat proteins, gp120, etc.	Transferrin-receptor#, EpCAM, HER2, EGFR, DC-SIGN	Liposomes#, polymer NPs, PDC	(Xu et al. (2015); Bertrand et al. (2014); Friedman et al. (2013); Allen (2002)
Carbohydrate	Biocompatible, can be easily derivatized	Requires multiple carbohydrate entities to achieve strong binding	Galactose, Mannose, Lactose, HA, Chitosan, etc.	Lectin, CD44	Liposomes, polymer NPs, polymer–drug conjugates	Xu et al. (2015); Bertrand et al. (2014); Friedman et al. (2013); Allen (2002)
Peptide	Small size, improved stability, facile synthesis and conjugation	Can elicit activity on substrate and alter the fate of the NP	RGD, Tet-1, E-selectin binding peptide, CLL1, TBP, etc.	Integrins, E-selectin, TRAP, CLL1 receptor	Liposomes, polymer NPs, PDC	Xu et al. (2015); Accardo and Morelli (2015); Friedman et al. (2013); Allen (2002); Newman et al. (2018); Wang et al. (2017)

# Indicates targeting ligands in clinical trials. Additional examples of active-targeted carriers in clinical trials can be found in Bertrand et al. (2014).
ACUPA, *S*,*S*-2-(3-(5-Amino-1-carboxypentyl)-ureido)-pentanedioic acid; *BP*, bisphosphonates; *CLL1*, C-type lectin domain; *DC-SIGN*, dendritic cell-specific intercellular adhesion molecule-3-grabbing nonintegrin; *EGFR*, epidermal growth factor receptor; *HA*, hyaluronic acid; *HER2*, human epidermal growth factor receptor 2; *NP*, nanoparticle; *PSMA*, prostate-specific membrane antigen; *TBP*, TRAP-binding peptide; *TRAP*, tartrate-resistant acid phosphate.

susceptibility to enzymatic degradation is a major limitation and may ultimately hinder the clinical utility of aptamer targeting. Additional information of aptamer-targeted DDSs can be found in Table 2.5.12.7 and in the following reviews (Xu et al., 2015; Bertrand et al., 2014; Friedman et al., 2013).

Carbohydrates

Carbohydrate-targeting groups, including galactose, mannose, fucose, and lactose, enable specific binding to lectin-expressing cells. Consequently, lectin-binding liposomes (Chono et al., 2008; Sato et al., 2007; Gregoriadis Neerunjun, 1975; Mauk et al., 1980; Garcon et al., 1988; Ying et al., 2010), polymeric carriers (Sutton et al., 2007), and PDCs have been explored to target a variety of drugs (Xu et al., 2015; Duncan et al., 1983; Seymour et al., 1987; Negre et al., 1992; Kim et al., 2006; Nahar and Jain, 2009). More detailed examples of carbohydrate-targeted DDSs can be found in Table 2.5.12.7.

Small Molecules

Small molecule ligands are associated with benefits, including small size, low cost, and ligand stability. The best-studied small molecule ligand is folic acid due to its nanomolar affinity toward folate receptors (FRs), which are highly expressed in ~40% of cancers (Guo and Lee, 1999; Lee and Low, 1995; van Steenis et al., 2003). Folic acid-targeting carriers have become so successful that they are being explored to screen and identify FR-positive patients prior to treatment. Unfortunately, one of the challenges associated with folate-targeted carriers is expression of FRs within healthy noncancerous tissues, leading to off-target tissue accumulation. Another active targeting carrier, BIND-014, uses a small molecule ligand *S*,*S*-2-(3-(5-amino-1-carboxypentyl)-ureido)-pentanedioic acid to specifically target PSMA and deliver docetaxel, resulting in progression of this DDS to Phase 2 clinical trials (Hrkach et al., 2012). Small molecule ligands have been conjugated to liposomes (Lee and Low, 1995; Wang et al., 1995; Yang et al., 2009; Sarti et al., 1996; Liao et al., 1998; Eavarone et al., 2000), polymeric carriers (Guo and Lee, 1999; van Steenis et al., 2003; Mislick et al., 1995; Yoo and Park, 2004; Flanagan et al., 1989; Wightman et al., 1999; Huang et al., 2007; Vinogradov et al., 1999), and PDCs. While this section highlights just a few small molecule-targeted systems, keep in mind that additional small molecule ligands exist, such as bisphosphonates and tetracyclines, which can target bone tissue (Farrell et al., 2018; Wang et al., 2015). Additional information on these approaches is listed in Table 2.5.12.7 and in various reviews (Bertrand et al., 2014; Friedman et al., 2013).

Maintaining ligand specificity, affinity, and multivalency to enhance binding potential is critical for successful active targeting. For example, DDSs acquire a protein corona almost immediately upon introduction systemically, which can limit active targeting group availability and affinity (Cedervall et al., 2007; Monopoli et al., 2012; Tenzer et al., 2013; Lundqvist et al., 2008). Attachment of spacer arms of various lengths has been explored to reduce both steric hindrances imposed by ligand conjugation as well as the protein corona (Fig. 2.5.12.10).

Regulatory and Intellectual Property Considerations for DDSs

Pharmaceutical companies routinely pursue DDSs not only to enhance therapeutic efficacy but also to maximize drug financial returns by patenting controlled-release formulations and extending market exclusivity. DDSs are combination products—those that combine drugs, biologics, and/or biomaterials using physical, chemical, or some other means to produce a biomedical device (Anderson et al., 2017; Couto et al., 2012). One of the earliest examples of a combination product was the metered-dose inhaler developed in the mid-1950s by Riker Laboratories, as described in the section "History of DDS Development" (Stein and Thiel, 2017; Anselmo and Mitragotri, 2014; Couto et al., 2012). Although combination products of drugs and devices have existed for more than 60 years, only in the last 15 years have regulatory authorities worldwide provided specific guidance for this product category (Table 2.5.12.8). Due to the increase in number and sophistication of combination products over the last few decades, the United States Congress enacted the Medical Device User Fee and Modernization Act in October 2002. Soon afterward, the FDA established the Office of Combination Products to address combination drug and device products entering the marketplace (Couto et al., 2012). Likewise, other regulatory agencies around the world also began considering or implementing similar changes. However, for simplicity this section focuses solely on the guidance offered by the FDA. The Office of Combination Products determines the product's primary mode of action (PMOA), designates the product's primary function, and then assigns it to the appropriate FDA center for regulatory evaluation (Couto et al., 2012).

Regulation

Ever since the FDA took these actions to provide guidance documents and offer a single point of contact for regulation of combination products, a general pattern in the process from discovery to development to market entry has been observed (Fig. 2.5.12.11). During product development, sponsors (typically companies) develop combination products. This design and development stage is based on the principle of Quality by Design (QbD). The FDA defines QbD as "a systematic approach to development that begins with predefined objectives and emphasizes product and process understanding and process control, based on sound science and quality risk management" (Q8(R2) Pharmaceutical Development,

TABLE 2.5.12.8 Summary of Global Regulatory Guidance Documents for Combination Products

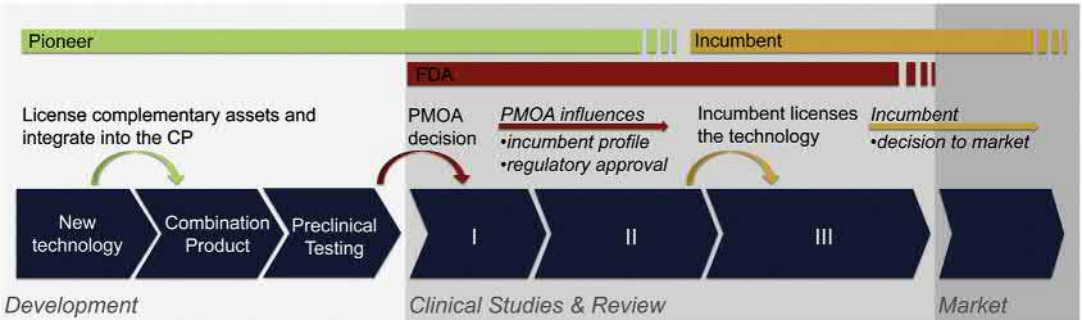
Country/Region	Regulatory Agency	Combination Products Regulatory Guidance
United States of America	Food and Drug Administration	21 CFR Parts 3 and 4
Australia	Therapeutic Goods Administration	Australian Regulatory Guidelines for Medical Devices Australian Register of Therapeutic Goods
Brazil	Agência Nacional de Vigilância Sanitária	Medical Devices BRAZIL Demarest e Almedia Advogados: Lex Mundi Publication. 2011
Canada	Health Canada	Food and Drug Regulations Medical Device Regulations Natural Health Products Regulations "Classification of Products at the (Medical) DeviceDrug Interface"
European Union	European Medicines Agency	Medicinal Products: Directive 2001/83 Medical Devices: Regulation 2017/745
Japan	Pharmaceuticals and Medical Devices Agency	"Handling of Approval Application for Combination Products" dated October 24, 2014 Pharmaceutical and Food Safety Bureau (PFSB) Notification No. 1024-(2) of the Evaluation and Licensing Division; PFSB Notification No. 1024-(1) of the Director of Medical Devices Evaluation, Evaluation and Licensing Division; PFSB Notification No. 1024-(9) of the Safety Division; PFSB Notification No. 1024-(15) of the Compliance and Narcotics Division

2017). More generally, QbD is a development approach where product Critical Quality Attributes are defined through a risk assessment and then development teams work backward to address these key items in the product design (Singh et al., 2010). Sponsor development teams must consider and include design controls (described in 21 CFR 820.30 and ISO 13485) when combining a drug or biologic with a specific delivery device (Anderson et al., 2017). Design controls are a system of checks and balances intended to make systematic assessment of the product design with a focus on the end user as a key part of development (21 CFR 820.30) (C.f.D.a.R. Health, 1997; Kinsel, 2012). This requirement has historically been associated with medical device development but was established for combination products as part of a 2013 revision to FDA guidance (21 CFR Part 4) on Current Good Manufacturing Practices (Anderson et al., 2017). The development stage concludes with rigorous preclinical testing that provides essential data to justify moving into clinical trials.

The PMOA assessment is affected by integration of the complementary technologies, execution of QbD during development, and completion of preclinical testing. Regulators use the PMOA to determine which agency center of excellence should support the regulatory approval process. Once the PMOA is defined, the regulatory approval pathway (e.g., drug, biologic, or medical device) becomes clear, and established companies in a specific market, termed incumbents, lead the clinical trials, commercialization, and marketing processes for the combination product (Fig. 2.5.12.11) (Couto et al., 2012). For example, Alza Corp. integrated transdermal patch technology into a product, assisted with the initial regulatory assessment, and modeled a corporate structure for commercialization and marketing that others later followed (Fig. 2.5.12.12) (Couto et al., 2012). Ultimately, if the combination product is successful in clinical trials, the company will execute a market launch to reach patients and maintain ongoing commercial manufacturing, marketing, and annual regulatory filing efforts for the duration of the product's lifetime.

Intellectual Property

It is not uncommon for the drug development process to require more than 15–20 years of research and development work, including preclinical animal studies and human clinical trials. Thus it is reasonable for pharmaceutical companies to maximize drug financial returns by extending the patent lifetime of the product, thereby postponing the inevitable introduction of generics. One means of doing this is to patent a combination product, such as a new controlled-release formulation with the same drug. However, the commercial feasibility of such a strategy is predicated on a demonstration that the controlled-release formulation is indeed superior in safety and efficacy to the single bolus dose formulation (or a previous controlled-release formulation). Moreover, the cost of the controlled-release formulation must be low enough to ensure a reasonable market penetration. Based on FDA guidance documents, the 505(b)(2) approval pathway allows companies to make small changes to a currently approved drug and still maintain market exclusivity for up to 7 years. This mechanism is less expensive, has a faster approval process, minimizes risk, and maintains market exclusivity. This strategy has led to annual DDS product revenues exceeding $100 billion as



• **Figure 2.5.12.11** Schematic summarizing the dynamics of the development and approval process for drug–device combination products from the corporate, technology, and regulatory perspectives. of 2014 (Anselmo and Mitragotri, 2014). This approach is an excellent example of life-cycle management for DDSs as the product approaches its patent expiry. Often, companies initiate future-generation products even before regulators have approved the previous version(s) of a drug. For more information regarding the combination product regulatory process, life-cycle management, and other related intellectual property considerations, the reader is referred to Chapters 3.5 and 3.6, as well as several review articles (Anderson et al., 2017; Couto et al., 2012; Zylberberg and Matosevic, 2016; Davar and Ghosh, 2010).

Final Remarks

Over the past 60 years, DDS materials and designs have progressed from external devices and simple off-the-shelf macroscopic polymeric materials to microscopic, degradable, drug-loaded microparticles and ultimately to complex, rationally designed nanocarriers. The DDS field has grown to a multibillion dollar industry over this timeframe. While DDSs have dramatically improved convenience and clinical usefulness of many drugs and enabled new therapeutics, such as siRNA, to become clinically viable, some of the most challenging problems of drug delivery have yet to be fully addressed. As the next generation of DDSs undergoes clinical trials utilizing less invasive DDSs with tissue-specific delivery and more efficient drug dosing, the trend in overcoming the remaining challenges will continue to be driven by innovations in biomaterials development and integration.

Chapter Review Questions

1. Biomaterial DDSs are also applicable for use with vaccines. Vaccines are biological preparations typically containing a pathogen-mimicking agent, known as an antigen (e.g., weakened or killed whole pathogen, a surface protein or sugar, or a toxin), that improve immunity to disease. You have been hired by a biotechnology company to help develop a new vaccine against Epstein–Barr virus (EBV), the herpes virus that causes infectious mononucleosis. To date, the company has identified and purified key polypeptides from EBV glycoprotein gp350. As the most abundant EBV glycoprotein, gp350 is a key virulence factor involved in the attachment of virus to B cells, so gp350 is hypothesized to be a good EBV vaccine candidate. Note: EBV is a ~120–200 nm spherical virus with an outer viral envelope that contains almost a dozen glycoproteins, and is often spread through saliva. Your manager informs you that the company is striving hard to implement alternative vaccine delivery systems to reduce the number of needle-based injections (e.g., booster shots) for patients, as well as overhead costs associated with the aseptic manufacturing processes necessary for parenterally delivered vaccines. In an attempt to reduce the number of booster shots needed, you suggest implementing a controlled-release delivery system that can gradually release antigen to the patient over time, thus reducing the need for additional booster shots. Name and briefly describe two different biomaterial technologies that could be considered as a novel delivery platform for this vaccine.

   Potential answers:

a. Nanoparticles and microneedles.

b. Nanoparticle vaccines can be used to conjugate, encapsulate, or adsorb antigens using a system that closely resembles the initial pathogen in size and shape. Additionally, they can be administered via sublingual or buccal delivery routes. Controlled release via degradation of the nanoparticle and release of antigen, degradation of a tether between the antigen and the nanoparticle, or diffusive release of an encapsulated antigen are potential delivery platform options.

Microneedles can be coated or filled with antigens and then inserted into the upper layers of the skin to deliver or slowly release the antigen into the body.

These two approaches can be used alone or in combination to deliver controlled amounts of vaccine antigen over time that could have booster-like effects on the immune response.

c. Hydrogel DDSs in the form of patches or oral films as well as nasal DDSs with appropriate supporting rationale.

2. You recently developed a new proton pump inhibitor for the treatment of heartburn and acid reflux. Unfortunately, the acid secretions of the stomach hydrolyze the drug, and the degradation products cause further irritation to the gastric mucosa. Your coworker suggested that you need to coat the drug to protect it from the stomach acid. Do you agree? If not, what other solution(s) can you offer to this problem? If so, which polymer (A, B, or C) would you use and why (i.e., how would it work)?

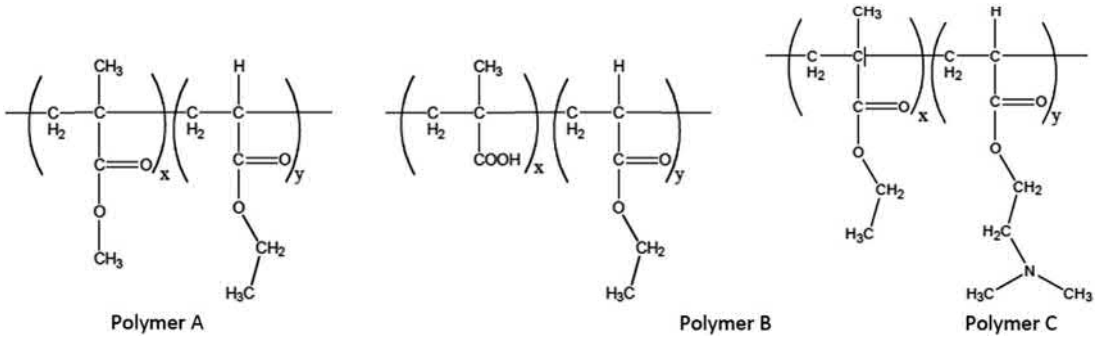
   Potential answer:

Polymer B is the right polymer to use for enteric coating of the PPI drug. Polymer B will be protonated and hydrophobic in the stomach, forming an impermeable coating. It will switch to the ionized and soluble form in the intestine, releasing the drug in a favorable pH environment.

If you do not agree with your colleague, other possible approaches could be to deliver the drug from a two-compartment osmotic device, where each compartment is designed to release it only in the small intestines.

3. Delivery of leuprolide, a polypeptide drug, is used as a prostate cancer treatment. The amino acid sequence is:
   Glu-His-Trp-Ser-Tyr-DLeu-Leu-Arg-Pro-NHEt
   Leuprolide acetate

   a. Two strategies to achieve zero-order release are to use a reservoir/membrane device or to encapsulate the drug in a surface-degrading/eroding degradable polymer. Cite a principal advantage of each of these strategies for the given application and a principal limitation.



Potential answers:

	Advantages	Disadvantages
Reservoir/ membrane	well-controlled environment for a drug formulation, allowing increased drug stability and prolonged *delivery* times. Increased drug stability.	Nondegradable—need for surgery for retrieval.
Surface-degrading/-eroding polymer	No retrieval necessary, simple formulation (e.g., mix of drug and polymers)	Underlying premise requires rapid polymer degradation, thus drug release may be limited to weeks rather than months; Zero-order release may not be sustained especially at end of degradation due to surface area-to-volume changes over degradation time; Degradation products may lead to side effects

b. Your research group decides to first test encapsulation of leuprolide in PLGA matrices formed as implantable wafers. Explain what your biggest concern would be with the use of PLGA encapsulation for delivery of the polypeptide in a biological environment.

Potential answer:

PLGA degradation products (lactic acid and glycolic acid) can build up in the matrix, causing locally acidic microenvironments that may expediate peptide chain scission and loss of potency due to degradation and increased drug release rates.

4. Name and describe the five parts or steps involved in DDS pharmacokinetics. Be sure to highlight the important anatomical structures and physiology of these structures involved in the steps. For one of the steps, suggest a formulation strategy to improve drug delivery.

Potential answer:

DDS PK follows the order of Liberation, Absorption, Distribution, Metabolism, and Elimination (LADME). Liberation is the release of drug from the DDS, which can occur by either diffusion, dissolution, mechanical release, or ion exchange. This release typically occurs in the delivery site for local DDS or in the small intestine for oral delivery routes. Liberation is not a factor for administration directly to blood. Absorption is the next step, where the liberated drug is taken up, typically into systemic circulation. Uptake can occur through mucosa or capillary diffusion. Distribution is the subsequent localization of the drug into various tissues, typically through systemic circulation. Liver, lung, spleen, and kidney are common sites of distribution for most drugs, while the brain is less likely to uptake drug. Metabolism occurs when enzymes act on the drug to modify it, which can occur during delivery via enzymes in the skin, mucosa, and GI tract as well as during systemic circulation in the liver or target tissues. Metabolism can be exploited for prodrug strategies and certain DDS depot chemistries, but it is typically responsible for drug inactivation and clearance. Elimination is the final step and typically occurs in the kidneys. Drugs in systemic circulation are secreted into urine, and the rate of this elimination controls drug AUC.

Answers for formulation changes can focus on any of the LADME steps; enteric coatings to protect drug from enzymatic degradation in the stomach, ion exchange resins to modify liberation rate, excipients to increase absorption, targeted DDSs to change distribution, and nanocarrier reservoir DDSs to modify elimination are all valid options.

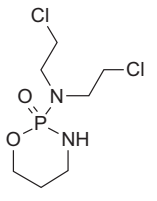
5.

a. What is the major barrier to drug permeation via the transdermal route of administration?

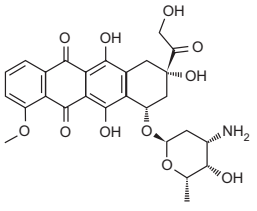
b. For the following chemical structures being considered for the transdermal route, categorize each according to Lipinski's rule of 5.

c. Predict if transdermal permeation is possible and justify your answer based on (b).

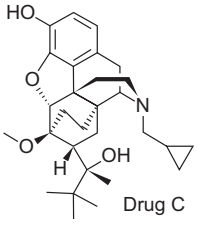
d. For the impermeable drugs, list and describe two methods that could be used to enhance drug permeation via the transdermal route of delivery.



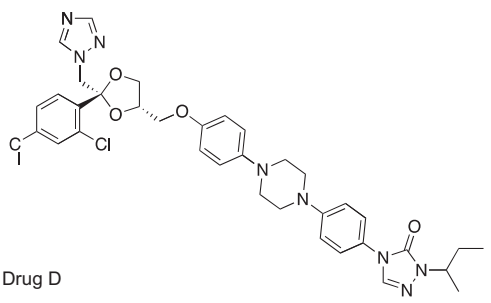
Drug A



Drug B



Drug C



Drug D

Drug A—Cyclophosphamide
Drug B—Doxorubicin
Drug C—Buprenorphine
Drug D—Itraconazole

Potential answers:

a. Stratum corneum.

b. Lipinsky's rule of 5 states that a molecule with molecular weight >500, H-bond donors >5, H-bond acceptors >10, and log P > 5 will not penetrate cell membranes and is unlikely to be drug-like.

Compound hydrophobicity determined based on meeting Lipinski's rule of 5:

(A) M_W < 500 g/mol, H-donor = 1, H-acceptor = 4, log P < 8

(B) M_W = 542.53 g/mol, H-donor = 6, H-acceptor = 12, log P = 1.3

(C) M_W < 500 g/mol, H-donor = 3, H-acceptor = 5, log P > 3—passively diffuses through stratum corneum per Table 2.5.12.4

(D) M_W > 500 g/mol, H-donor = 0, H-acceptor = 12, log P > 5

The drugs that are able to permeate the epidermis will need to be small (<500 g/mol) and lipophilic/hydrophobic (log P > 1). Drug C meets these criteria and can be expected to penetrate lipids well. Drug A is not currently intended for transdermal delivery; however, it has been shown to penetrate the stratum corneum through handling by nurses. Drug B is too hydrophilic for these criteria, while drug D is too large and hydrophobic. Per Table 2.5.12.4, drug C has been formulated to be used for transdermal delivery as well, likely due to M_W < 500 g/mol and log P > 3.

Approaches that can be used to enhance transdermal drug delivery of the remaining drugs could be iontophoresis, electrophoresis, microneedles, transdermal microjet, etc. (Table 2.5.12.4).

6. Several key scientific findings in the 19th and early 20th centuries (e.g., Ehrlich's magic bullet and Banting, Best, and Macleod's discovery that insulin treated diabetes) laid the groundwork for DDS development in the late 20th century. What recent scientific findings have occurred since the start of the 21st century and how might they impact the future of DDS design and development? What challenges will need to be overcome to take full advantage of these scientific findings in DDS design and development?

Answers could include discoveries such as mapping of the human genome, siRNA, and CRISPR (as well as others). Certainly, these technologies will be useful for future design of targeted DDSs. For example, the human genome map will likely highlight genes or proteins that enable targeted cancer therapies to only destroy cancerous and potentially cancerous cells while leaving healthy cells unaffected. Technologies such as siRNA or CRISPR will likely provide specific molecular tools that facilitate this targeting process, but suitable DDS designs using these technologies will need to overcome multiple challenges, including biocompatibility, preliminary drug degradation, biological barriers to enable targeted drug delivery, etc.

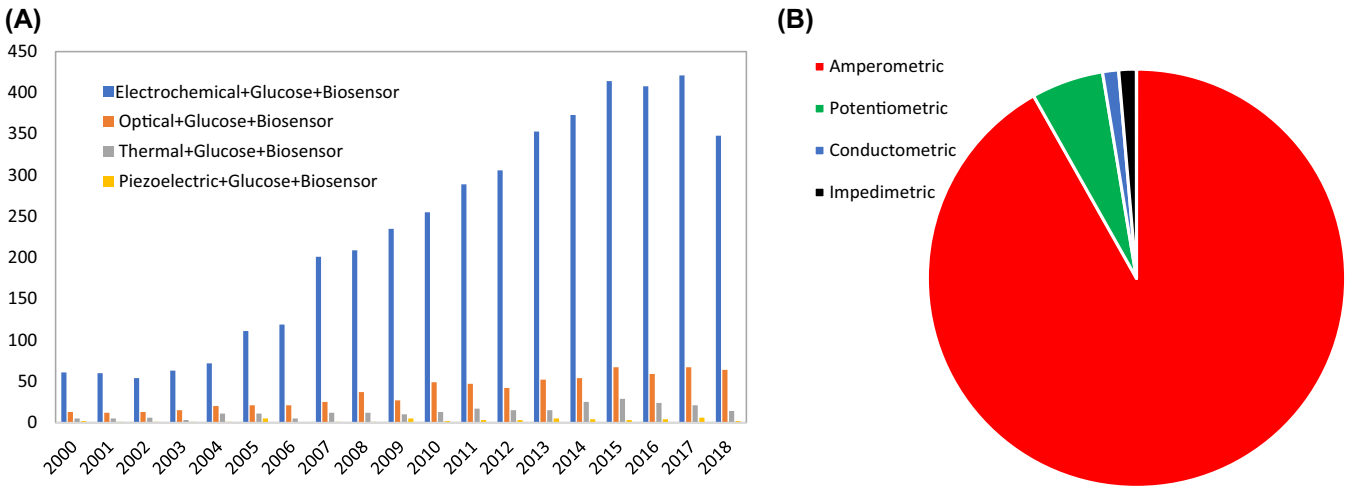
Introduction

The detection and measurement of glucose (static or continual; in vitro, in situ, or in vivo) has been studied in great depth since the description of the first biosensor by Clark and Lyons in 1962 and the subsequent patent of the original amperometric glucose enzyme electrode in 1970 (Clark and Lyons, 1962; Clark et al., 1970). In addition to the well-studied benefits of glucose sensing for diabetic patients, continuous measurement of glucose can serve as a gauge to identify shock states for patients who have undergone hemorrhage-associated trauma (Guiseppi-Elie, 2011) and may be experiencing insulin resistance. A biosensor is a fully integrated system capable of receiving an input/stimulus from its environment through a biotransducer and outputting a signal that can be processed into readable, actionable information through its instrumentation. The development of biosensors over the last several decades has been driven not only by need in the medical industry, but by needs in the food, environmental, and national defense industries (Idros et al., 2015; Neethirajan et al., 2018; Justino et al., 2017).

Biosensors can be split into four main groups, based on the type of physicochemical transduction employed: electrochemical, optical, thermal, and piezoelectric. From 2000 to the present, over 5000 peer-reviewed articles have been recorded in the ISI Web of Knowledge relevant to these four types of glucose biosensors. From the data shown in Fig. 2.5.13.1A, the number of articles written for each type of glucose biosensor has increased sixfold over the past 2 decades. The most widely studied glucose biosensor systems are electrochemical (48%), followed by optical (32%), thermal (15%), and piezoelectric (5%). Electrochemical glucose biosensors have been the most widely researched type of biosensor since their inception. Electrochemical glucose biosensors, specifically amperometric biosensors, offer many advantages over the other types of transduction mechanisms. Specifically, the low cost of instrumentation, the small footprint that is possible, and the low power requirements coupled with high sensitivity and fast response times (dictated by enzyme kinetics/diffusion) have all been exploited to realize miniaturized, portable, point-of-care glucose-biosensing systems. Moreover, amperometric glucose biosensors are highly studied because they offer the highest sensitivity and are more easily produced on a large scale than other enzymatic electrochemical biosensors (Gaudin, 2017).

Optical glucose biosensors, which continue to be highly researched, also offer several advantages. Optical biosensors offer label-free detection of many types of biological or chemical analytes at high specificity and sensitivity. In addition, optical biosensors show great promise for noninvasive biosensing (Bandodkar and Wang, 2014). However, the equipment required for optical measurements is often costly and requires higher power consumption than most electrochemical glucose biosensors.

Enzymatic electrochemical glucose biosensors, which utilize glucose oxidase (GOx) (an oxido-reductase: EC number 1.1.3.4) as the bioreceptor, can be classified into four groups based on the type of electrochemical transduction



• **Figure 2.5.13.1** (A) The number of electrochemical, optical, thermal, and piezoelectric glucose sensor-related articles since the year 2000, by year. (B) The total number of electrochemical glucose biosensors since the year 2000, split into the transduction type: amperometric, conductometric, impedimetric, and potentiometric. (Data collected from ISI Web of Knowledge.)

employed: amperometric (apply a constant voltage and measure current), conductometric (apply a current and measure a voltage drop), impedimetric (apply a sinusoidally varying voltage and measure the ensuing phase-shifted current as the transfer function), and potentiometric (measure the time-varying voltage relative to a reference voltage). Of the articles recorded on the ISI Web of Knowledge since 2000, over 90% are related to amperometric sensing, followed by potentiometric, impedimetric, and conductometric, as shown in Fig. 2.5.13.1B.

Recently, responsive polymers have been incorporated into enzymatic electrochemical biosensor systems. In part, stimuli-responsive polymers (and addition of nanoparticles) have been incorporated into the transduction element and bioreceptor element in passive and active roles. Many important reviews have been written on glucose biosensors, but a deep understanding and topical review of the incorporation of stimuli-responsive polymers into the various parts of the biosensing system has not been a major area for review. This review discusses the basic principles and types of enzymatic biosensors, with a focus on electrochemical glucose biosensors, the roles and advantages of incorporating stimuli-responsive polymers in electrochemical glucose biosensors, and the current and future outlooks of systems integration of biosensor fabrication.

Classic Biosensor System

The classic biosensor system consists of a bioreceptor established within a recognition layer, a physicochemical transducer, instrumentation or hardware, and signal/computer processing with accompanying signal processing, conditioning, and the production of actionable information as output. The latter is often overlooked but is in fact the central reason for adopting a biosensor format for any analyte measurement.

Bioreceptor (Recognition Layer)

The bioreceptor layer of a biosensor system can be any organic or biomimetic component which has high selectivity toward the target analyte to be measured. The role of the bioreceptor is to receive a stimulus from a target analyte and to present that stimulus to a transducer. Commonly used bioreceptors include antibodies/antigens, nucleic acids/DNA, whole cells, synthetic biomimetics (molecularly imprinted polymers), and enzymes (Tavakoli and Tang, 2017).

Antibodies are large, Y-shaped glycoproteins used by the immune system of the body to identify and neutralize bacteria and viruses by binding to a specific epitope of the pathogen called the antigen. The high specificity of the antibody–antigen binding ($k_{aff} > 10^{-4}$ M) has led to its widespread use as a bioreceptor in immuno-biosensors. Sandwich assays utilize a capture antibody and a detection antibody labeled with an enzyme to "sandwich" the analyte of interest, followed by a measurement of the catalytic activity between the enzyme attached to the detection antibody and an enzymatic substrate (Cho et al., 2018). In general, antibodies are not available for small molecules (haptens) such as glucose. However, the potential does exist for the development of peptide mimetics with high binding affinities to build biosensors (Thyparambil et al., 2017).

Nucleic acids and DNA used as bioreceptors undergo a recognition process called complementary base-pairing (i.e., adenine-thymine and cytosine-guanine in DNA). Spontaneous hydrogen bonding between the bioreceptor and target complementary strand can be measured by labeling with an electroactive indicator or measurement of a signal produced by the DNA (Asal et al., 2018). The use of RNA or DNA as a bioreceptor is easily prepared via polymerase chain reaction (PCR). Aptamers, which are short, single-stranded oligonucleotides that are able to bind to target molecules have been used as bioreceptors, but the similarity between glucose and other monosaccharides such as fructose and galactose

(similar structures and hydroxyl groups) creates difficulty in selecting an aptamer with high specificity (Ruscito and DeRosa, 2016). Hence, high-specificity aptamers are generally not available for glucose detection and monitoring.

Immobilized cells, organelles, and tissues have been used as transducers in the detection of many biological agents which affect cells. The response of the cell, and signals that form their homeostasis, can be transduced into measurable signals. These cellular biosensors utilize cells which rely on several different biological signals. For example, pancreatic β-cells are able to sense multiple nutrient levels (glucose, lipids, amino acids) and signal for insulin via hormones (i.e., GLP-1, GIP), which were measured through electrode arrays and amplified to extract glucose concentration (Nguyen et al., 2013). Kim et al. utilized red blood cell membrane (RBCM) to fabricate a permiselective glucose diffusion barrier based on transport of glucose by glucose transporter-1 in tandem with glucose dehydrogenase to create an amperometric glucose biosensor with high selectivity against interfering molecules (uric acid, ascorbic acid, cysteine, and galactose) (Kim et al., 2018). These cellular bioreceptor systems show future promise for biocompatible, closed-loop feedback systems for sensing and regulation of insulin within the human body.

Molecularly imprinted polymers (MIPs) are polymers which utilize the analyte of interest, acting as a template, to create a cavity in the polymer matrix with affinity toward a target molecule. Monomers are polymerized around the target analyte (via gelation, dispersion, bulk polymerization, etc.), which are then removed (usually by cleavage) and extracted via a solvent. The cavities left behind are expected to have high affinity for the template molecule. Several materials have been reported for synthesis of glucose sensitive MIPs, such as methacrylic acid (MAA) and ethylene glycol dimethyl acylate (EGDMA) (Widayani, 2017), poly(N-isopropylacrylamide-acrylamide-vinylphenylboronic acid) [poly(NIPAM-AAm-VPBA)] (Wang et al., 2015a,b), O-phenylenediamine (o-PD) (Cheng et al., 2001), and metal–organic copolymers (Qian et al., 2016). This nonenzymatic detection mechanism shows great promise due to the direct electron transfer (DET) functionality, freedom of molecular design and functional groups (to respond to different stimuli such as pH, electric field strength, etc.), high stability, high sensitivity, and low production cost (Alexander et al., 2017).

Recently, other enzyme-free systems have been used for detection of glucose, including synthetic boronic acids as molecular receptors (Wang et al., 2013). These systems which do not rely on proteins are less susceptible to enzyme denaturation and short shelf-life. Boronic acid forms reversible covalent complexes of boronate esters with the *cis*-diols of sugars, which alter changes in optical properties or conductivity (Wang and Lee, 2015). Hence, boronic acid-containing sensors are usually optically or electrochemically based (Cambre and Sumerlin, 2011). Boronic acid derivatives have been directly immobilized on electrodes using various surface chemistries as well as electropolymerized with various conductive polymers to create a conductive network capable of glucose sensing (Wang et al., 2017; Çiftçi et al., 2013).

Enzymes, which are macromolecular biological catalysts, are the most widely used bioreceptors in biosensing. Specifically, the most commonly used enzyme is glucose oxidase for the sensing of glucose. Biosensors utilizing enzymes as the molecular recognition layer offer several distinct advantages over other types of bioreceptors, including high sensitivity, high selectivity, and short response time (Mulchandani, 1998). However, variables such as bioreceptor film thickness, temperature, pH, and amount of active enzyme contribute to instability of electrode devices (Hossain and Park, 2017). Methods such as electropolymerization have been developed to control the thickness of conductive and nonconductive polymers using various electrochemical techniques (cyclic voltammetry, amperometry, etc.) (Mousa et al., 2019). The known temperature and pH dependence of enzymatic electrochemical biosensors can be accounted for and have been shown to be accurate even outside of their optimum conditions (Rocchitta et al., 2016).

Physicochemical Transducers

The transducer in a biosensor system converts physicochemical changes (temperature, light intensity, pH, conductivity, etc.) which take place at the bioreceptor into another type of energy signal through a process called "signalization" (Rocchitta et al., 2016). The signal measured should be proportional to the concentration (chemical potential) of the target analyte. The type of transduction used in the biosensor dictates the type of biosensor (i.e., electrochemical, optical, colorimetric, gravimetric). Examples of transducers are shown in Fig. 2.5.13.2.

Computer Processing

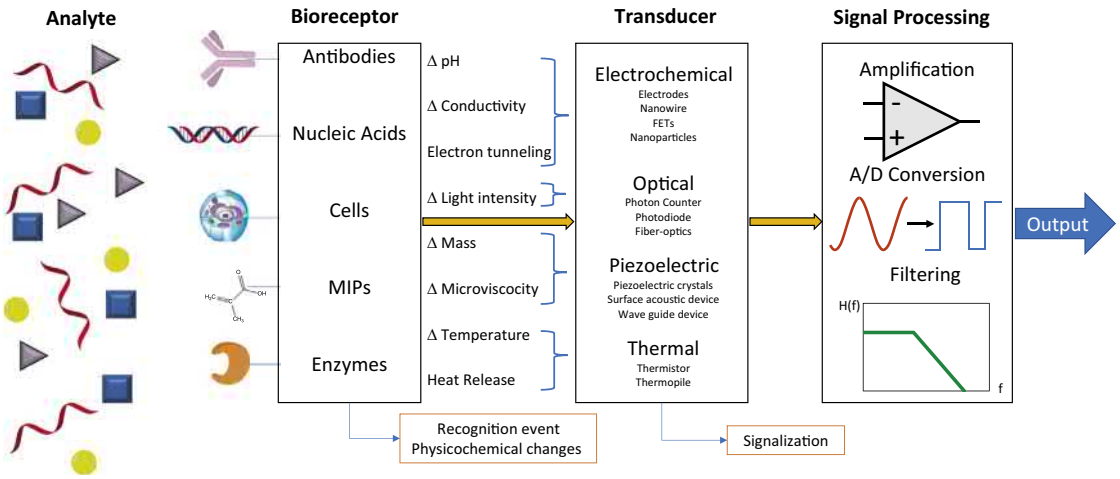
The computer processing and electronics of a biosensor system are comprised of various complex electronics used to digitize, amplify, filter, and multiplex electronic signals and present the processed signal in a display.

Recently, many advances in miniaturization of electronics, low power consumption, and wireless communication (Bluetooth, ZigBee, RFID, NFC, etc.) have been utilized to either bring computer processing as well as power delivery "on-board" for implantable biosensors or wireless transmission of signal data for "off-board" processing (Kotanen C and Guiseppi-Elie, 2014; Jung et al., 2017; Zhao et al., 2017; Kassal et al., 2018).

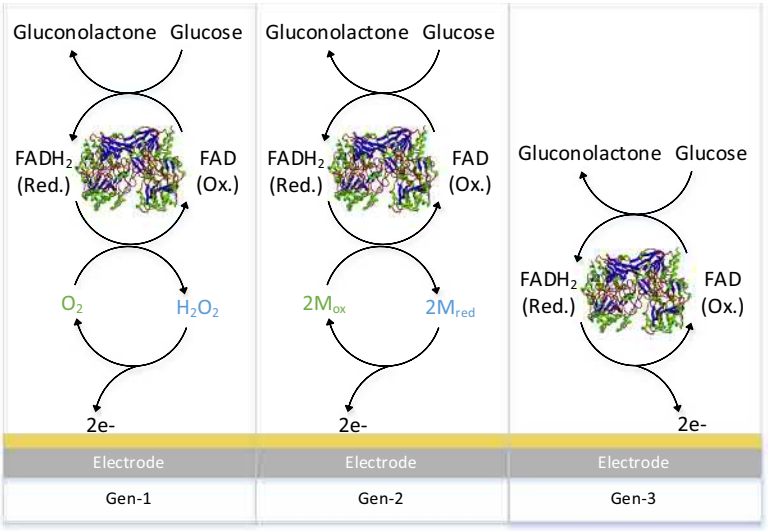
Types of Enzymatic Glucose Biosensors

Electrochemical Biosensors

A major percentage of developed enzymatic glucose biosensors used are electrochemical, because they offer sensitivity and reproducibility at a low cost that cannot be offered by many of the other sensing modalities. In fact, many of the commercially available point-of-care glucose biosensors measure glucose electrochemically (Yoo and Lee, 2010). Electrochemical biosensors can be grouped into four main transduction types: amperometric, conductimetric, impedimetric, and potentiometric.



• **Figure 2.5.13.2** General mechanism of biosensor operation. Analytes of interest are recognized by various types of bioreceptors, where some form of energy transduction can be displayed as an output through computation.



• **Figure 2.5.13.3** The three generations of enzymatic glucose sensors. (Adapted from Karunwi et al. (2013)).

Amperometric Biosensors

Amperometric glucose enzyme biosensors measure the movement of electrons (current) produced in a redox reaction beginning with the oxidation of glucose to gluconolactone via GOx (the redox cofactor, FAD, serves as the electron acceptor) (Eq. 2.5.13.1). Gluconolactone is converted to gluconate$^-$ and H^+ (Eq. 2.5.13.2) and H_2O_2 is converted to O_2, $2H^+$ and electrons in the form of current (Eq. 2.5.13.3) (Weibel and Bright, 1971; Chou et al., 2018).

$$\text{Glucose} + O_2 + H_2O \xrightarrow{GOx} \text{gluconolactone} + H_2O_2 \qquad (2.5.13.1)$$

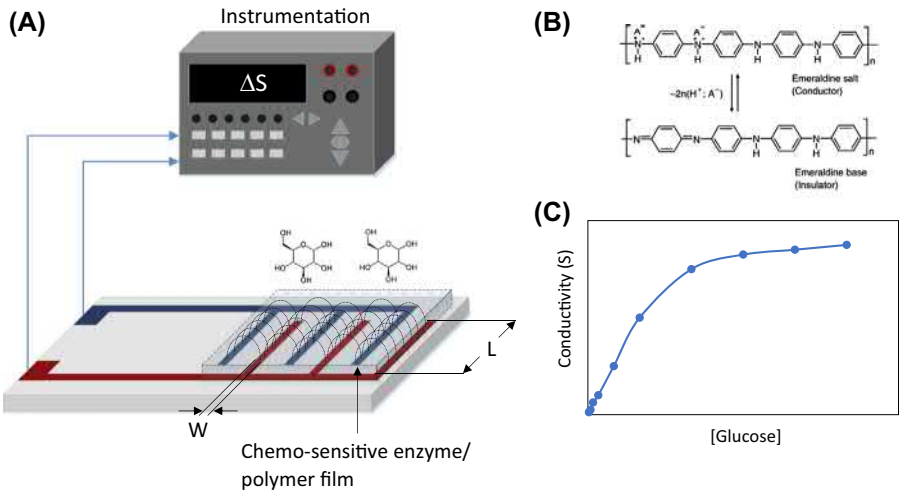
$$\text{Gluconolactone} \rightarrow \text{gluconate}^- + H^+ \qquad (2.5.13.2)$$

$$H_2O_2 \rightarrow O_2 + 2H^+ + 2e^- \qquad (2.5.13.3)$$

In an electrochemical cell, measurements can be made to monitor the consumption of oxygen or the production of hydrogen peroxide in the reaction, the current of which is directly proportional to the glucose concentration.

Amperometric glucose biosensors have been divided into three generations, based on the mechanism of electron transfer used to measure the concentration of target analyte. The reader is directed to several reviews for a comprehensive discussion of the three generations (Rocchitta et al., 2016; Wang, 2008; Chen et al., 2013). Briefly, the three generations of amperometric glucose biosensor are summarized below and visualized in Fig. 2.5.13.3:

- **Generation 1**: Generation 1 glucose biosensors monitor the consumption of oxygen or the production of hydrogen peroxide (Eq. 2.5.13.1) at the cathode or anode, respectively.



• **Figure 2.5.13.4** (A) Typical interdigitated conductometric biosensor. A chemi-sensitive film is deposited on an interdigitated electrode system. (B) Protonation and deprotonation of polyaniline as a result of hydrogen ion formation. (C) Typical conductometric glucose biosensor response.

- **Generation 2**: The second generation of glucose biosensors utilized a redox mediator, such as ferrocenes, viologens, quinones, etc., to shuttle electrons from the redox center of the GOx molecule to the electrode, effectively eliminating the need for oxygen.
- **Generation 3**: The third generation of glucose biosensors involves a direct transport of the electron (DET) from the active site of the GOx to the electrode itself, without the need of a mediator.

Conductometric Biosensors

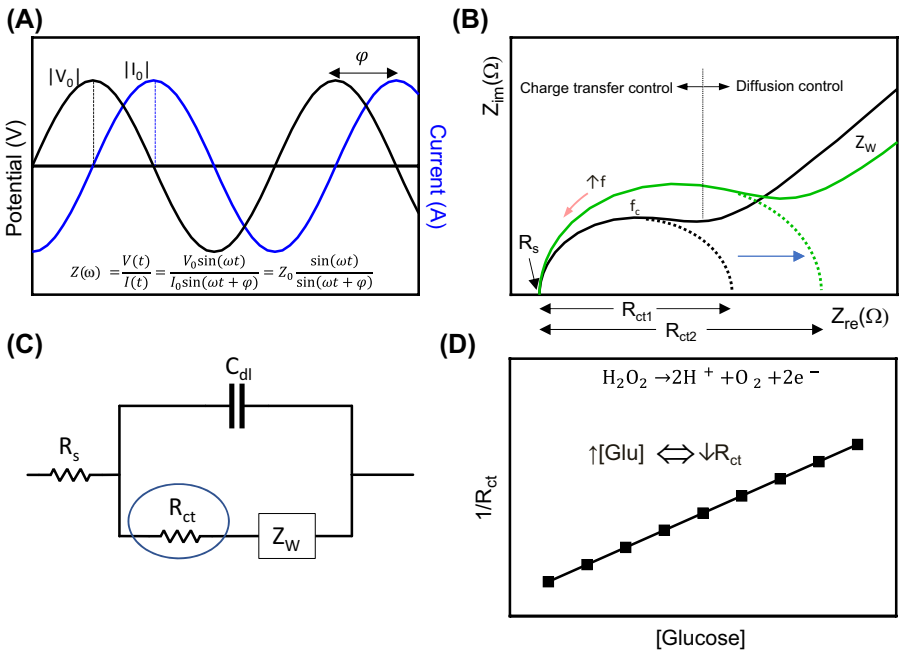
Conductometric enzyme biosensors measure the changes in conductivity of a membrane or medium, usually between two interdigitated electrodes spaced very close to each other (tens of microns) and sometimes a pair of interdigitated electrodes, one serving as measurement and one serving as reference (Nouira et al., 2013). Conductometric devices are sometimes presented as a subset of impedimetric devices but are discussed separately here. As glucose oxidase reacts with glucose, the local concentration of H^+ ions increases (Eq. 2.5.13.3), resulting in an increase in acidity and conductivity near the electrode (Kucherenko et al., 2016). However, since most assays are done in buffered solutions, these ions are neutralized quickly and don't take part in measurable net charge transport (Bănică, 2012). In fact, solution parameters such as ion strength, buffer capacity, and pH have a significant impact on solution conductivity and in turn the biosensor response (higher ion strength or buffer concentration tend to reduce sensitivity) (Pyeshkova et al., 2009). An elegant solution involves preparation of conductometric transducers utilizing chemoresistive materials, such as conductive polymers. The pH of responses of conductive polymers such as polyaniline and polypyrrole have been used as stimuli-responsive films in conductometric glucose biosensors (Miwa et al., 1994). Polyaniline, which can be protonated to its conductive emeraldine salt or deprotonated to its insulating emeraldine base, has been used as films on interdigitated microelectrodes (IDEs) with GOx (Fig. 2.5.13.4). In particular, the conductivity of the conductive polymer polyaniline is determined by the *degree* of protonation, and therefore unless in contact with a very strong acid, the conductivity can vary several orders of magnitude over several pHs. The resistance of such films is measured using small-amplitude AC signals (see "Impedimetric biosensor" section) or mV level DC signals, according to the type of instrumentation used.

While conductometric biosensors offer advantages such as nonsensitivity to light, no need for a reference electrode, and low cost, many efforts have afforded poor signal-to-noise ratios in comparison with other types of enzymatic biosensors.

Impedimetric Biosensors

Based on the fact that changes in conductivity of a membrane or medium are a factor of resistance and reactance, impedimetric biosensors emerged as a means to deconvolute and monitor the capacitive and resistive changes occurring in a biosensor system (Katz and Willner, 2003). Electrochemical impedance spectroscopy (EIS) is a commonly used nondestructive measurement tool that has been utilized in applications including electrode characterization (Aggas et al., 2018), corrosion (Ribeiro and Abrantes, 2016), and biosensors (Kotanen et al., 2018).

Impedance is measured by application of a small sinusoidal voltage (<50 mV peak-to-peak) and measurement of the resultant current response (magnitude and phase) over a range of frequencies, as shown in Fig. 2.5.13.5A. Measurement over a range of frequencies allows the researcher to visualize frequency-dependent phenomena in the electrochemical system. A typical Nyquist plot is shown in Fig. 2.5.13.5B. EIS spectra are analyzed by equivalent circuit analysis (ECA), a technique in which experimental data are fitted to a circuit which can describe the electrochemical system in order to quantify electrical parameters and extract kinetics and charge transfer mechanisms. The most basic of these circuits, the Randles circuit, includes a solution



• **Figure 2.5.13.5** (A) Sinusoidal current response in a linear EIS system. (B) Typical Nyquist plot of enzymatic glucose electrodes in analyte. (C) Equivalent circuit used to analyze Nyquist plots. (D) Typical Rct response of increasing amounts of glucose.

resistance (R_s), charge transfer resistance (R_{ct}), double layer capacitance (C_{dl}), and Warburg impedance (W) (Fig. 2.5.13.5C).

Changes in the charge transfer resistance (faradaic impedance biosensors) and double layer capacitance (non-faradaic impedance biosensors) of glucose biosensor systems have been shown to correlate to the glucose concentration (Pänke et al., 2007). Recently, Asrami et al. demonstrated a reusable novel nanostructured copper oxide film on fluorinated-tin oxide with glucose oxidase immobilized in chitosan for impedimetric sensing of glucose. EIS measurements showed a linear scale of ΔR_{ct} [ΔR_{ct} (kΩ) = 0.306(±0.027) + 0.261 (±0.003) × [glucose] (mM); R^2 = 0.998] over the range of 0.2–15 mM glucose (Naderi Asrami et al., 2018). Wang et al. demonstrated a bifunctional impedimetric and amperometric glucose biosensor utilizing self-assembled monolayers (SAMs) of GOx with Prussian blue mediator able to operate at low potentials (0.0 V vs. Ag/AgCl). EIS measurements showed a linear scale of $1/R_{ct}$ [$1/R_{ct}$(kΩ) = 0.225 + 0.0773 × [glucose] (mM); R^2 = 0.994] over the range of 0.0–25 mM glucose (Wang et al., 2015a,b). A typical linear response curve of $1/R_{ct}$ versus glucose concentrations is shown in Fig. 2.5.13.5D.

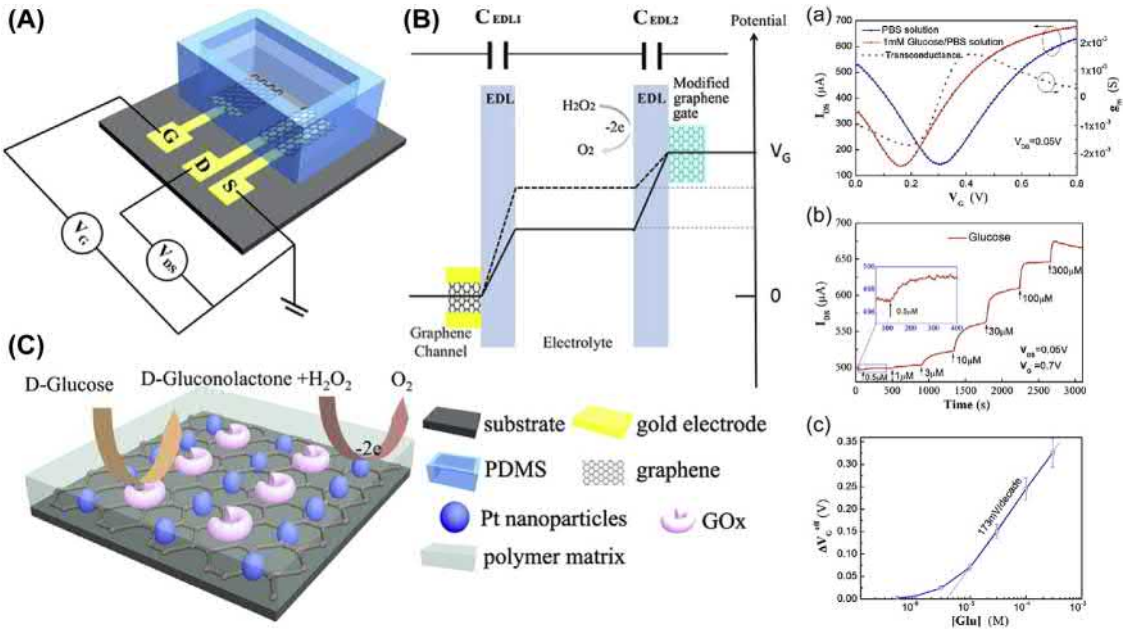
Potentiometric Biosensors

Potentiometric enzyme biosensors measure changes in electric potential generated by an analyte reacting with an enzyme due to concentrations of ions, usually at an ion-selective electrode (ISE), ion-selective field effect transistor (ISFET), or enzyme field effect transistor (EnFET) (Mulchandani, 1998). The most simple of these potentiometric biosensors is the glass pH electrode, of which GOx has been immobilized by means of cellophane, nylon, and nitrocellulose (Pisoschi, 2016). In a more complex fashion, GOx has been immobilized on ion-sensitive membranes of ion-selective FETs. The changes in electrical field at the enzyme/electrode interface alter the conductivity of the n and p channels of an ISFET. While potentiometric biosensors are mostly used for measurement of ion concentration (pH, Na^+, K^+, Mg^{2+}, NO^{3-}, etc.), there is some recent work utilizing potentiometric methods to measure glucose via glucose oxidase. A typical glucose-sensitive enzyme transistor is shown in Fig. 2.5.13.6A. Generation of H_2O_2 by oxidation of glucose at the gate of the transistor and the modulation of gate voltage by oxidation of H_2O_2 (Zhang et al., 2015). The potential drop at the gates is determined by the Nernst equation:

$$V_{EDL2} = -\frac{kT}{2q}\ln[H_2O_2] + C \qquad \textbf{(2.5.13.4)}$$

where the voltage on the channel surface, V_{EDL2} is a function of the Boltzmann constant (k), the temperature (T), electronic charge (q), concentration of H_2O_2, and a constant C. The changing concentration of H_2O_2 at the electrode governs the current through the channel (I_{DS}) by the field effect. Typical channel currents from 0 to 300 mM glucose are shown in Fig. 2.5.13.6D.

Recently, nanomaterials, such as zinc oxide (ZnO) nanowires, have been utilized as transducers in potentiometric glucose biosensors due to their high aspect ratio, chemical stability, and ease of fabrication (Usman Ali et al., 2010). Wahab et al. prepared glucose oxidase



• **Figure 2.5.13.6** (A) Schematic of glucose-sensing transistor. (B) Typical channel current and gate voltage changes with respect to glucose concentration. (Adapted from Zhang, M., Liao, C., Mak, CH., You, P., Mak, CL., Yan, F., 2015. Highly sensitive glucose sensors based on enzyme-modified whole-graphene solution-gated transistors. Sci. Rep. 5, 8311.)

immobilized on ZnO nanorods on both conductive plastic and silver wire. Potentiometric measurements vs. Ag/AgCl showed a logarithmic scale of 165.5 mV/decade ($R^2 = 0.980$) (Wahab et al., 2018). Parrilla et al. developed a low-cost, paper-based potentiometric glucose biosensor by entrapping GOx in Nafion deposited on paper which was first sputter coated with platinum. Potentiometric measurements vs. Ag/AgCl showed a logarithmic scale of 119 mV/decade ($R^2 = 0.9900$) with a limit of detection of 0.03 mM glucose (Parrilla et al., 2017). Chou et al. prepared a flexible glucose sensor utilizing GOx entrapped in Nafion/magnetic beads (MBs) on a graphene oxide (GO) nickel oxide (NiO) film. Potentiometric measurements vs. Ag/AgCl showed a logarithmic scale of 35.3 mV/decade ($R^2 = 0.999$) with a limit of detection of 1.0 mM glucose (Chou et al., 2018). Potentiometric biosensors have the advantage of not requiring an extra potential (compared to amperometric biosensors), which reduces the effects of interfering analytes such as ascorbic or uric acid (Usman Ali et al., 2010).

Optical Biosensors

Whereas electrochemical biosensors utilize electrodes to measure an electric signal, optical biosensors utilize a light source, substrate, and photo-detector. Optical glucose biosensors measure changes in optical properties of the reactants (O_2) or products (H_2O_2) brought about by the enzymatic GOx reaction. Specifically, changes in the absorption, luminescence, or reflectance can be measured via direct or indirect optical detection (Vargas-Bernal et al., 2012; Grieshaber et al., 2008). Direct optical detection methods (label-free), which measure changes in transducer properties, include photoluminescence, reflectometry, TIRF, and SPR. Indirect optical detection methods (require labels) include fluorescence, SERS, and photoluminescence based on quantum dot labels (Syshchyk et al., 2015).

Syshchyk et al. developed a highly sensitive novel glucose biosensor based on the photoluminescence of porous silicon. Photoluminescence intensity increases were measurable from 0 to 3.0 mM glucose in the emission range of 590–620 nm, as a product of changing pH due to the enzymatic reaction (Syshchyk et al., 2015). ZnO nanomaterials have also been used in optical biosensors due to their intense room temperature photoluminescence and electron transport properties, and they show great promise for use in SERS, SPR, and fluorescence glucose sensors (Tereshchenko et al., 2016; Aini et al., 2015; Sodzel et al., 2015). Singh et al. developed an opto-chemical glucose-sensing fiberoptic capable of sensing glucose from 20 to 400 ppm (0.1–2.2 mM), with a limit of detection of 5 ppm. The inclusion of polyaniline into a NiO/PAn matrix was shown to increase effective glucose oxidation and was responsible for discerning measurements at 20 ppm glucose (Singh and Shukla, 2018).

Piezoelectric Biosensors

Piezoelectric enzyme biosensors are created by immobilizing the bioreceptor on the surface of a piezoelectric crystal. Interaction with the target analyte alters the oscillation frequency of the piezoelectric crystal. The oscillation frequency will decrease when a substance is adsorbed onto the

surface, allowing for measurement of analyte concentration as a function of oscillation, following Sauerbrey's equation (Chuang and Shih, 2001; Chou et al., 2008):

$$\Delta F = \frac{K \cdot f^2 \cdot \Delta m}{A} \quad (2.5.13.5)$$

where ΔF, the change in resonant frequency (Hz), is governed by the original oscillation frequency, f (Hz), the change in mass, Δm (grams), the area, A (cm^2) of the coating, and K is a constant for the particular crystal. Piezoelectric sensors utilize antibody/antigen pairs, MIPs, and DNA for selective biosensing. As enzymes are only used in enzyme-linked immunosorbent assays (ELISA), the concepts of piezoelectric biosensors are not covered in depth here but can be found reviewed elsewhere (Pohanka, 2018).

Thermal Biosensors

Thermal, or calorimetric, biosensors exploit the fact that enzyme reactions generate heat—the amount of which is proportional to the concentration of reacted substrate, following the first law of thermodynamics:

$$Q = -n_p \sum \Delta H \quad (2.5.13.6)$$

where Q (Joules) is the total heat energy, n_p (mol) is the moles of product generated through the enzymatic reaction, and ΔH (Joule/mol) is the molar enthalpy change (Zhou et al., 2012). Specifically, the glucose oxidase enzyme with glucose reactant generates ~100 kJ/mol (Yakovleva et al., 2013). Enzyme thermistors are able to transduce the small changes in heat of the biochemical transformation according to (Zhou et al., 2012):

$$\Delta T = -\frac{n_p \Delta H}{C_s} \quad (2.5.13.7)$$

where the change in temperature, ΔT (K), is governed by the moles of product generated through the enzymatic reaction, the molar enthalpy change, and the total heat capacity of the system, C_s (Joule/K). Heat generated by the reaction alters the resistance of the working thermistor, and the difference between the working thermistor and reference thermistor are used to determine analyte concentration.

Thermistors, usually used in pairs as a reference and working thermistor in a flow injection system, function by changing their electrical resistance in relation to temperature:

$$R = R_0 e^{\beta\left(\frac{1}{T} - \frac{1}{T_0}\right)} \quad (2.5.13.8)$$

where R (Ω) is the resistance at temperature T (K), R_0 (Ω) is the resistance at temperature T_0 (K), and β is a constant associated with the thermistor. Thermistors are often used in Wheatstone bridge configuration in order to determine the resistance as it changes with respect to temperature (Yakovleva et al., 2013). A typical enzyme thermistor includes an insulating layer (usually polyurethane) covering a thermostated aluminum block holding two fluidic columns. Typically, one column is activated with the enzyme used for measurement, while the other is used as a reference. Flow of the sample through the columns results in temperature fluctuations as the enzyme reacts with the substrate, altering resistance of the thermistor, and in turn measured voltage change in the balanced Wheatstone bridge (Yakovleva et al., 2013).

Recently, Xie et al. developed an enzyme thermistor utilizing pyrroloquinoline quinone glucose dehydrogenase (PQQGDH) compared to the more commonly used GOx enzyme thermistor, showing higher catalytic activity and insensitivity to availability of oxygen. Calorimetric measurements showed a linear range of 0.009–100 mM glucose with higher specificity than GOx (Xie et al., 2018).

Thermal biosensors offer high sensitivity to small changes in heat but nonspecificity, baseline drift, and heat lost through radiation, conduction, or convection have limited their use in biosensors (Yi-Hua et al., 2006).

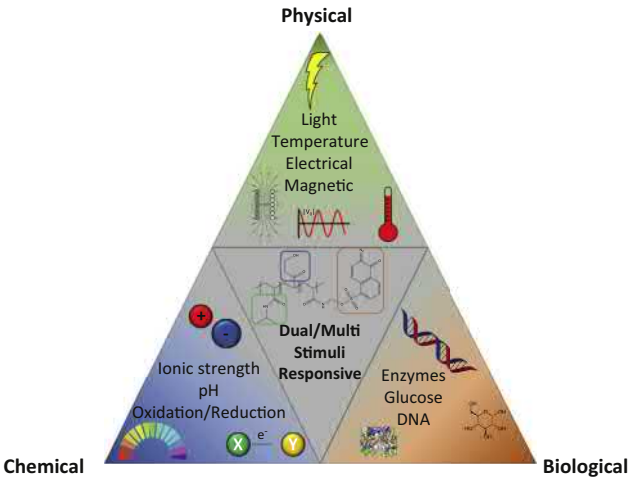
Roles of Responsive Polymers in Enzymatic Biosensors

In the past several decades, the exponential increase in enzymatic biosensor development and performance can be credited to the incorporation of both nanomaterials and/or stimuli-responsive polymers within the biosensor (Chen et al., 2013; Hu and Liu, 2010). Stimuli-responsive polymers are polymers which exhibit reversible or irreversible changes in physicochemical properties in response to physical, chemical, or biological stimuli from their environment, such as pH, temperature, electric/magnetic fields, bioactive molecules, and light (Fig. 2.5.13.7) (Russell, 2002).

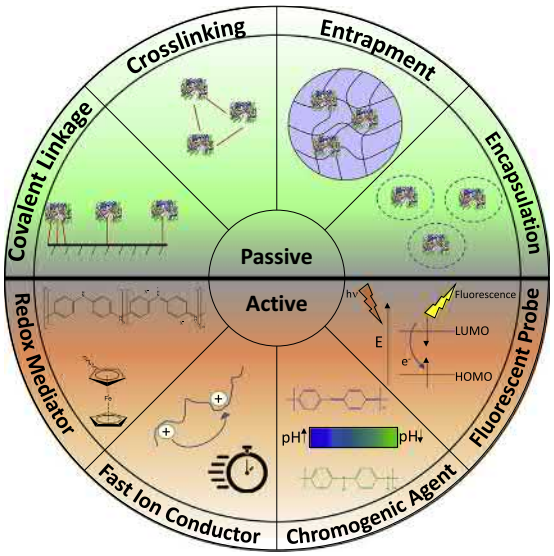
The roles in which stimuli-responsive polymers have been used in biosensor systems can be described as active or passive. Active roles are generally used in the sensing of the analyte, while passive roles are attributed to nonsensing components of the biosensor system, such as physical support, increasing biocompatibility, decreasing biofouling, maintaining sensor viability, and increasing sensor lifetime (Hahm, 2011). A summary of the passive and active roles of polymers in biosensors is shown in Fig. 2.5.13.8. A summary of recent work involving responsive polymers in glucose biosensors is shown in Table 2.5.13.1.

Passive Roles (Physical Support)

In enzymatic biosensors, immobilization of the enzyme within the biosensor's surface in close proximity with the transduction element while simultaneously presenting the enzyme active site to the analyte is of utmost importance for biosensor performance (Pan et al., 2017). Enzymes are typically immobilized physically, through adsorption, entrapment, encapsulation, and SAMs, or chemically, through



• **Figure 2.5.13.7** Summary of classes of stimuli-responsive polymers.



• **Figure 2.5.13.8** Summary of passive and active roles of stimuli-responsive polymers in biosensors.

covalent linkage, cross-linking, or electrochemical polymerization (Wang and Uchiyama, 2013).

Covalent Linkage

Immobilization of enzymes through covalent linkage of their amino acids has been reported utilizing polymer brushes, EDC/NHS chemistry, and glutaraldehyde as well as semicovalent linkage through thiol chemistry, such as cysteine (Lee et al., 2018). Covalent linkage of an enzyme to a transducer support is carried out in two stages. First, the transducer surface is activated by linker molecules. Second, the enzyme is covalently linked to the linker on the transducer (Hoang Hiep and Moonil, 2017).

Polymer brushes, which are polymer chains attached to a surface, have been used as an interface between biosensors and the media of interest (Welch et al., 2015). Specifically, these brushes have been used as an anchor to attach enzymes to electrode surfaces in electrochemical biosensors. Welch et al. presented an organic glucose-sensitive transistor device which immobilized GOx onto PEDOT:PSS through a simple process using polymer brushes comprised of PGMA and PHEMA (Fig. 2.5.13.9) (Welch et al., 2015).

Activation of carboxylic groups on the enzyme and covalent linkage to the electrode surface or a conductive polymer using EDC/NHS chemistry has been used extensively. Kotanen et al. fabricated an implantable dual-responsive glucose/lactate biosensor by covalent conjugation of GOx with a pyrrole moiety and subsequently electropolymerized onto the electrode surface (Kotanen et al., 2014).

Cross-Linking

Through cross-linking, a polymer such as glutaraldehyde (GA), polyethylene glycol (PEG), or polyethylene glycol diglycidyl ether (PEGDE) is used to covalently link free amino acid groups to other enzyme molecules (Hoang Hiep and Moonil, 2017). In similar fashion to the covalent linkage of GOx to the monomer pyrrole and subsequent electropolymerization by Kotanen et al., Colak et al. first electropolymerized poly-pyrrole-poly(vinyl sulfonate) (PPy-PVs) films onto a platinum electrode, and subsequently immobilized GOx through glutaraldehyde cross-linking (Çolak et al., 2012). While glutaraldehyde cross-linking is the most commonly used cross-linking method for enzymes, PEGDE has recently been shown to be more advantageous, offering higher sensitivity and specificity. This is thought to be a result of the more mild method of cross-linking in addition to the lower toxicity of PEGDE (Vasylieva et al., 2013; Sirca et al., 2014). Cross-linking is commonly used in conjunction with enzyme entrapment to retain higher amounts of enzyme loading.

Entrapment

Through entrapment, an enzyme is not directly bonded with any polymers, rather it is entrapped within a cross-linked polymer network, such as a hydrogel. Entrapment of an enzyme in a polymeric matrix offers good retention of enzymatic activity and high enzymatic stability, and is often the most simple method of immobilization (Wang et al., 2005). However, careful selection of polymers must be used in order to allow diffusion of analyte to the active site of the enzyme. Entrapment within hydrogel matrices (Mariani et al., 2013), electropolymerized conductive polymers such as polypyrrole (Wang et al., 2005), synthetic polymers such as Nafion (Beyene et al., 2004), or a combination (Brahim et al., 2002), have been successfully used to create glucose biosensors. During electropolymerization in proximity of counteranion dopants, negatively charged glucose oxidase will form in the polymer layer directly on the electrode (Kotanen and Guiseppi-Elie, 2012).

Encapsulation

Enzyme encapsulation, similar to entrapment, involves immobilizing the enzyme within a semipermeable membrane (without chemical bonds), which serves to preserve enzyme

TABLE 2.5.13.1 Table Recent Uses of Passive/Active Polymers in Glucose Biosensors

Stimuli-Responsive Polymer	Passive/ Active	Stimulus	Role	Sensor Type	References
Poly(ethylene terephthalate) (PET)	Passive	–	Flexible support substrate	Electrochemical (amperometry)	Pham et al. (2010)
Poly(2- hydroxyethyl methacrylate) brushes	Passive	–	Link Gox and HRP to microfluidic channel surface	Optical (UV vis)	Costantini et al. (2013)
Poly-N-isopropylacrylamide (PNIPAM)	Passive	Temperature	Enzyme adsorption/release	Electrochemical (amperometry)	Xiong et al. (2013)
Poly-N-isopropylacrylamide (PNIPAM)	Passive	Temperature	Covalent linkage of enzyme	Optical (fluorescent)	Wang et al. (2013)
Poly-N-isopropylacrylamide (PNIPAM)	Passive	Temperature	Covalent linkage of enzyme	Electrochemical (amperometry)	Xiong et al. (2013), Mugo et al. (2019)
Poly-N-isopropylacrylamide (PNIPAM)	Passive	Temperature	Covalent linkage of enzyme	Optical (fiber optic)	Lin et al. (2019)
Poly-N-isopropylacrylamide (PNIPAM)-ferrocene	Active	Temperature	Covalent conjugation to enzyme	Electrochemical	Nagel et al. (2007)
P(NIPAM-co-OEGMA)	Active	Temperature	Current response tuning via temperature change	Electrochemical (amperometry)	Bünsow et al. (2010)
Poly-N-isopropylacrylamide (PNIPAM)	Active	Temperature	PNIPAM color changed from red to purple to blue at different temperatures	Optical	Maji et al. (2016)
Poly-N-isopropylacrylamide (PNIPAM)-boronic acid	Active	Temperature/ glucose	Hydrogel swelling/shrinking in response to glucose, with increasing sensor response rate at higher temperatures	Optical (fiber optic spectrometry)	Ben-Moshe et al. (2006)
Boronic acid–polyacrylamide–PEG (BA–AA–PEG)	Active	Glucose	Hydrogel swelling/shrinking in response to glucose	Optical (spectrometry)	Alexeev et al. (2003)
Poly(N-(3-amidino)-aniline) (PNAAN)	Active	CO_2 concentration	PNAAN is protonated at higher CO_2 concentration, causing AUNps to aggregate and produce a color change	Optical	Ma et al. (2016)
Poly(N-isopropylacrylamide-acrylamide-vinylphenylboronic acid) [poly(NIPAM-AAm-VPBA)]	Passive/ active	Glucose	NIPAM: Enable precipitation polymerization above LTST VPBA: pH dependent, reversible glucose binding Hydrogel swelling/shrinking in response to glucose	Optical	Wang et al. (2015a)
Rhodamine-carbazole- thienyl pyrrole derivate (P(RDC-co-SNS)	Active	O_2 concentration	Fluorescence probe	Optical (fluorescence)	Ayranci et al. (2018)
4-Phenyldiboronic acid	Active	H_2O_2 concentration	Fluorescent probe	Optical (fluorescence)	Yu et al. (2017)
Poly(butyl methacrylate-co-(2-dimethylaminoethyl) methacrylate-co-methyl methacrylate) (Eudragit E PO)	Active	pH	Fluorescent probe	Optical (fluorescence)	Park et al. (2017)
PMA/DMAEMA/TEGDMA/EG	Active	pH	Reversible swelling	Piezoelectric	Schmidt et al. (2016)
Poly(N-isopropylacrylamide)-copoly(acrylic acid)-(3-aminophenyl-boronic acid) (PNIPAAM-coPAA-PBA)	Active	pH	Boronic acid/glucose complex	Piezoelectric	Chen et al. (2010)

structure/activity and protect against degradation (Besic and Minteer, 2017). Organic polymers such as Nafion, chitosan, and alginates are commonly used for enzyme encapsulation (Klotzbach et al., 2008). While both entrapment and encapsulation are more gentle roles for physical support, they tend to show continuous loss of enzyme activity over time.

Active Roles

Conductive electroactive polymers (CEPs) are conjugated polymers which display both controllable and stimuli-responsive changes in electrical, electrochemical, and optical properties (Guiseppi-Elie, 2010). CEPs such as poly(3,4-ethylenedioxythiophene) (PEDOT), polythiophene (PTh), polypyrrole (PPy), and polyaniline (PAn) offer mild polymerization conditions suitable for incorporation of enzymes in optical, electrochemical, and piezoelectric biosensors (Guiseppi-Elie, 2010). Furthermore, incorporation of CEPs into hydrogels to create electroconductive hydrogels (ECHs) retains the favorable properties of CEPs within a highly swellable, biocompatible polymer matrix (Wilson et al., 2010). The active roles that CEPs play within glucose biosensor systems are summarized in this section and shown in Fig. 2.5.13.8.

Redox Mediators

Redox-active polymers can be split into two groups: conductive polymers where the reversible redox reaction occurs in the main chain, or in side groups, such as conjugated polymers with pendant mediators (i.e., ferrocene) (Gracia and Mecerreyes, 2013; Kim et al., 2017). These polymers have generated much interest for their potential use in enzymatic biosensors stemming from their electrochemical, electronic, optical, catalytic, and biological properties (Pietschnig, 2016). Of utmost importance is the immobilization (while retaining high diffusivity) and availability of such redox mediators within proximity of the enzyme (Boztas and Guiseppi-Elie, 2009). Redox polymers have attracted attention for their use in nonenzymatic glucose biosensors. Recently, Li et al. designed a novel nonenzymatic electrochemical glucose biosensor using ferrocene-terminated hyperbranched polyurethane (HPU-Fc) with high selectivity and sensitivity (Li et al., 2016). Redox-responsive ECHs utilizing CEPs such as polyaniline and polypyrrole have been reported, whereas a subunit of the polymer backbone is oxidized, leading to a swelling response of the entire hydrogel (Pan et al., 2012; Mano et al., 2007). A reversible redox reaction can take place in the polymer main chain, as in the case of conducting polymers such as polyaniline, or in side groups, as in the case of a polymer carrying ferrocene side groups.

Chromogenic Agents

Conductive conjugated polymers, such as polythiophene, polypyrrole, and polyaniline have been researched for their electrochromic properties in biosensors. An electrochromic material is one that shows reversible change in optical properties as a result of an applied electrochemical potential (switching of redox states) (Jenekhe and Kiserow, 2004). For example, polyaniline exhibits color transition from yellow to green to blue to violet depending on the oxidation state (and pH) via protonation/deprotonation and ion exchange (Dhand et al., 2011). Other conjugated polymers, such as PEDOT, are used as chromogenic agents as it offers fast switching speed from deep to pale blue, high electronic conductivity, and resistance to degradation after doping (Saxena et al., 2011). In addition to direct chromogenic properties, pendant groups such as ferrocene have been conjugated to polymer backbones to enable electrochromic behavior (Pietschnig, 2016).

Fast Ion Conductors

Fast ion conductors are solids which can conduct ionic current at levels similar to liquid electrolytes and molten salts (10^{-1}–10^{-2} S/cm). Solid-state ionics, many of which exhibit ionic and electronic conductivity, have found use in energy storage, fuel cells, and sensor technologies (Tuller, 2017). Fast ion conduction has been exploited through the use of nanoporous ECHs, where impedance between electrode surface and electrolyte is decreased by the ionic conductivity of conductive polymers. Ionic conductivity in polymer electrolytes, σ, is expressed as:

$$\sigma = \sum_i n_i z_i e \mu_i \qquad \textbf{(2.5.13.8)}$$

where μ_i ($m^2/s^{-1/V-1}$) is the ionic mobility, n_i (m^3) is the number of ionic carriers per unit volume, z_i is the valency of ionic carriers, and e is the charge of an electron (Harsányi, 2000). In the case of conducting polymers such as polypyrrole, ions can by cycled in or out of the polymer (hence changing conductivity) by controlling the applied potential. Positive potential applied to polypyrrole oxidizes the polymer, enticing small anions to enter the material. Inversely, negative potential reduces the polymer and expels anions (Ferraz et al., 2012).

Fluorescence Probes

Fluorescence is the emission of light energy by some substance that has absorbed light or radiation (Klonoff, 2012). Fluorescent conductive polymers utilize (1) covalent linkage

of fluorescent molecules to polymer backbone (extrinsic fluorescence), or (2) copolymerization with fluorescently polymerizable monomers (intrinsic fluorescence) (Basabe-Desmonts et al., 2007). Conjugated polymers, such as polypyrrole, polyacetylene, polyaniline, and polythiophene provide electronic conjugation (molecular wiring) and are excellent fluorescent probes because they can amplify molecular recognition by electron migration along the polymer chain (photoinduced electron transfer fluorescence quenching) (Basabe-Desmonts et al., 2007). Ayranci et al. demonstrated a multifunctional copolymer of rhodamine-carbazole and thienyl pyrrole derivate with glucose oxidase [P(RDC-co-SNS)/GOx] for the fluorescent sensing of glucose (Rukiye et al., 2018).

Polymer composites including carbon nanotubes, graphene oxide, and quantum dots (most recently carbon dots) have been widely studied as biocompatible probes for fluorescent glucose biosensors, but their mechanism of fluorescence is still not fully understood (Chen et al., 2018). Barone et al. reported shifts in emission spectra of single-walled carbon nanotube (SWCNT) hydrogel composites by inducing reversible hydrogel swelling using poly(vinyl alcohol) (PVA) capable of sensing glucose (Barone et al., 2009). While traditional quantum dots are not suitable for in vivo sensing due to cytotoxicity, polymer shells have been applied to QDs to improve biocompatibility (Chen et al., 2018).

Boronic acid fluorescent sensors, which operate according to nitrogen (N)–B interactions and photoinduced energy transfer, can form reversible covalent complexes capable of creating a discrete "ON–OFF" fluorescent response (Wang and Lee, 2015). The fluorophore-spacer-receptor model has been widely used in fluorescent biosensors, where electrons freed during the binding process of sugar to boronic acid are used to excite the fluorophore (James, 2006). In addition, boronic acid-functionalized graphene quantum dots and carbon quantum dots have been used for selective and rapid glucose sensing (Qu et al., 2013; Shan et al., 2014).

Carbon dots (CDs) (and their polymeric form, PCDs), which appear to violate the Kasha-Vavilov rule of excitation-dependent photoluminescence, seem to show good candidacy for biosensing and a new alternative to traditional fluorescent nanomaterials (Sau et al., 2018; Li et al., 2018). Recently, Li et al. proposed a preparation of yellow-emissive carbon dots by one-pot hydrothermal treatment of p-phenylenediamine and aspartic acid. By addition of silver nanoparticles, the optical capacity was suitable for glucose sensing (Li et al., 2018).

Integrating Responsive Polymers With Enzymes

Integration of responsive polymers with enzymes, specifically electrical contact with the active site of the enzyme, is a highly studied area in the pursuit of second- and third-generation electrochemical biosensors (Zayats et al., 2002). This section discusses the different methods in which responsive polymers have been integrated with enzymes.

Physicochemical Conjugation With CNTs

Carbon nanotubes have been used extensively as supports for enzymes due to their high surface area, enzyme-loading capabilities, biocompatibility, and electrical/mechanical properties (Saifuddin et al., 2013). In 2002, Guiseppi-Elie et al. demonstrated direct electron transfer (DET) of glucose oxidase on carbon nanotubes by demonstrating spontaneous adsorption to carbon nanotube bundles (Anthony et al., 2002). Since then, there has been considerable research on the use of carbon nanotubes and other nanomaterials in the fabrication of third-generation (mediator-free) enzymatic glucose sensors. Glucose biosensors utilizing carbon nanotubes, graphene, nanoparticles, and nanocomposites have been studied for use in DET of GOx (Luong et al., 2017).

Active Site Conjugation Using Boric Acid

Boric acid (an organoborane) has been used in an attempt to establish direct electrical communication between the electrode and enzyme. Direct conjugation of the active FAD site of GOx has been reported to bestow direct electrical contact between the enzyme and electrode. Zayats et al. demonstrated the reconstitution of GOx on an FAD monolayer using boronic acid ligands to create a boronic acid–FAD complex, bypassing the need for a mediator or oxygen (Zayats et al., 2002). More recently, Bai et al. immobilized GOx on a planar boron-doped diamond electrode using 3-aminopropyltriethoxysilane (APTES) to create a third-generation electrochemical glucose biosensor capable of DET (Bai et al., 2014). Chen et al. demonstrated proof of concept for a piezoelectric glucose biosensor based on a 3-aminophenyl-boronic acid (PBA) complex with glucose, showing glucose binding to ionized boronate species to induce polymer brush swelling on a microcantilever (Chen et al., 2010). Ben-Moshe et al. developed glucose-sensing photonic crystal utilizing boronic acid groups covalently linked to a hydrogel which cross-links with glucose, without the need for sodium ion-chelating agents such as PEG or crown ethers, to measure an increase in hydrogel volume via a fiberoptic spectrometer (Ben-Moshe et al., 2006). Wang et al. utilized molecularly imprinted polymers of poly(N-isopropylacrylamide-acrylamide-vinylphenylboronic acid) [poly(NIPAM-AAm-VPBA)] with fluorescent carbon dots able to reversibly swell and shrink upon the pH-dependent, reversible binding of glucose to the boronic acid moiety (Wang et al., 2015a,b). Tierney et al. developed a similar responsive gel, wherein the hydrogel swells as glucose binds to the boronic acid due to a shift in osmotic potential rising from conversion of neutral boronic acids to anionic boronate esters (Tierney et al., 2009).

Molecular Wiring

The simultaneous immobilization and electrical "wiring" of enzymes (specifically the active site) with responsive redox polymers has been widely studied for use in electrochemical biosensor applications (Wang, 2008). In 1987, Degani and Heller reported on wiring of GOx to an electrode surface demonstrating covalently linked electron relays (Degani and Heller, 1987). Several strategies have been implemented for electrical wiring to electrodes, including conjugation of ferrocene mediators to enzymes, surface reconstitution of enzymes, and conjugation within polymer networks (Schuhmann et al., 1991; Xiao et al., 2003; Gerard et al., 2002). Recent work, involving wiring of mediators consisting of poly(4-vinylpyridine) (PVP) backbones, has shown great promise as wires for GOx as well as pyrroloquinoline quinone glucose dehydrogenase (PQQ-sGDH) in electrochemical glucose sensors (Flexer and Mano, 2014).

Covalent Conjugation

Covalent conjugation of enzymes to amphiphilic responsive copolymers (either in the main chain or on side chains) has shown promise within biosensing, due to the fact that conformational changes of the polymer can be induced by stimuli (Shakya and Nandakumar, 2018). Enzymes can be covalently conjugated either randomly or at specific sites of the polymer dependent on the polymer and enzyme in use. The bioconjugation of stimuli-responsive polymers has been reported in thermo-, ion-, and photo-responsive biosensors (Xiong et al., 2013; Dübner et al., 2017).

Integrating Responsive Polymers With Transducers

Interface Engineering

Electrochemical reactions in biosensors take place at the interface between some surface-modified electrode and a liquid electrolyte with a charge being exchanged between the electronically conductive electrode and ionically conductive electrolyte (Xu, 2017). Research in the engineering at the bio-electrochemical interface level of biosensors using functional and responsive nanomaterials has burgeoned the development of transducers with high sensitivity, stability, and selectivity (Zhou and Dong, 2011). Techniques utilizing self-assembled monolayers (SAMs), layer-by-layer assembly, polymer brushes, sol–gels, and hydrogels have been used to integrate responsive polymers to the transducer.

SAMs are considered the most simple approach for the bio-electrochemical interface, but offer high bonding strength to both the organic or inorganic components, and long-term stability (Putzbach and Ronkainen, 2013). Wan et al. produced glucose-sensitive electrodes by first oxidative graft polymerization of polyaniline to gold electrodes using 4-aminothiophenol SAMs, followed by covalent linkage (via glutaraldehyde) of chitosan/CNTs immobilized with GOx (Wan et al., 2010). The combination of polyaniline and chitosan resulted in a biocompatible transducer with excellent electron transfer properties and high enzyme retention.

Layer-by-layer (LbL) assembly uses a combination of dip coating strategies and self-assembly based on electrostatic Coulombic interactions between subsequent layers (Barsan et al., 2014). LbL techniques utilizing redox polymer/enzyme complexes have been shown to increase biosensor current densities using thinner polymer matrices (Sirkar et al., 2000). Using a self-assembled layer-by-layer N-doped graphene/GOx/chitosan, Barsan et al. developed a highly stable amperometric glucose biosensor able to operate at low potential with high sensitivity and stability (Barsan et al., 2014).

Sol–gel technology, which is a room-temperature preparation technique using organic precursors, has been popularized for enzyme encapsulation and favorable features such as tunable porosity, chemical inertness, and thermal stability (Wang, 1999). The sol–gel technique and molecular imprinting are commonly used in tandem to create electrochemical biosensors. Recently, Zohourtalab et al. created an amperometric sol–gel biosensor of GOx immobilized in a chitosan/Nafion/ferrocene composite sol–gel (Zohourtalab and Razmi, 2018). They reported excellent mechanical stability and high selectivity of the sol–gel electrode.

Polymer brushes are thin polymer films of which the end of individual polymers are bonded to an electrode surface through covalent, hydrophobic, cationic, or zwitterionic interactions (Takasu et al., 2015). Electroconductive polymers, such as polyaniline, have been utilized as polymer brushes exhibiting excellent electron transfer in redox and enzyme reactions (Swamy et al., 2017).

Systems Integration

The integration of bioreceptors, transduction elements, electrodes, and computer processing has led to several methods of systems integration to create functional, implantable biosensors, such as microfabrication, layer-by-layer techniques, and (most recently) 3-D printing.

Microfabrication

Microfabrication involves etching, patterning, and layering of thin films through processes such as chemical vapor deposition (CVD), physical vapor deposition (PVD), electroplating, spin-, or spray-coating to create complex (yet essentially 2-D) electrode architectures (Hierlemann et al., 2003). This technique is enticing for creation of biosensors due to its batch-processing ability (and inherently lower costs associated with batch production) and low-tolerance structure designs available through technologies adopted from the semiconductor industry (Hesketh et al.,1997). Conventional lithography and microfabrication techniques have enabled production of implantable biotransducer electrode architectures such as interdigitated microelectrodes (IMEs) and multidisc electrode arrays (MDEAs) for use in glucose biosensors.

Interdigitated microelectrodes modified with films of bioactive conductive polymers and electroconductive

hydrogel have found use in electrochemical biosensors, as they are able to exploit measurable changes in film impedance that accompany redox reactions of enzymes entrapped or linked within the film (Dastider et al., 2013). With fringing field effects in mind, the geometry of such electrodes (line/space dimensions and density) has been studied extensively, and in the case of impedimetric biosensing, new equivalent circuits have been developed to account for low device dimensions (Yang et al., 2010). In the case of glucose sensing, IMEs have been used as capacitive (Khan et al., 2016) and resistive (Haarindraprasad et al., 2016) impedimetric sensors, voltammetry sensors (Jin et al., 2001), and amperometric sensors (Collyer et al., 2010).

The microdisc electrode array (MDEA) is another microlithographically produced electrode architecture intended for implantable biosensors. As with IMEs, design considerations have been taken into account to achieve low background current, high SNR, and improved sensitivity (Justin et al., 2009). Kotanen et al. used a dual-responsive MDEA to wirelessly sense glucose and lactate on a single biochip (Fig. 2.5.13.10) (Kotanen and Guiseppi-Elie, 2010). This same chip, the MDEA-5037 biotransducer and Pinnacle 8151 wireless dual potentiostat, was then successfully characterized in vivo in the trapezius muscle of a Sprague–Dawley rat (Kotanen et al., 2014).

In addition to the well-known rigid electronic systems, soft electronic systems, which utilize conjugated polymer systems able to closely match the moduli of human tissues, have shown great promise in biosensing systems. Where traditional electronics tend to fail at >3% strain, soft bioelectronics are able to withstand strains that the human body experiences (~30%) (Sekitani, 2016). Recently, Fuketa et al. developed a 1 μm thick ultraflexible surface EMG electrode using organic transistors capable of measurement of the myoelectric signal (Fuketa et al., 2014). The organic transistors microfabricated on polyethylene naphthalate (PEN) films boasted high flexibility, high electrode density, and high signal intensity. Several soft enzymatic biosensors utilizing similar fabrication methods have been created to measure analytes such as glucose/lactate in bodily fluids (sweat, saliva, tears). Of particular interest is a newly developed flexible glove biosensor, termed "lab-on-a-glove" or "forensic finger" (Mishra et al., 2017). The system incorporates a microfabricated three-electrode enzymatic system produced directly on low-cost disposable polymer gloves capable of rapid detection of organophosphate and subsequent wireless transmission, as shown in Fig. 2.5.13.11.

Common microfabrication steps have been combined with micromachining techniques to create 3-D microstructures for biosensing, termed microelectromechanical systems (MEMS), which have been utilized for the base electrodes in electrochemical, optical, and thermal glucose biosensors (Huang et al., 2009).

Three-Dimensional (3-D) Bioprinting

More recently, microfabrication techniques have utilized hydrogels (rather than semiconductive metals) to create 3-D tissue arrays, organ-on-chips, and biosensors (Verhulsel et al., 2014). Micromolding, photolithography, stereolithography and 3-D bioprinting have led to construction of precise, 3-D hydrogel microstructures. Here, the focus of discussion is on the growing use of 3-D bioprinting. Detailed reviews on other fabrication methods can be found elsewhere (Yanagawa et al., 2016; Li et al., 2015; Vaezi et al., 2013).

3-D bioprinting utilizing an array of biocompatible materials has become of great interest recently, due to commercialization of 3-D bioprinting technologies. Supported by the growing catalog of "bio-inks," 3-D bioprinting technology has the ability to produce biosensors without the need for masks required in photolithography (Sharafeldin et al., 2018). The inclusion of stimuli-responsive polymers within bioinks to create 3-D-printed biosensors has led to the so-called 4-D printed constructs: 3-D printed structures capable of biomolecular recognition by response to stimuli (Mandon et al., 2017). This research area utilizes all concepts presented in this review and is indeed at the forefront of ongoing research.

(F, G) Photographs of the wearable glove biosensor, consisting of a sensing finger, containing the immobilized OPH enzyme layer, and the collector/sampling finger. The electrodes are connected via an adjustable ring bandage to the portable potentiostat (attached to the back of the hand) for on-site detection with wireless communication to a smartphone for rapid presentation of the voltammetric results. (Inset) Schematic of the interface between potentiostat and glove sensor. The connections consist of a (iii) velcro fabric containing (ii) the aluminum-tape based pins that are adjusted as a ring with the glove sensing connectors and (i) the wiring with the potentiostat (Mishra et al., 2017).

modulus closer to that of human tissue present a clear advantage over traditional solid electronics for both wearable and implantable biosensors. Gowers et al. 3-D printed a microfluidic system using FDA-approved microdialysis probes for continuous monitoring of glucose and lactate (Gowers et al., 2015). Integration with existing technologies, such as cellphones for point-of-care diagnostics, has also been of great interest. Roda et al. introduced low-cost 3-D printed optics for a microfluidic chemiluminescence glucose sensor as an autonomous lab-on-a-chip (Roda et al., 2014).

Future Outlook

Since its inception, electrochemical detection of glucose has undergone radical development toward the goal of sensitive, selective, miniaturized sensors for point of care, bed-side, or implantable devices. The use of stimuli-responsive polymers in biosensors has been studied for decades, but only recently have they been used to their full extent either integrated with enzymes or as transduction elements. The integration of conductive stimuli-responsive polymers in biosensors and a push toward autonomous sensing and self-sufficiency seems to be an area requiring further study.

As new materials are created or discovered for biosensing, such as the little understood carbon dot, considerable work is required to functionalize and utilize these molecules in biosensing. With new developments of systems integration, including the boom in 3-D bioprinting within the last decade, there are new opportunities for low-cost, rapid prototyping of 4-D responsive biosensor architectures which were not achievable before. The pairing of these new types and architectures of biosensors, nanomaterials, and wireless communication and handheld devices, such as cell phones, remains a promising endeavor in telemedicine, remote health care, and biosensing.

2.6.1 Rebuilding Humans Using Biology and Biomaterials

SHELLY E. SAKIYAMA-ELBERT

Department of Biomedical Engineering, The University of Texas at Austin, Austin, TX, United States

Over the past four decades, biomaterials have been increasingly used for applications in tissue engineering to rebuild tissues lost due to disease or injury, as well as to build in vitro models of complex tissue systems. For applications in tissue engineering, our growing understanding of how biological systems function at a mechanistic level and our ability to modulate them at both genetic and epigenetic levels have allowed the development of more elegant approaches to tissue engineering. However, underlying these approaches is still the critical need to understand how the biomaterials used for these applications interface with the physiology environment. This section focuses on the fundamental principles and approaches used for designing and fabricating biomaterials for tissue-engineering applications, stressing common themes and challenges. This edition of the textbook has refined the focus more on the materials, so the chapters in this section stress examples and a model selection of tissues rather than seeking to cover all topics. For additional discussion of specifics for given tissues, there are a variety of references on the topic of tissue engineering, which we do not seek to reproduce in this section.

The first half of this section focuses on tissue engineering broadly, the materials used for tissue-engineering applications, and the transmission of mechanical cues between materials and tissues. The first chapter focuses on a general overview of tissue engineering, including a brief history and common components of tissue-engineering approaches. It highlights common applications, including new areas such as organoids, and newer approaches, such as genome editing. The second chapter focuses specifically on the use of biomaterial scaffolds for tissue-engineering applications. It highlights the key scaffold design criteria, applications, and materials. It also highlights options for fabrication techniques (which are covered extensively in Section 1.4) and characterization methods. The third chapter focuses on micromechanical criteria of biomaterials scaffolds for tissue engineering. It covers mechanotransduction from scaffolds and extracellular matrices to cells and tissues. It also discusses the effects of scaffold topography and roughness on transduction, as well as the effects of mechanical stimulation on tissue formation.

The remaining three chapters in this section provide examples of three tissues, and the thought processes behind selecting materials and designing biomaterial scaffolds for tissue-engineering applications in each area: musculoskeletal (tendon), cardiovascular, and soft tissues. The fourth chapter focuses on the design of scaffolds for the tissue engineering of tendons, as an example of a tissue where mechanical properties of the resulting tissue are critical for the return of load-bearing function after injury. Examples of using material fiber alignment to guide cell infiltration and extracellular matrix deposition are given that apply broadly to many tissues. The fifth chapter focuses on biomaterials used for cardiovascular tissue engineering. It highlights different types of materials used for different applications along with the advantages and disadvantages of those materials for each type of application. The final chapter in this section focuses on the use of biomaterials in soft tissue engineering, such as skin, adipose, and gastrointestinal tissue. The pros and cons of different materials are highlighted as well as design criteria for each type of tissue with regard to scaffold design.

Overall this is a large research and commercial space for biomaterials-derived products and those interested in this field can find extensive primary literature, reviews, and texts on the topics, which are further described in Appendix E.

2.6.2

Overview of Tissue Engineering Concepts and Applications

General Introduction

History of Tissue Engineering

The term "tissue engineering" as recognized today was likely first introduced at a panel meeting of the National Science Foundation in 1987, which led to the first tissue-engineering meeting in early 1988 (Vacanti, 2006). Despite these early approaches for replacement, repair, and regeneration of failing organs, the true emergence of tissue engineering as a medical field began in the early 1990s when tissue engineering was defined as an interdisciplinary field that applies the principles of engineering and life sciences toward the development of biological substitutes that restore, maintain, or improve tissue function (Langer and Vacanti, 1993). The field has since rapidly progressed worldwide with an increasing market size, with nearly $4 billion invested in the field in the 1990s resulting in over 70 companies and several products on the market by the end of the millennium (Lysaght and Reyes, 2001). From a commercial perspective, tissue engineering carries a broad definition and can include companies focused on several products such as cells/stem cells, biomaterials, preclinical testing, clinical trials, commercially approved products, and specialized services (e.g., cord blood banking, tissue grafts). By 2011, 106 companies selling tissue-engineering-based products or services and employing almost 14,000 people were documented worldwide, with a total estimated sales of $3.5 billion, a roughly threefold increase from 2007. As of mid-2018, in the United States alone there were 49 public tissue-engineering companies with nearly 146,000 employees and a cumulative of $9 billion in sales. Well over a million patients have been treated with tissue-engineered products. Additionally, 66 interventional clinical trials in various phases involving tissue-engineering products were active between 2011 and 2018 and both public and private sector companies continue R&D investment for new products and technologies (Kim et al., 2019). While early success has been challenging, technological advances alongside biological discoveries continue to propel the field of tissue engineering into exciting new frontiers (Vacanti, 2006).

Goals of Tissue Engineering and Classification

Goals of Tissue Engineering

Tissue engineering aims to restore tissue and organ function by employing biological and engineering strategies to clinical problems. The functional failure of tissues and organs is a severe and costly healthcare problem as their replacements are limited by the availability of compatible donors. Artificial prostheses and mechanical devices help millions of patients; however, they are not ideal due to poor long-term performance. Furthermore, mechanical devices rarely integrate with host tissues and can trigger a host immune response that may damage healthy tissue around the implant. In addition, surgical reconstruction of organs and tissues involves the replacement of damaged tissue from the patient's own tissue, e.g., saphenous vein as bypass graft, patella tendon for anterior cruciate ligament repair, and autologous skin grafts. However, often this strategy fails to replace all the functions of the original tissue and can cause issues such as development of malignant tumors, surgical complications, and morbidity at the donor sites. Thus tissue engineering has emerged as an alternative for tissue or organ transplantation with the primary goal of providing a clinically relevant substitute by integrating engineering, biology, materials science, chemistry, and medicine. By recapitulating the normal tissue development process, tissue engineering represents a

• **Figure 2.6.2.1** Tissue engineering approaches for regeneration can consist of various methods. In acellular grafts donor-derived or synthetic biomaterial platforms devoid of any cellular components are implanted into the patient body to promote and aid native regeneration. Cellular grafts consist of patient-derived or donor cells that are used to cellularize and mature a scaffold prior to implantation. Cell therapy consists only of the desired cell and biological populations devoid of any scaffolds, that is administered to the patient.

strategy to restore, maintain, and improve tissue function, with the ultimate aim of complete tissue or organ regeneration.

Classification of Tissue-Engineering Approaches

Strategies for the clinical implementation of tissue-engineering methods can be broadly classified according to the implantation or application of the materials or biologics. In addition to traditional tissue engineering, cell therapies and closed looped systems used as implantable or extracorporeal devices are also examples of regenerative medicine approaches. While classically these methods are not regarded as tissue engineering, they have contributed significantly to tissue regeneration and are therefore briefly introduced here.

Traditional tissue engineering: Traditional tissue engineering includes two main approaches: (1) transplantation of a tissue grown in vitro consisting of an artificial matrix with cells and growth factors, and (2) in situ regeneration of tissue utilizing a combination of an artificial matrix and growth factors as a guiding template to induce host cell regeneration of the tissue in vivo (Fig. 2.6.2.1). These two strategies and their components are explained in detail throughout this chapter.

Cell therapy: The main strategy in cell therapy is the harvesting of desired cell populations and their expansion in large numbers for in vivo transplantation. This involves the delivery of cells through systemic injection into the bloodstream or through direct transplantation into a local tissue. A few examples of cell therapy include cell transplants from bone marrow, peripheral blood, or umbilical cord, which have been used to treat several blood-related diseases, including leukemia, multiple myeloma, and immune deficiencies (Rao et al., 2012). The main challenges for cell transplantation are growing large numbers of cells without bacterial contamination; preservation of cell phenotype; and preventing accumulation of genetic mutations during culture expansion. These challenges must be combated for cell therapy to become clinically successful and federally approved.

Closed-loop methods: This involves the use of extracorporeal or implantable devices that house transplanted cell-laden polymers within a semipermeable membrane, which allows diffusion of nutrients and excreted products, but prevents the movement of antibodies, pathogens, or immunocompetent cells (Murua et al., 2008). Microcarrier or microcapsule-based cell encapsulation can function as an effective drug delivery system and requires the use of biomaterials engineered for the desired cell–matrix interactions, therapeutic drug release, and transport properties to influence the targeted cell population, defect, or wound site (Hernández et al., 2010). Closed-loop extracorporeal

devices have been used for the treatment of liver, pancreas, and kidney pathologies (Patzer, 2006; Hueso et al., 2019). Natural as well as synthetic biomaterials such as alginate, collagen, and polyethylene glycol (PEG)-based systems have been explored as carriers where factors such as material degradation, immunogenicity, encapsulation, and release kinetics, among others, have been studied to achieve the desired therapeutic effect (Hernández et al., 2010).

Components of Tissue Engineering

Tissue-engineering strategies typically involve multiple components, including cells, a physical template (scaffold), and a combination of biological cues that promote regeneration and integration of the construct into a functional and organized tissue.

The Cell

Cells are the building blocks of tissues and play a critical role in promoting tissue healing and regeneration. Within tissue engineering, cells may be a component of the in vitro construct or may be recruited in vivo with the aid of immobilized or soluble signals. Cell types utilized for tissue engineering are selected from a variety of sources, which include autologous cells from the patient, allogeneic cells from another human, and xenogeneic cells from a different species. However, allogeneic and xenogeneic cells often suffer from immune rejection.

Cell type: Common cell types utilized for tissue-engineering purposes include stem cells, differentiated mature cells, or a mixture of differentiated cells. Stem cells are capable of self-renewal and differentiation into multiple lineages and may include embryonic stem cells (ESCs), adult stem cells such as mesenchymal stem cells (MSCs) and hematopoietic stem cells, or induced pluripotent stem cells:

- Embryonic stem cells: ESCs are capable of self-renewal without differentiation, can be culture expanded, and most importantly can differentiate into any cell type. Since ESCs are isolated from an embryonic stage, they can develop into any of the three germ layers: endoderm (interior stomach lining, gastrointestinal tract, and lungs); mesoderm (muscle, bone, blood, and urogenital); or ectoderm (epidermal tissues and nervous system) (Song et al., 2018). However, because of several ethical issues and regulatory limitations concerning human ESCs, induced pluripotent stem cells (iPSCs) are now an attractive alternative in tissue engineering for clinical approaches.
- Adult stem cells: Adult stem cells include, for example, hematopoietic, mesenchymal, neural, and hepatic stem cells. In particular, hematopoietic stem cells have been used in clinics for a few decades for treating blood diseases (i.e., bone marrow transplantation) (Mosaad, 2014). MSCs, which can be transplanted as an allogenic cell source to another patient without immunosuppressive drugs, are capable of differentiation into multiple lineages that may produce tissues, including bone, cartilage, and muscle, and have been approved for use in multiple systems to treat bone defects (Su et al., 2018). MSCs can also modulate the host immune response through paracrine or endocrine mechanisms, and are currently being applied in clinical trials for the treatment of immune diseases (Leyendecker Jr. et al., 2018). Nevertheless, adult stem cells are rare, challenging to isolate and expand without altering cell phenotype, and limited in their differentiation potential.
- Induced pluripotent stem cells: Successful reprogramming of differentiated human somatic cells into pluripotent cells has led to the creation of iPSCs (Takahashi et al., 2006). These cells are functionally similar to ESCs, but do not require the destruction of an embryo and can be created from a patient's own cells, eliminating the risk of host rejection (Yamanaka, 2008). Since their groundbreaking discovery in 2006, there have been significant advances in our ability to control the induction of pluripotency from multiple tissue sources such as skin fibroblasts, peripheral blood, hair-derived keratinocytes, and urine-derived epithelial cells. Studies have also focused on their targeted differentiation, as well as applications in tissue engineering and therapeutics (Mora et al., 2017). iPSCs hold significant promise as a universal, patient-derived cell source for the generation of multiple cell types in a single application. However, iPSC differentiation and subsequent expansion of targeted cell populations is technically challenging and often limited to low passage numbers, making it difficult to obtain clinically relevant cell numbers. In the case of uncontrolled downstream differentiation, it is further necessary to isolate cell populations for desired purity. Thus the application of patient-derived iPSCs for on-site therapeutics requires facilities, equipment, and expertise that may not be readily available. Additionally, challenges such as maintaining genomic stability, role of epigenetic factors, downstream mutations, potential immunogenicity, and regulatory hurdles need to be overcome for iPSCs to be applied clinically (Menon et al., 2016).
- Mature cells: These cells, either parenchymal or stromal, represent the large population of fully differentiated, functionally, as well as tissue-specific cell types in the body such as fibroblasts, smooth muscle cells, epithelial cells, endothelial cells, hepatocytes, etc. They are routinely used in research, either as immortalized cell lines or as primary cells isolated from native tissue to help improve our understanding of cell biology as well as investigate drug screening and toxicity (Jackson and Lu, 2016). Within a clinical setting, these cells can be classified as autologous (patient derived), allogeneic (donor derived), or xenogeneic (nonhuman derived). Examples include the use of chondrocytes for cartilage repair, keratinocytes and fibroblasts for skin repair and cardiac cells for heart patches. Although autologous cells are less likely to cause an immune response, their

availability depends on the tissue type, injury, or patient in question. In contrast, allogeneic and xenogeneic cells are more widely available but often suffer from immune rejection. Another potential complication is the possibility of the undesired dedifferentiation of cells during in vitro expansion, which should be avoided prior to any in vivo or clinical application. Although advanced reprogramming strategies and adult stem cells are a more efficient cell source, mature cell types are easier to use for translation because of their ease of availability and application.

- Direct reprogrammed cells: The process of direct reprogramming of cells, also known as transdifferentiation, circumvents the iPSC induction of the seed (original) cells and differentiates them directly into the target cell type. Reprogramming can occur via many ways such as transfection via small molecules, small RNAs, or proteins. Successful reprogramming of adult cells such as fibroblasts into neuronal cells cardiac progenitors, hepatocytes, and more has already been demonstrated (Qin et al., 2017). It can be argued that based on the method of reprogramming, this process is safer than that for iPSCs in terms of mitigating downstream epigenetic or mutagenic factors. Particularly during the miRNA-mediated direct conversion of human fibroblasts into neurons, nonneuronal cells were induced to be postmitotic, thus limiting the proliferation of cells that have not undergone full reprogramming (Lu and Yoo, 2018). In tissue engineering, direct reprogramming can be utilized as an alternative site-specific or patient-specific cell source with potential regenerative and clinical applications such as cardiac, renal, and neural tissue engineering. Extrinsic factors such as the 3D microenvironment, the substrate biomaterial, and scaffold fabrication method have also been shown to play a role in guiding cellular reprogramming (Lee et al., 2016). Although still in their early stages, these approaches are extremely promising for the availability and expansion of an ideal cell source for tissue-engineering-based clinical applications.

Further investigation is needed to identify the best source of cells for each tissue-engineering application. Multiple variables should be addressed in the selection of the best stem cell population, including: (1) stem cell accessibility (e.g., the isolation of autologous or allogenic neural stem cells is invasive and relatively difficult compared to other stem cells); (2) number of cells needed, where undesired differentiation during expansion has to be prevented; (3) proliferation capacity, where extra resources and expertise are needed for cells with limited proliferation; (4) differentiation profile; (5) cell population purity, depending on whether the cell source is a specific tissue or differentiated from pluripotent/stem cells, population homogeneity, and purity; (6) absence of random mutations that can potentially cause uncontrolled proliferation and tumors; and (7) ethical issues. In addition to primary cells, the intrinsic biological potential and performance of a cell can be modified by transient or permanent alteration of specific genes, often accomplished with vectors created by modifying naturally occurring viruses such as retrovirus, lentivirus, adenovirus, or adeno-associated virus (Hannallah et al., 2003). There are several concerns for these approaches, such as transformation efficiency, safety of viral transfection, vector stability, and optimal function of the inserted genes. Nonviral transfection techniques have been developed to circumvent some of these issues; however, the long-term fate of these genetically modified cells still presents a potential risk.

The cell phenotype can also be regulated through manipulation of isolation and culture conditions. Although this may expand the available tools to manipulate cell characteristics, it can create more hurdles for consistently manufacturing high-quality cells. Rigorous characterization must be completed to ensure maintenance of cell phenotype, purity, and differentiation state. In addition, it is important to consider that cell culture may "activate" cells, altering their phenotype from those found in situ. Factors such as the ideal number of cells to be transplanted, the maximum number of times cells can be passaged, the maximum length of time cells should be maintained in culture, the ideal differentiated state of the cell (determined via phenotypic or genotypic expression) to produce a therapeutic effect, and the ideal cell storage conditions can significantly alter the outcome of a regenerative approach, and often need to be optimized on a case-by-case basis for specific animal models.

Materials

Biomaterials are used to develop scaffolds that provide a template for cells to organize and restore structure and function to damaged or dysfunctional tissues. The bioactive matrix provided by these materials presents well-defined biochemical (e.g., growth factors and surface chemistry) and biophysical (e.g., fibrous structure, hydrophilicity, and stiffness) cues to effectively regulate cellular behaviors such as attachment, migration, proliferation, and differentiation for restoring the functionality of damaged tissues. Biomaterials can, at the same time, be used to supply nutrients, drugs, and bioactive factors that direct specific tissue growth. Accordingly, the material should be nontoxic and be fully biocompatible upon degradation. Ideally, the material should also possess physicomechanical and engineering properties suitable for the intended application and be compatible for further functionalization with bioactive molecules. Biomaterial scaffolds for tissue engineering are also discussed in more detail in Chapter 2.6.3.

To accommodate these material requirements, the field of tissue engineering has witnessed tremendous development of new biomaterials over the past few decades. These materials are derived from both natural and synthetic sources and possess a broad spectrum of structural and functional properties that make them suitable for many clinical applications.

Natural materials: A wide range of natural-origin polymers, generally including proteins and polysaccharides, are

used as carriers for cells and bioactive molecules (Seyednejad et al., 2011). Natural materials are advantageous due to their inherent biological recognition through receptor–ligand interactions, cell-mediated proteolysis and remodeling, and low toxicity.

Protein-based natural polymers include collagen, gelatin, silk fibroin, fibrin, and elastin. Collagen is the most prevalent protein in the human body and offers both physical support and essential signals for cell anchorage, migration, proliferation, differentiation, and survival. As a result, collagen has been studied for engineering artificial skin (collagen IV), bone (collagen I), and cartilage (collagen II), resulting in several tissue-engineering products. For example, bilayered collagen gels seeded with human fibroblast and keratinocytes are used as a bioengineered artificial skin by Organogenesis, Inc. under the name of Apligraf. Collagraft (Angiotech Pharmaceuticals), a composite of fibrillar collagen, hydroxyapatite, and tricalcium phosphate, has also been approved by the Food and Drug Administration (FDA) as a biodegradable synthetic bone graft substitute. Gelatin is a natural polymer derived from collagen that has significantly lower antigenicity in contrast to collagen and has been used for engineering bone, cartilage, and skin. Gelatin is also well suited to serve as a carrier for bioactive molecules, including growth factors, cells, and drugs, and displays a useful gelation mechanism at low temperatures that is commonly utilized in extrusion-based 3D printing practices. Silk fibroin has received significant attention as a versatile natural polymer due to its high strength-to-weight ratio and slow degradation. Its semicrystalline structure and self-healing modifications (via cross-linking) make it an attractive material to include as part of a composite scaffold for tissue engineering. Another commonly used natural material is fibrin, the structural component of blood clots that provides a transitory matrix for cell migration during wound healing. Fibrin has been used as a matrix for studying the regeneration of numerous tissues, such as adipose, bone, cardiac, cartilage, muscle, nervous, ocular, respiratory, skin, tendons and ligaments, and vascular tissue, as well as a carrier vehicle for bioactive molecules. Elastin is an insoluble, high-elastic polymer that is a major component in vascular and lung tissue. It is a promising material for synthetic vascular grafts: however, its insolubility and its ability to elicit an immune response have limited its use.

Another class of natural polymers is polysaccharides that contain monosaccharide units joined together by glycosidic linkages (Celikkin et al., 2017). Several polysaccharides, including chitosan, hyaluronic acid (HA), and alginate, have been studied for tissue-engineering applications. Chitosan, the fully or partially deacetylated form of chitin found particularly in the shell of crustaceans, has attracted significant attention, due to its biocompatible properties, for regeneration of ligaments, muscle, skin, bone, cartilage, nerves, and for vascular grafts. Alginate, a polysaccharide derived from the cell wall of brown seaweed, is a widely utilized biomaterial due to its biocompatibility, mild and physical gelation process, chemical and physical cross-linking abilities, nonthrombogenic nature, and the resemblance of its hydrogel matrix texture to that of the native extracellular matrix (ECM). Alginate happens to be easily modified into any form, such as microspheres, sponges, foams, elastomers, fibers, and hydrogels, thereby broadening the scope of application of this biomaterial. HA is a linear anionic polysaccharide, a member of the glycosaminoglycan family, and plays an important structural role in articular cartilage and skin tissues. Moreover, HA has been shown to promote both epithelial and mesenchymal cell migration and differentiation, regulate injury-induced inflammation as a free radical scavenger, and stimulate angiogenesis making it vital for tissue repair. Other commonly employed polysaccharides include starch, chrondoitin sulfate, cellulose, and dextran.

Unfortunately, there are several limitations of natural materials, which include purification, cost, immunogenic responses, and lack of control over mechanical properties. There also exists the potential for a natural polymer to carry microbes or viruses. Although some of these disadvantages have been avoided through recombinant protein expression (Werkmeister and Ramshaw, 2012), synthetic biomaterials present a paradigm shift that overcomes many of these challenges while enabling custom-designed biomaterials. Natural materials are discussed in further detail in Chapter 1.3.6.

Decellularized extracellular matrix: Decellularizing tissues, a process that eliminates all cellular and nuclear materials with various detergents, and using the remaining matrix as building blocks for therapeutic purposes, has provided a facilitated approach that contains critical physical and chemical properties for site-specific tissue regeneration. The use of decellularized ECM from donor tissue has been utilized in the repair of skin bladder, heart valve, and small intestinal submucosa. In addition, several commercialized decellularized scaffolds have received FDA approval for use in humans, including dermis tissue (Alloderm; LifeCell), porcine heart valves (Synergraft; Cryolife), porcine urinary bladder (urinary bladder matrix; ACell), and processed nerve allografts (Axogen; Acell).

Decellularization of organs such as kidney, heart, lung, and liver has been documented and further seeding of functional parenchymal or stem cell populations onto these acellular three-dimensional (3D) biologic scaffolds provides the opportunity for direct connection to the patient's vasculature. Decellularized tissues have also been used as lyophilized powders that are incorporated into natural or synthetic hydrogels (Kuo et al., 2018a). This allows chemical cues to be present to influence the behavior of coencapsulated cells, and gives customizable shapes for the application of the scaffold. The process of decellularization is preferred in the use of donor grafts for regenerative purposes since allogeneic and xenogeneic antigens are usually recognized as foreign by the host and can either cause destructive inflammatory response or overt immune-mediated rejection. Though the type of tissue governs its decellularization process, a general protocol contains physical (mechanical agitation, freeze/thaw, sonication), enzymatic (trypsin, endonucleases, exonucleases), and chemical (alkaline/acid, hypotonic and hypertonic solutions,

EDTA/EGAT, Triton X-100, sodium dodecyl sulfate, deoxycholate, tri(*n*-butyl) phosphate) degradation steps (Brown et al., 2017). Since it is exceedingly difficult to rid of all cells in dense tissues, nearly all decellularization protocols result in residual DNA and other cytoplasmic and nuclear material. Additional applications of decellularized ECM are discussed in further detail in Chapter 1.3.6A.

Synthetic materials: Many synthetic polymers have been designed and fabricated for tissue-engineering purposes. Biodegradable synthetic polymers offer several advantages compared to natural materials such as controlled mechanical properties and degradation kinetics, easy processability into custom shapes and structures, and easy modification of the material for specific applications.

Saturated aliphatic polyesters, such as polylactide (PLA), polyglycolide (PGA), and poly(caprolactone) (PCL), are the most commonly used biodegradable synthetic polymers for 3D scaffolds in tissue engineering (Seyednejad et al., 2011). The chemical properties of these polymers allow hydrolytic degradation, and the rate and extent of degradation depends on the polymer's molecular weight, structure, and composition. Polyesters have been widely used for scaffold construction because of their merits such as ease in synthesis, controllable degradable properties, and minimal inflammatory response. They have long been used in the clinic in the form of degradable sutures, but have more recently been used to mimic the aligned structures of native fibrous ECM in tissues (e.g., nerve, heart, skin, and tendon) with fibers ranging from several nanometers to several micrometers in diameter via electrospinning and 3D printing fabrication processes. A copolymer formulation of these two materials—poly(L-lactide-*co*-caprolactone)—has also been documented to improve the quality of regenerated cartilage tissue during microfracture when 3D printed into a scaffold that directs chondrocyte attachment and alignment (Guo et al., 2018a). Poly(lactide-*co*-glycolide) (PLGA) is another widely investigated copolymer formulation of PLA and PGA, and its properties can easily be tailored to its application. Specifically, with 25%–75% lactide composition, PLGA forms amorphous polymers, which are very hydrolytically unstable when compared to PCL. This allows for various degradation times depending on the ratio of lactidyl:glycolidyl used (50:50 can be degraded as quickly as 1–2 months, while 85:15 can sustain 5–6 months in vivo) (Ulery et al., 2011).

Poly(ortho esters) are hydrophobic, surface-eroding polymers, and their capacity to be used as tissue-engineering scaffolds is limited due to their weak mechanical properties and their capacity to induce a mild to moderate inflammatory response (Tschan et al., 2017). Alternatively, poly(propylene fumarate) (PPF) is a high-strength, elastic polymeric biomaterial that can be cross-linked through unsaturated bonds in its backbone. The polymer degradation is therefore dependent not only on its molecular weight and cross-linker, but also on the material's cross-linking density. For osteogenic tissue engineering, PPF can be mixed with ceramics such as hydroxyapatite or natural biomacromolecules like fibrin to create stronger, more bioactive scaffolds (Trachtenberg et al., 2017). Polyhydroxyalkanoates are semicrystalline isotactic polymers that also undergo surface erosion and are excellent candidates for use in long-term tissue-engineering applications (Ulery et al., 2011). Elastomeric polyesters such as poly(glycerol sebacate) and poly(diol citrate) have shown significant promise as tissue-engineering biomaterials that mimic the mechanical properties of soft tissues.

Poly(anhydrides) are synthetic polymers developed from the condensation of diacids or a mixture of diacids. These polymers are biocompatible and have well-defined degradation characteristics. They were initially designed for drug-delivery applications due to their hydrophobicity and surface erosion that allowed a constant release profile for certain drugs. Several poly(anhydride) homopolymers and copolymers have been synthesized to control their degradation rate and mechanical properties. Polyurethanes are also favorable in tissue engineering because of their modifiable mechanical properties and biodegradability due to their segmented block structural character. These elastomers have also been developed as synthetic biomaterials for the regeneration of soft tissues, vasculature, and cartilage.

As the foregoing materials are used for the creation of dry, fibrous scaffolds, synthetic polymers can also be dissolved and chemically cross-linked in solution to form 3D hydrogel networks. Photopolymerizable groups are needed for the creation of these gels so that the matrix remains intact once submerged in in vitro culture. PEG, poly(*N*-isopropylacrylamide), poly(vinyl alcohol), and poly(acrylates) are examples of these materials, and upon exposure to ultraviolet radiation or cross-linking agents, these polymers can cross-link to form polymeric networks.

Biological Factors

Biomolecules are the next essential component of a tissue-engineered construct and an important part of the strategy to guide and regulate cell response, both in vitro and in vivo. They are the mediators of molecular signaling mechanisms and crosstalk between cells and their immediate microenvironment, with one biomolecule often serving multiple functionalities.

Type of biological factors: Biological factors satisfy a broad category, including hormones, cytokines, growth factors, ECM molecules, cell surface molecules, and nucleic acids. The temporal and spatial coordination of cellular processes is orchestrated by these signals from the extracellular environment (Lee, 2000). A large number of biomolecules have been explored to induce tissue regeneration and can be broadly categorized as follows (1) small molecules (e.g., corticosteroids, hormones) are used for intercellular and intracellular signaling by binding to specific protein receptors; (2) proteins and peptides act on the cells as mitogens, morphogens, growth factors, and cytokines where they bind to a target cell receptor, triggering an intracellular signal transduction and a biological response; and (3) oligonucleotides (DNA or RNA) can affect either gene transcription and/or translation or can be incorporated into the cell's genome. Cell-secreted biomolecules regulate cell–cell communication through

different mechanisms (endocrine, autocrine, paracrine, juxtacrine, intracrine) and have significant implications on the cell's response to its external environment.

Delivery and presentation of biological factors: The challenges and strategies to deliver these factors vary due to differences in their chemistry, biological response, as well as the scaffold biomaterial in question (Magin et al., 2016). Factors can be presented as soluble cues in vitro, where diffusive properties of the scaffold may be leveraged to further regulate cell response through autocrine–paracrine mechanisms (Mahadik et al., 2017), although controlling their release kinetics can be challenging. Several strategies exist for the encapsulation and release of biological factors, often via degradation of the scaffold or diffusive release of the agent. For example, researchers have demonstrated the delivery of vascular endothelial growth factor and platelet-derived growth factor for improved angiogenesis, and of dextrin-conjugated growth factors for neural stem cell culture. Additionally, controlling the spatiotemporal presentation of biomolecules via advanced fabrication methods (such as 3D printing) is particularly advantageous for complex tissues, e.g., multiple drug release from a single scaffold as an advanced drug delivery mechanism (Liu et al., 2016).

Biomolecules can also remain active when membrane bound or tethered to surfaces via immobilization techniques. Noncovalent association of the matrix components, e.g., glycosaminoglycans, can slowly release and potentiate binding to the cell membrane receptors (Sakiyama-Elbert, 2014). Alternatively, covalently bound growth factors can also influence cell behavior, such as the immobilized stem cell factor on hematopoietic stem cells (Mahadik et al., 2015), or the osteochondral differentiation of MSCs (Di Luca et al., 2017). A class of conjugation method known as "click" chemistry is widely used in tissue engineering for the functionalization of biomolecules (McKay and Finn, 2014). A subset of photocross-linkable thiol-ene chemistry is used extensively due to the high degree of spatial control and multiple conjugation offered by this technique. This is regularly used for biomolecule patterning within hydrogels, as well as for photo-controlled degradation for biomolecule release. In addition, cell adhesion on the scaffold can be controlled by the presentation of specific peptides and carbohydrates. In particular, a prototypical three amino acid sequence arginine–glycine–aspartic acid (RGD) is frequently found in many adhesion proteins and binds to many integrin receptors on cells. RGD peptide sequences have therefore been covalently immobilized on a synthetic material surface at a defined density and orientation to guide cell adhesion. Other sequences have also been successfully explored in the literature (Gao et al., 2017). Finally, the covalent immobilization of protease-sensitive cleavable linkages (i.e., matrix metalloproteinase [MMP]-sensitive links) on synthetic matrices mimics the native ECM, which can be used, in addition to soluble growth factors and other chemotactic cues, to guide migration of cells (Stevens et al., 2015).

Mechanochemical factors in tissue growth: The physical and/or chemical nature of the scaffold is an equally important factor in regulating cell fate. Integrin-mediated cell adhesion to the ECM as well as the corresponding mechanotransduction signals facilitate cell response to their immediate microenvironment (Sun et al., 2016). Modifying the material surface chemistry can control many aspects of cell response such as adhesion, migration, and differentiation. Moreover, nanoscale geometry, surface topography, matrix size, and fiber alignment can also influence cell adhesion, proliferation, and migration. Altering surface topography leads to cytoskeletal reorganization, which directly influences molecular and biomechanical signals (Wu et al., 2017). Furthermore, mechanical forces exerted by the scaffold matrix and the elasticity of the material also influence cell fate. For instance, matrix stiffness in concert with surface chemistry regulates the differentiation of stem cells (Engler et al., 2006; Choi and Harley, 2012). This response is further enhanced via mechanical loading and cyclic or constant tension exposed to the scaffold, and consequently the cells, and is a strategy commonly used for engineering scaffolds for native tissues that are under constant stress (e.g., bone, cartilage, muscle, tendon etc.).

In conclusion, the physical environment, consisting of geometry, time-varying stress, strain, fluid flow, pressure, and potentially other biophysical parameters (e.g., osmotic pressure and electrical field), can regulate cell phenotype and tissue structure in a 3D environment.

Scaffold Design

Scaffolds act as the synthetic analog of the natural ECM. The role of scaffolds is to recapitulate the normal tissue development process by allowing cells to formulate their own microenvironment. The scaffold provides the necessary support for cells to attach, proliferate, and maintain their differentiated function and subsequent regeneration of new tissues. Ideally, a scaffold should have the following characteristics: (1) 3D highly porous structure with an interconnected pore network to facilitate cell/tissue growth and diffusion of nutrients, metabolic waste, and paracrine factors; (2) biodegradable or bioresorbable features with controllable degradation and resorption rates to match cell/tissue growth in vitro and in vivo; (3) suitable surface chemistry for cell attachment, proliferation, and differentiation; (4) mechanical properties to match those of the tissues at the site of implantation; and (5) easy processability to form a variety of shapes and sizes (O'Brien, 2011).

Conventionally fabricated scaffolds: The formation of a porous structure is the main goal of scaffold fabrication. Most methods for fabricating porous scaffolds, including particulate leaching, freeze drying, gas infusion, and phase separation, rely on casting the scaffold within molds with specific designs to create isotopically distributed interconnected pores. Porous structures can be developed by introducing particles or bubbles when the scaffold is solidified, which are later removed leaving behind an interconnected network of pores. Although these techniques are relatively simple for developing a 3D structure, they are limited by

uncontrolled pore size and connectivity, poor mechanical strength, and residual solvent/porogens. Hydrocarbon templating is a process where a polymer is dissolved in a solvent, mixed with a hydrocarbon porogen, compacted, immersed in a solvent to precipitate the porogen polymer solvent, and vacuum dried to create a porous foam (Shastri et al., 2000). This process has several advantages, including control over scaffold thickness and pore structure, although use of organic solvents is typically a disadvantage for biological applications as it is difficult to remove completely.

Hydrogel scaffolds: Hydrogels are commonly used as tissue-engineering scaffolds because of their ability to be formed into specific shapes based on their applications. They are typically cross-linked networks swollen in water that have the capability to encapsulate cells in a 3D network. The specific hydrogel material determines the particular cross-linking capabilities. Some hydrogels are cross-linked using light, while others may be cross-linked through heat, ionic bonding, or covalent bonding. Photocross-linkable hydrogels are polymerized into 3D networks in the presence of cross-linkers under ultraviolet or visible light radiation and are frequently used for cell encapsulation (Ferreira et al., 2007). By controlling the structure with defined cross-linking density, mechanical properties, mass transport, and degradation characteristics, the gels can be tuned for a range of applications. Hydrogels are an appealing 3D scaffold because they are structurally similar to the ECM of many tissues, can often be processed under relatively mild conditions, and may be delivered in a minimally invasive manner (Drury and Mooney, 2003). They can either be durable or biodegradable and are advantageous due to their high water content, facile transport properties, and controlled degradation kinetics. Furthermore, hydrogels can be chemically modified to improve the adhesion and proliferation of the cells on the gel matrices through inclusion of adhesion peptides. However, major problems with using hydrogels include poor mechanical properties that lead to their use in only soft and nonload-bearing tissues and difficulty in engineering complex tissues with multiple cell types due to unique ECM requirements.

Fiber-based scaffolds: Fibrous scaffold structures may be developed by electrospinning of polymers to generate continuous micro- or nanoscale diameter fibers. Electrospinning has the ability to mimic the ECM due to its ability to create nanofibers on the scale of naturally occurring collagen fibrils such as those in tendons and ligaments (Sensini and Cristofolini, 2018). Additionally, the orientation of fibers can be controlled during electrospinning to develop random or aligned fibers. Electrospun scaffolds are advantageous due to their high surface-to-volume ratio and structural similarity to natural ECM. Although it is possible to control the orientation of the fibers, it can be difficult to control the distance between fibers, an important factor that influences the migration of cells. Self-assembly of biopolymers, e.g., peptides and nucleic acids, using noncovalent interactions, including H-bonding, hydrophobic, electrostatic interactions, and van der Waals forces, has also been used for scaffold development. The main advantage of such biopolymers is that their self-assembly relies on specific biorecognitions (e.g., DNA hybridization), which therefore make the formation of scaffold highly predictable and programmable. This type of fabrication has been used to create biocompatible fibers on the micro- or nanoscale and has the ability to enhance cell attachment (DeFrates et al., 2018). However, due to its self-assembly capabilities, the composition and size of these fibers can be difficult to regulate.

Additive manufacturing: 3D printing is a modern fabrication method where digital data of a 3D structure is converted into a physical object. In contrast to traditional fabrication methods (involving molds or solvents), 3D printing can create complex structures in a layer-by-layer fashion. Generally, a structure is first visualized digitally with the help of computer-aided software (such as SolidWorks and CreoParametric) and later sliced into individual layers by the specific printer software. Three major approaches for 3D bioprinting currently exist: inkjet printing, extrusion printing, and stereolithography. The chosen fabrication method will vary in terms of materials used, time required, and printing parameters used to develop the desired part. The following is a brief description of each major printing method, as well as its positives and pitfalls:

- *Inkjet printing:* Much like how a traditional printer utilizes ink cartridges to deliver droplets to paper to create documents, inkjet bioprinters can deliver biomaterials and/or cells in controlled small volumes. These printers have an extremely high resolution in bioink deposition (up to 50 μm) and the highest printing speeds (15–25 kHz) (Gudapati et al., 2016). However, droplets are synthesized through either thermal or mechanical means, which can perturb cells during the printing process. Instant heat exposure and shear stress can also induce cell damage. In addition, ink for this printer must be fluid so that droplets can form, which limits cell density of the ink (Skardal and Atala, 2015). As such, inkjet printing is best for two-dimensional (2D) tissues with relatively low cell density and complexity.
- *Extrusion printing:* This printing process extrudes continuous filaments of shear-thinning, thixotropic material (of which either biomacromolecules or cells are seeded) through a nozzle under pneumatic pressure. Though extrusion printing is an efficient and low-cost method for printing cell-encapsulated constructs, the printing resolution is limited by the print head's diameter, the viscosity of the biomaterial, and size of the incorporated biologic (Ozbolat and Hospodiuk, 2016). Shear-thinning biomaterials, in regard to strain rate or temperature-dependent properties, are limited as this fabrication process requires the material to maintain strand shape. Examples of inks compatible with this deposition method include gelatin, fibrin, alginate, HA mixtures, and silicate nanoplatelet mixtures (Panwar and Tan, 2016). The combination of multiple materials via different printing cartridges allows for facile engineering of chemically and structurally complex tissues.

- *Stereolithography:* A photopolymerizable material is printed layer by layer in this printing process. The light source, located directly below the printing platform, is instructed to focus at specific points in space to project a 2D mask with a specific light intensity that locally polymerizes the biomaterial. As the print progresses, the build platform moves up, and new masks are projected and cross-linked onto the existing shape. The overall print is complete when all mask layers have been projected and the material has been cross-linked into the desired 3D shape. Digital micromirror device-based printing is a similar platform in which an array of digitally controlled mirrors reflects light to create a 2D projection on a surface. Advantages of this process include the high precision able to be obtained by the light source, and that a 3D object of any desired shape can be made by changing the 2D projection over the height of the printing stage (Wang et al., 2017). One major disadvantage of this methodology is that only one material can be printed at a time.

Integration of Multiple Factors

The environment in which a particular cell resides in vivo, also known as its "niche" microenvironment, plays a significant role in determining cell functionality. This environment is composed of other cell types, the ECM proteins, and a host of biomolecules, with a high degree of crosstalk between all these components. In vitro, successful integration of the appropriate cells, scaffolds, soluble cues, and mechanochemical factors is key in regulating cell fate and ultimately regenerating a functional tissue. Hence, combinatorial approaches that recapitulate key components of this niche microenvironment are extremely important in tissue engineering, as well as to advance our basic understanding of cell biology. A number of studies have utilized this approach for tissue niche engineering, such as bone marrow (Torisawa et al., 2014), lung (Petersen et al., 2010), cardiac (Jang et al., 2017), and more (Donnelly et al., 2018; Kobolak et al., 2016), with promising results. However, static in vitro tissue-engineering systems often fail to consider the multiple factors that contribute to the healing and regeneration process. Thus it is necessary to understand the system as a whole through dynamic in vitro systems, such as bioreactors and relevant in vivo models.

Models for Tissue Engineering

Bioreactors

The traditional tissue-engineering approach of growing tissues on 2D surfaces (i.e., Petri dishes) or in 3D scaffolds is limited by mass transfer, since the diffusion of metabolites, oxygen, and carbon dioxide under static conditions can only support a certain thickness of tissue. Depending on the biomaterial, this limits the maximum thickness of a tissue-engineered construct to <250 μm from a media source (Martin and Vermette, 2005). Bioreactors are utilized in in vitro culture to increase nutrient transfer by continuously mixing media and convectively transporting nutrients to cells, while higher rates of mass transfer provide improved oxygen influx and waste disposal, leading to improved cell seeding efficiency and proliferation. More importantly, dynamic in vivo conditions such as flow rate, oxygen tension, fluid shear stress, and the corresponding biomechanical signals can be recapitulated in vitro (Selden et al., 2018). Bioreactors are also instrumental in developing large-scale tissues for the purpose of biomanufacturing, where culture homogeneity and uniform cell response are critical elements in the industrial design (Kumar and Starly, 2015).

Types of bioreactors: Traditional industrial reactors such as the continuous stirred-tank reactor have been adapted as bioreactors in tissue engineering. In particular, the stirred-flask reactor improves reactor performance by agitating the media used for seeding scaffolds. Another system is the rotating wall vessel, which aims to minimize the shear stress and turbulence of previous approaches. This system was developed for cell culture experiments in space, and thus is often referred to as a microgravity reactor (Freed and Vunjak-Novakovic, 1997). Another interesting bioreactor is the hollow fiber reactor that permits the cultivation of highly sensitive cells such as hepatocytes. These reactors can introduce two different solutions to the tissue culture system that are optimized to either provide metabolites or remove waste products. Several commercial bioreactors exist on the market and have been investigated for good manufacturing practice-compliant scale-up. In perfusion-based bioreactors, culture medium is continuously perfused through the scaffold under pressure, allowing for nutrient exchange both within and without the scaffold. This system can increase the efficiency and uniformity of cell seeding and proliferation. The tubular perfusion system bioreactor designed by the Fisher lab is particularly suited for bead-based hydrogel culture and aggregation for osteochondral tissue engineering (Yeatts and Fisher, 2011; Nguyen et al., 2016). Finally, there are several other novel bioreactors designed specifically for particular tissues (Mori et al., 2017), or developed for targeted mechanistic studies (Lembong et al., 2018).

Limitations and challenges: While bioreactors have been shown to enhance uniformity of cell seeding and perfusion, reactor conditions such as mass transfer properties, mechanical environment, and hydrodynamics must be uniquely optimized for each tissue. Mathematical modeling and computational fluid dynamics simulations can be employed to help understand the complex interactions of these factors. However, there are several other limitations and considerations such as media costs for high-volume bioreactors, undesired shear stress or shear-induced biophysical response of cells, dynamic changes in the microenvironment due to cellular remodeling, difficulties in in situ monitoring for complex bioreactor setups, and limitations in nutrient transport for large tissue constructs. These limitations need to be addressed prior to employing bioreactors for their proposed tissue-engineering or clinical applications (Ravichandran et al., 2018).

Organoids

An advancement to the conventional 2D cell culture models, organoids are 3D systems that better mimic in vivo physiology and the tissue microenvironment. Though very important in basic in vitro imaging and drug applications, 2D cell culture systems are unable to reach the complexity of 3D cell–tissue organization, and lack tissue-specific architecture, cell–ECM interactions, and mechanical–biochemical cues (Jin et al., 2018). Colloquially termed "organ buds in a dish," organoids are person-specific 3D cell cultures that mimic true in vivo microanatomy. Two forms of these models exist, where (1) tissue organoids containing epithelial cells can be formed by mechanically and enzymatically separating the primer organ into small tissue fragments, and (2) stem cell organoids are produced from ESCs, induced pluripotent stem cells, or organ-restricted adult stem cells (Jin et al., 2018). Several approaches in organoid production exist, such as (1) culturing cells atop feeder cells or ECM-coated surfaces, (2) hanging drop culture systems for embryoid bodies, and (3) use of serum-free floating culture of aggregates on low adhesion plates (Fang and Eglen, 2017). The main applications of organoids are drug testing as organ models (bone, kidney, brain, lung, bladder, colon, liver, intestine pancreas, mammary gland, esophagus, and prostate), and also disease models such as infectious (Zika), hereditary (cystic fibrosis), neurodegenerative (microcephaly), and cancer. Organoids are specifically ideal 3D in vitro systems of the tumor microenvironment, as they can contain a regional hypoxic core when created with rapidly dividing cancer cells. This hypoxic heterogeneity, a consequence of poor nutrients and oxygen supply, triggers the release of lactic acid as cells reach the incomplete oxidation pathway. Ultimately, the pH gradient formed can affect certain drug release profiles depending on its chemical nature as well as the cellular expression of genes controlling multiple drug resistance. Thus tumor organoids are very important in investigating signaling pathways involved in both chemotherapy sensitivity and cancer cell biology (Huang and Gao, 2018).

In Vivo Models

While in vitro development of tissues is the starting point of a tissue-engineered product, an appropriate in vivo model is crucial to validate the tissues' function. There exist many medical, legal, and ethical considerations when new biomedical products come to fruition, and thus intense preclinical investigations are needed before the product is available to the masses. Several factors need to be assessed in macroscale once the product is introduced to the host, for example, the role of angiogenesis in a newly created tissue, complex host immune reactions to the graft that could ignite inflammation and/or rejection, as well as functional considerations, such as innervation, rheological graft properties, or the effects of surgical interventions (Muschler et al., 2010). The complexity of these factors makes it impossible to effectively evaluate the product in vitro and predict its success upon implantation. Since different animal models are used to investigate different tissue products, anatomical, physiological, and pathophysiological properties of the chosen species must be considered when determining the type of animal model. For example, small species such as mice and rabbits are used as models for critical-sized bone defects, as well as some larger species such as dogs and sheep. The pig remains the most popular large animal model due to similarities to humans in physiology, ease of availability, and relatively low cost, and is most commonly used in cardiovascular and skin pathologies/wounds research. Thus for any tissue-engineered product it is critical to analyze the outcomes of an in vivo study in the context of the model and its efficacy.

Applications of Tissue Engineering

Transplantation

Cell-free scaffolds: Another strategy involves in situ tissue regeneration by providing an instructive scaffold that can guide and control the regeneration process in vivo (Zhao and Karp, 2009). This process uses an artificial scaffold matrix that, once implanted, recruits host cells and relies on the body's innate regenerative ability. The scaffold recruits such cells through signal presentation. For example, transplantation of PEG–collagen matrices with enzyme cleavable MMP links that release bone morphogenic protein-2 (BMP-2) can promote regeneration of critical size bone defects effectively through invasion of the host cells. The absence of MMP-sensitive linkages and/or BMP-2 hindered the regeneration process, indicating that transplantation of scaffolds with appropriate soluble and insoluble signals is critical (Lutolf et al., 2003). Additionally, in cartilage defects, microfracture techniques that incorporated functionalization of 3D printed scaffolds functionalized with aggrecan have been shown to improve cartilage tissue regeneration with increased expression of type II collagen (Guo et al., 2018a). Thus the success of scaffold transplantation-based approaches largely depends on the appropriate presentation of signals to mediate host cell mobilization and coordination of the subsequent behavior of the cells, e.g., adherence, migration, and proliferation.

Cellular scaffolds: Scaffolds provide a substrate upon which cells attach, proliferate, and produce ECM within a predefined 3D orientation. However, it is also possible to incorporate cells into the scaffold directly with the aid of 3D printing and casting methods. Typically, this process allows cells to be integrated into the inner structure of the scaffold to diminish the need for cells to migrate on their own. One example of this is in vitro cell culture that incorporates multiple cell types and growth factors to prevascularize the scaffold prior to implantation (Kottamasu and Herman, 2018).

The main challenges for this strategy include: generating a complete functional tissue; preserving cell viability and function during transplantation; biological and mechanical integration with the surrounding tissue; and supplying oxygen and nutrients to the transplanted cells. The transplanted cells within the core of large defects often die before contributing to the healing process. Regardless, this strategy can be useful for transplantation of thin tissue grafts, such as corneal and skin grafts, where an immediate connection to the vascular system is not essential.

Replacing/Regenerating Target Organs

With clinical application being the primary focus of tissue engineering, investigators have attempted to engineer almost every mammalian tissue with varying degrees of success. The following section describes some key developments in organ engineering.

Skin: Tissue-engineered skin aims to restore barrier function for patients with severe trauma, e.g., burns, chronic wounds, ulcers, acute injuries, etc. Integra (Integra Life Sciences), one of many commercial products for skin regeneration (Table 2.6.2.1), is a collagen-based dermal graft aimed to improve tissue healing (Chu et al., 2002). Collagen, fibrin, HA, and PLGA are the main matrix components in most tissue grafts. Keratinocytes and fibroblasts are the primary cellular components of native skin and are investigated as the biological component (Vijayavenkataraman et al., 2016). To achieve effective healing, tissue-engineered skin must attach to the wound bed and avoid rejection by the immune system. Despite great success in engineering skin tissue, pitfalls include scar tissue formation, wound contraction, incomplete healing of deep wounds, lack of full recovery of skin function, and imperfect regeneration of skin components such as glands and hair follicles. Skin tissue-engineering applications are described further in Chapter 2.6.7.

Liver: Liver transplantation is end-stage treatment for many liver diseases. Several factors, including drug use, alcohol abuse, and viruses like hepatitis, can cause liver failure. Tissue engineering offers the potential for an engineered liver that can help address organ shortage and has two main strategies: (1) transplantation of suspended hepatocytes with ECM components, and (2) use of biodegradable scaffolds to provide a platform for hepatocyte attachment. Advancements in 3D printing offer us new strategies and avenues to recreate the biological and architectural complexity of the engineered tissue (Lee et al., 2016). However, because of challenges such as recapitulating the complex liver vasculature, relatively high volumetric oxygen consumption rate of the tissue, high cellular density, and long-term functionality regarding toxicity, efficacy, and infection, researchers are still far from developing a fully engineered, transplantable liver.

Heart: Cardiovascular disease is the leading cause of death in the United States and leads to damaged or malfunctioning cardiac tissue, resulting in arrhythmias and diminished cardiac output. Tissue engineering is actively pursuing treatments for myocardial infarction, congenital heart defects, and stenotic valves through regenerating cardiac tissues (Hirt et al., 2014). Currently, heart valves are developed by transplanting autologous cells onto a scaffold, growing and maturing the cell-seeded scaffold, and finally transplanting the valves into the patient. Examples of heart valve scaffolds include decellularized heart valve ECM from donors or animals (Ott et al., 2008) and biomaterial-based heart valves designed from various natural and synthetic materials (collagen, fibrin, PLGA, and poly(hydroxy butyrate)). There are several successful applications of tissue-engineered heart valves for both in vitro and in vivo models. However, the complex metabolic, electrical, and mechanical nature of heart tissues continues to present a significant challenge to engineering myocardial tissues. Additional examples of cardiovascular tissue-engineering applications are described in Chapter 2.6.6.

Kidney: The current treatment for patients with end-stage renal disease is a kidney transplant. Although an established procedure, there is a constant shortage of donors with a median wait time for patients of up to 3.6 years and chances of host rejection and loss of functionality of the graft over time remain. Renal tissue engineering aims to restore kidney function, either by in situ regeneration of the damaged kidney with a cell-based approach or through the implantation of bioengineered grafts. The cell source can either be tissue-derived renal cells or differentiated stem cells such as ESCs, iPSCs, or amniotic fluid-derived stem cells (Moon et al., 2016). The anatomical and architectural complexity of the kidney poses challenges for whole organ engineering as the kidney consists of complex 3D tubular structures and multiple cell types. Consequently, the use of decellularized ECM from animal and human kidney is highly appealing as structure complexity, architecture, and biocompatibility are maintained. While this field continues to make tremendous progress, challenges such as poor in vivo integration, limited endothelialization, immunogenic response, and lack of consensus on the ideal cell type remain.

Orthopedic tissues: Musculoskeletal tissues such as bone, cartilage, and tendon are well researched in tissue engineering. Numerous clinical therapies are currently on the market for cartilage (e.g., MACI [Verical], Maix [Matrical], and Hyalograft [Fidia Advanced Biopolymers] (Vinatier and Guicheux, 2016)) and bone (e.g., Bio4 [Osiris Therapeutics], Bond Apatite [Augma Biomaterials], and TruGraft [Osteobiologics]). A primary challenge in bone tissue engineering is its unique architecture consisting of a mineralized, stiff cortical bone, a softer highly vascularized marrow, and distinct niche microenvironments. Although several inorganic-, polymeric-, and hybrid-based scaffolds have been examined to engineer bone, it has been difficult to develop a material that displays optimal mechanical properties and degradation kinetics for bone repair. Similarly, current treatments for cartilage defects, such as hyaline cartilage loss due to osteoarthritis, are microfracture and

TABLE 2.6.2.1 List of Commercially Available Tissue Engineering Products for Regenerative Applications

Tissue	Commercial Name	Scaffold Material	Cells	Manufacturer
Skin	Dermagraft	PGA and PLA fibers and silicon film	Fibroblasts	Advanced Biohealing, USA
	Apligraf	Bovine collagen	Keratinocytes and fibroblasts	Organogenesis, USA
	Orcel	Bovine collagen sponge	Keratinocytes and fibroblasts	Ortec International, USA
	TissueTech Autograft System (Laserskin and Hyalograft 3D)	Hyaluronic Acid	Keratinocytes and fibroblasts	Fidia Advanced Biopolymers, Italy
	Matriderm	Human acellular dermis	Keratinocytes and fibroblasts	Dr. Suwelack Skin & Health Care, Germany
	Alloderm	Human acellular dermis	none	LifeCell, USA
	FlexHD	Human acellular dermis	none	Ethicon, USA
	Allopatch HD	Human acellular dermis	none	Conmed, USA
	BellaDerm	Human acellular dermis	none	Muscloskeletal Transplantation Foundation, USA
	DermaMatrix	Human acellular dermis	none	Synthes, USA
	Epicel	Cultured epidermal autograft	Keratinocytes	Vericel, USA
	ReCell	none	Spray-On Cell suspension of keratinocytes	Avita, USA
	BioDFactor	Morselized, flowable tissue allograft derived fom human placental tissues	none	Integra, USA
	GINTUIT	Bovine collagen	Allogeneic cultured keratinocytes and fibroblasts	Organogenesis Incorporated
	Grafix	Cryopreserved placental membrane	Neonatal mesenchymal stem cells, fibroblasts, and keratinocytes	Osiris, USA
	Epidex	none	Autologous outer root sheath keratinocytes expanded into sheets	EuroDerm Biotech & Aesthetics, Germany
	EpiGraft	Cellulose film	none	Cuticell, USA
Bone	Osteocel	Demineralized human allograft bone	Human mesenchymal stem cells	NuVasive, USA
	AlloStem	Demineralized human allograft bone	Allograft stem cells from human adipose tissue	AlloSource, USA
	Trinity/Trinity Evolution	Demineralized human allograft bone	Human mesenchymal stem cells and osteoprogenitor cells	Orthofix, USA

TABLE 2.6.2.1 List of Commercially Available Tissue Engineering Products for Regenerative Applications—Cont'd

Tissue	Commercial Name	Scaffold Material	Cells	Manufacturer
Cartilage	MACI	Porcine collagen membrane	Autologous cultured chondrocytes	Vericel, USA
	Carticel	none	Autologous cultured chondrocytes directly injected into defect with Dulbecco's Modified Eagles Medium (DMEM)	Vericel, USA
	ChondroCelect	none	Autologous cultured chondrocytes cell suspension	TiGenix, Belgium
	BioSeed-C	Bioresorbable two-component gel-polymer scaffold	Autologous cultured chondrocytes	BioTissue, Switzerland
	DeNovoNT	Human particulated juvenile cartilage	Allogeneic chondrocytes	Zimmer, USA
	Co.don Chondrospheres	none	Autologous chondrocytes expanded in vitro and condensed into spheroids	co.don AG, Germany
	Cupistem	none	Autologous adipose-derived mesenchymal stem cell suspension	Anterogen, South Korea
	Cartistem	none	Allogeneic umbilical cord blood-derved mesenchymal stem cell suspension	Medipost, South Korea
Eye	Prokera	Amniotic membrane tissue	none	BioTissue, USA

autologous chondrocyte implantation, but their efficacy and long-term recovery are still limited. Cartilage tissue presents a unique challenge as it is largely acellular with low regenerative capacity, and it is a highly anisotropic structure with distinct zonal architecture, high elasticity, and strength. Several biomaterials both natural (collagen, fibrin, cellulose) and synthetic (PLA and PLGA) have been utilized for cartilage engineering. Currently, there are several ongoing clinical trials to determine the efficacy of MSCs for cartilage regeneration (Huang et al., 2016). To recapitulate the zonal architecture of the cartilage, researchers are also investigating the applications of 3D bioprinting for generating cartilage scaffolds. Despite all these efforts, development of a high-quality artificial cartilage as a long-term solution still evades researchers and this continues to be an area of active research. Orthopedic tissues are described in further detail in Chapter 2.6.5.

In addition to the tissues already described, many other tissues such as pancreas, muscle, trachea, nervous system, tendon, ligament, placental barrier, cornea, gastrointestinal tract, and vocal cord have been targeted for regeneration by tissue-engineering strategies.

Drug Delivery

One important technique in regenerative medicine is the controlled delivery of therapeutic agents to achieve targeted and sustained long-term effects. Localized delivery of growth factors and small molecules is known to have a significant impact on tissue regeneration and healing. For example, the bone regeneration process involves multiple stages of inflammation, vascularization, scar formation, and mineralization, with each stage being controlled by different growth factors and cytokines. Optimal wound recovery demands a localized dosage of the relevant biomolecules such as the incorporation of recombinant human bone morphogenic protein-2 on an absorbable collagen sponge carrier for bone grafts (InFUSE Medtronic) (McKay et al., 2007). Strategies for engineering the encapsulation of biomolecules and therapeutic compounds within biomaterials and with predefined release rates have been examined extensively in tissue engineering (Thambi et al., 2017; Rahman et al., 2018). 3D printing has also made a foray into drug delivery, with the FDA approving its first 3D printed drug Spritam (Aprecia Pharmaceuticals) in 2015 for seizures and epilepsy. Strategic printing and layered deposition of bioinks with multiple biomolecules enables control over the release profiles of different factors at different times from the same construct. The clinical impact of drug delivery in tissue-engineered scaffolds is enormous. Finally, novel therapies such as RNA delivery, in situ injectables, oral delivery systems for extended release, and biological carriers for drug delivery play an important role in pushing the boundaries of

regenerative medicine and improving the overall impact on patient life. Materials for drug delivery are discussed in detail in Chapter 2.5.12.

Disease Models and Therapy

There are several nontraditional, yet useful and important applications of tissue-engineering strategies. In particular, the field of drug screening is in need of advanced in vitro methods for the assessment of the activity and toxicity of drugs before clinical studies are initiated. The development of synthetic tissue microfabrication has allowed for the opportunity to test drugs and/or other biological agents while analyzing system-level responses in real time. There have already been exciting examples of developed systems capable of mimicking organ-level functions and recapitulating disease etiology and progression, including engineered models of heart (Ralphe and de Lange, 2013), lung (Chen et al., 2017), intestine (Kämpfer et al., 2017), liver (Broutier et al., 2017), kidney (Tiong et al., 2014), cartilage (Peck et al., 2018), skin (Danilenko et al., 2016), placenta (Arumugasaamy et al., 2018), nervous systems (Hopkins et al., 2015), as well as models of infectious diseases and cancer (Benam et al., 2015). Many of these models are relatively simple; however, increasing the complex facets of the design can result in the creation of unique disease models. In the future, tissue-engineering-based drug testing and toxicity assays can provide an alternate strategy to reduce the use of in vivo animal testing. However, challenges remain since many diseases are chronic in nature and involve complex interactions between different organs.

The development of 3D tumor models has positively impacted the understanding of cancer progression and provides an exciting prospect in drug screening for patient-specific tumor types. Though valuable insights have been gained by traditional 2D stromal and cancer cell studies, they do not reflect the essential features of tumor tissues. For example, 2D cultures inaccurately display cell cytotoxicity of chemotherapeutic agents and low intensity radiation, since the treatment only needs to penetrate merely one single layer of cells to be effective. Furthermore, fundamental understanding of cancer metastasis cannot be obtained readily from the 2D studies because of the lack of spatial depth and cell connectivity, complex and dynamic cell–cell communications, and cell–matrix interactions that occur during cancer metastasis. Realizing the limitations of monolayer cultures, researchers have developed various 3D models that recapitulate certain features of solid tumor tissues such as tumor morphology, gradient distribution of chemical and biological factors, expression of proangiogenic and multidrug resistance proteins, and both dynamic and reciprocal interactions between the tumor and its stroma. With the advent of 3D models, the efficacy of therapeutic agents can be more rigorously tested in their ability to penetrate the core of the complex tumor microenvironment. In addition, numerous studies have provided compelling evidence that ECM remodeling is an essential component of the metastatic cascade in cancer (Wittekind and Neid, 2005). Hence, strategic integration of biological factors and engineering approaches have improved our understanding of tumor progression and invasion and support discovery of more personalized treatments for cancer patients.

Organ-On-a-Chip Systems

Microfluidic chip-based platforms enable a more sophisticated approach toward cell culture by engineering an environment more complex than the simple 2D substrates, yet simpler and more high throughput than complex 3D biomaterial platforms. It also enables constant perfusion of nutrients, and the relative ease of fabrication via soft lithography provides a high degree of control over all biochemical and biophysical aspects of the cell culture (Bhatia and Ingber, 2014). Each chip system transforms into a "mini" bioreactor where fluid flow can be regulated to study a broad range of cell responses. Several on-chip models such as lung-on-a-chip (Benam et al., 2017), gut-on-a-chip (Jung Kim et al., 2013), heart-on-a-chip (Parsa et al., 2017), and liver-on-a-chip (Bhise et al., 2016) have been demonstrated and continue to be improved upon. This field has also seen the commercialization of on-chip technologies with the establishment of companies such as Emulate Inc., Hesperos Inc., Tissue, Tara Biosystems, and many more.

Multiorgan-on-a-chip systems are extremely beneficial for in vitro absorption, distribution, metabolism, excretion, and toxicity studies (Ishida, 2018). These are used to evaluate the pharmacokinetics and pharmacodynamics of potential drug candidates to determine their safety, efficacy, and dosage. Although in vivo animal studies are the gold standard for preclinical trials, these studies are very expensive and time consuming. Consequently, multiorgan interconnected on-chip platforms (Maschmeyer et al., 2015) with human-derived cell sources offer a rapid, reliable way to screen a large number of drugs while being more relevant to clinical applications.

Current Challenges and Opportunities

Despite the excitement and early success, there are many hurdles to be addressed before tissue engineering reaches its eventual goal to treat millions of patients. In addition to efficacy, scale-up potential, reliability, established regulatory routes, and societal acceptance issues, there are many technical challenges to overcome. Some of the major challenges are discussed next.

Cell Source

As stated previously in this chapter, cells utilized in tissue-engineering applications may be in the form of autologous, allogeneic, or xenogeneic cells. Choosing the appropriate cell source for a particular tissue-engineering application has a significant impact on construct efficacy. In the case of allogeneic and xenogeneic cells, although the cell source is in abundance, patients suffer a higher chance of immune rejection of the graft because of the body's inherent response of attacking

foreign cells or objects. For allogeneic transplants, factors such as human leukocyte antigen matching plays an important role in determining donor engraftment (Ruggeri et al., 2016). It is also important to monitor patient response to avoid fatal complications such as graft versus host disease. The ideal situation for patients would be the incorporation of personalized medicine in the form of patient-derived autologous cells. However, donor-site limitations and restrictions with cell expansion make this form of personalized medicine costly and time consuming.

It is also important to access reliable cell sources with a high degree of consistency for various applications. For example, when developing tissue models for disease modeling or drug screening, the cell source and phenotype must remain consistent across all studies, as well as be relevant to human clinical trials. We must also recognize that locally administered cells often die before significantly contributing to the healing response, either due to diffusion limitations of nutrients and oxygen or due to the dynamic in vivo environment. This significantly reduces the capacity for an exogenous cell source to contribute to the regenerative process. Finally, although stem cells are a promising cell source with a high proliferative and differentiation capacity, they suffer unique challenges. ESCs are fraught with several ethical concerns that limit their use in widespread applications. The recent development of iPSCs may replace embryo-derived ESCs. However, challenges such as low yields from the viral transfection techniques for iPSC generation and uncertainties in long-term effects of genetic modification have limited their application. Consequently, there is currently a plethora of ongoing research to develop highly efficient iPSC techniques (e.g., clustered regularly interspaced short palindromic repeats [CRISPR]) and understand downstream effects.

Vascularization

Vascularization, the growth of blood vessels, is a major engineering hurdle to overcome in creating artificial organs, particularly large-scale 3D tissues. It is critical to have effective transport of oxygen, nutrients, and removal of cell-secreted waste for the survival of cells in any environment. However, it is particularly important that cells are located within 250 μm of an oxygen source to thrive and function (Martin and Vermette, 2005). The lack of vascularization within tissue-engineered constructs is the major reason why most successful engineered organs are restricted to tissues, such as skin, cartilage, and ligament. For these tissues, thin layers of cells (e.g., one to two cell layers in skin tissue) that are well accessible to the blood vessels are sufficient and a proximal blood supply is not essential for survival. To effectively develop large-scale tissues, researchers must understand the formation of vasculature and develop methodologies to incorporate vasculature into their large tissue constructs. For these tissues and organs, several potential strategies exist to address the issue of vascularization. An increased knowledge of 3D scaffolding materials and research into the incorporation of angiogenic factors has shown progress toward vascularization. One popular idea for overcoming this challenge is prevascularization of the construct where a vascular network is developed prior to implantation (Kottamasu and Herman, 2018). In addition, many researchers have utilized 3D bioprinting to print lumen-incorporated strands within predefined structures. Although these methods have shown promising results, more critical issues remain such as the development of complex vascular networks using scalable technology and the integration of these systems to the host vasculature.

Tissue Maturation

Commonly in tissue engineering, a complete 3D tissue is grown in vitro and is later implanted once it has reached "maturity." Appropriate maturation of these scaffolds is very difficult to define since full in vitro regeneration of a tissue is challenging; many biological factors, systems, and actual presence of surrounding host tissue is needed to help recreate the complexity of certain tissues. Cells grown on 3D scaffolds in vitro can secrete biochemically appropriate ECM molecules yet can fail to acquire the appropriate tissue architecture. One way to address this challenge is to culture these grafts under compression, shear stresses, and pulsatile flow via a bioreactor. Such stresses have shown profound improvements in the mechanical properties of engineered tendon, cartilage, and cardiac muscle. Another major challenge is biomaterial longevity and its interactions with seeded cells. This is where material selection and scaffold engineering are crucial as the chosen biomaterial should display properties that match the cellular environment and remodeling rate.

In Vivo Integration

Once developed and fully matured in vitro, tissue-engineered constructs are implanted into the host where successful integration with the surrounding natural environment is of paramount importance. A poorly integrated scaffold often leads to impaired functionality within a few months. True integration can be achieved by designing smart templates made from biomaterials that also provide cues and signals to promote host cell migration and functional tissue connections. Scaffold porosity, pore network architecture, and surface roughness can drastically affect the diffusion of nutrients and cellular migration within the tissue-engineered construct (Bružauskaitė et al., 2016). Ideally, a scaffold's mechanical properties should match those of the tissue being regenerated. However, care must be taken not to hamper the regeneration of proper functional tissue if nutrient diffusion and tissue necrosis occur. Thus scaffold physical cues should be engineered to mimic the mechanical properties with its surrounding environment without inhibiting necessary host cell infiltration.

Additionally, the host immune response is a factor that influences regeneration. The immune reaction to an implant begins with an acute response to the injury and innate recognition of foreign materials and continues with subsequent chronic immune response when specific recognition of antigens is stimulated. More specifically, polymorphonuclear neutrophils infiltrate the wound and release reactive oxygen species that not

only clear cellular debris, but can also result in rapid degradation of the biomaterial scaffold. Monocytes and fibroblasts that are recruited to the injury site also release inflammatory cytokines, which can cause secondary damage to the surrounding tissue. If the reaction is significant, it can lead to total rejection of the implant (Boehler et al., 2011). Strategies can be taken to modulate implant rejection, such as antiinflammatory cytokine release from the scaffold and immune cell recruitment and transplantation (Corradetti et al., 2017).

FDA Regulations for Clinical Translation

With the advancement of tissue engineering, a number of medical products and devices have been developed to address unmet clinical needs. Although preclinical research is important in developing new technologies, their application at the clinical stage must satisfy regulatory oversight at the government level. Each country in the world has its own regulatory agency that oversees this translation to ensure patient safety, such as the European Medicines Agency for the European Union, the FDA for the United States, etc. The approval of a biomedical product occurs in multiple rigorous stages of clinical trials starting with Phase I (safety and dosage assessment), Phase II (efficacy and side effects), Phase III (safety and adverse reactions), and Phase IV (post-approval assessment) (Witten et al., 2015).

The application of these regulations is highly regimented and well established for drug therapies. However, it becomes more challenging for multicomponent tissue-engineering products, biomedical devices, or 3D printed products where the safety and efficacy of each component and process have to be thoroughly examined (Morrison et al., 2015). Combination products under the FDA are treated as comprising two or more regulated components that are physically, chemically, or otherwise combined and produced as a single entity. For products that contain cells, biologics, and a scaffold matrix, product classification is determined by several factors such as the claimed mode of action, intended medical purpose, the active substance(s) and the way in which it is combined in the finished product (Hourd et al., 2015). Depending on the product in question, the process of FDA approval can take as long as 10 years and can differ for regulatory agencies throughout the world. For example, ReCell, a skin engineering product by Avita Medical, was introduced into clinical practice in the United Kingdom in 2005 (Gilleard et al., 2013), but received FDA approval in September 2018. However, the recently passed 21st Century Cures Act of December 2016 is intended to expedite the availability of novel therapies to patients in dire need and for compassionate use.

Gene Editing and CRISPR

Genome editing, or gene editing, is a toolkit that enables researchers to modify an organism's DNA by accurately targeting specific locations in the genome. These gene edits result in a cascade of downstream changes in transcription, protein expression, and eventually tissue and organ-level effects (Hsu et al., 2014). Ever since the first documented procedure of cloning and recombinant DNA by Cohen et al., in 1973 (Cohen et al., 1973), this field has grown at an astronomical rate. Today, there are several tools available, capable of precise modifications to the DNA double strand, including meganuclease, zinc finger nuclease, transcription activator-like effector nuclease, and most recently CRISPR and CRISPR-associated protein 9 (Cas9). The CRISPR-Cas9 editing technique parallels the highly adaptive immune system of bacteria and was first demonstrated successfully in eukaryotic cells in 2013 independently by four different groups (Lander, 2016; Gupta and Musunuru, 2014).

In tissue engineering, gene editing and particularly CRISPR have been well explored for the generation of disease models and platforms for advanced drug screenings and relevant therapies. This is particularly useful toward strategies involving iPSCs because of their vast potential for differentiation and application for multiple tissue types. For example, Freedman et al. developed 3D spheroid models of human pluripotent stem cell-derived kidney cells to recapitulate aspects of the kidney niche, and used CRISPR genome editing to functionally model polycystic kidney disease within the spheroids (Freedman et al., 2015). It has also been applied for investigating cardiomyopathies where off-target effects and high-throughput screening models can be investigated. Although advances in gene editing and their corresponding applications to tissue engineering and disease modeling continue to be made, much of this progress is still at its research stage. There are significant regulatory hurdles and uncertainties associated with the long-term effects and unintended consequences for both iPSCs and CRISPR that need to be addressed. However, one can expect this research area to provide critical breakthroughs and clinical applications in the years to come.

Future Perspectives

Multiple challenges remain for the translation of tissue-engineered products to the clinic. Cell type, source, and manipulation are critical parameters that need to be further studied and defined to achieve the best clinical outcomes. In addition, many approaches are too complex for scale-up at a manufacturing level. Ideally, tissue-engineered products involving cells should be amenable to cryopreservation. It is also critical to consider that in vivo animal models may not adequately represent the human condition. Furthermore, it is still not clear how the FDA will regulate combination products. This significantly increases the risk for new companies to develop multicomponent systems.

Recent developments in the field such as those outlined in this chapter provide valuable tools and strategies for advancing tissue engineering. However, more quantitative approaches such as computational modeling and systems biology are needed to understand the mechanism of tissue development and regenerative processes. Although significant advances have been accomplished, most regenerative therapies are still in the developmental phase and require additional research and clinical trials to achieve effective cell differentiation and tissue formation necessary for clinical use.

Tissue Engineering Scaffolds

HANNAH A. PEARCE, YU SEON KIM, LUIS DIAZ-GOMEZ, ANTONIOS G. MIKOS

Department of Bioengineering, Rice University, Houston, TX, United States

Introduction

Over the past 30 years, tissue engineering has experienced an intense evolution facing the need to restore, replace, or regenerate tissues that have suffered structural or functional damage following injury or disease. To induce and guide tissue growth, tissue engineering has aimed to combine scaffolds that provide a mechanical support structure, cells that populate the scaffolds and drive the regeneration process, and bioactive molecules that regulate cell differentiation and functionality (Langer and Vacanti, 1993). Scaffolds are highly interconnected porous structures that aim to recreate the extracellular environment while providing appropriate mechanical support and stability until the new tissue is regenerated (O'Brien, 2011). For these reasons, scaffolds should be prepared with biodegradable materials and the degradation rate should ideally match the regeneration rate of the tissue where it will be implanted while maintaining mechanical support (Thomson et al., 1995). This chapter describes the functional requirements, processing techniques, applications, and characterization methods of biomaterials to provide a state-of-the-art overview of scaffolds for tissue engineering developments in the last decade.

Scaffold Design Criteria

Three criteria that need to be considered when designing a polymeric scaffold for tissue engineering applications are (1) biocompatibility, (2) physicochemical properties, and (3) bioactivity. Biocompatibility of a material will dictate whether it is suitable to be used as a scaffold in vitro and in vivo, whereas its physicochemical properties and bioactivity are factors that can be tuned to be specific for a certain tissue/cell type, and to optimize the scaffold's ability to regenerate the tissue.

Biocompatibility, when used to describe a material, refers to its ability to perform with an appropriate host response in a specific application (Temenoff and Mikos, 2008). Unlike implants that are not meant to undergo degradation such as poly(methyl methacrylate) (PMMA) bone cements and metallic hip joints, tissue engineering scaffolds will gradually degrade over time and be replaced by the native tissue. As such, the cytotoxicity of degraded components of the original material should also be taken into consideration when choosing a material for scaffold design. Implanted scaffolds undergo degradation most often via hydrolysis and/or enzymatic activity, depending on the chemical structure of the scaffold material. Polymers with hydrolysable bonds such as esters and amides are often chosen as biodegradable materials. Notable examples include poly(lactic-*co*-glycolic acid) (PLGA), poly(ε-caprolactone) (PCL), and polyurethanes. Scaffolds fabricated from natural polymers such as collagen, gelatin, and polysaccharides will be enzymatically degraded by proteases that are present in the extracellular matrix (ECM).

The rate of scaffold degradation must also be considered for tissue regeneration. Ideally, the degradation rate of an implanted scaffold should be similar to the regeneration rate of the surrounding tissue. The degradation rate of hydrophobic polymers can be enhanced by increasing the content of hydrophilic groups. For instance, PLGA foams that contain higher glycolic acid content (50:50 lactic acid:glycolic acid) were shown to degrade more quickly than those that have higher lactic acid content (85:15) (Lu et al., 2000a). Similar results can be obtained by incorporating hydrophilic segments within the polymer chain; block copolymers of poly(lactic acid) (PLA) and poly(ethylene glycol) (PEG) have shown an increased degradation rate when compared to PLA homopolymers due to the increased hydrophilicity the PEG blocks bring to the polymer. The polymer's molecular weight will also affect the degradation time, where scaffolds fabricated with higher molecular weight polymers will degrade slower than those fabricated with lower molecular weight polymers. In addition to its chemical properties, the scaffold's physical properties will also affect the scaffold's degradation rate. It has been demonstrated that pore size and pore wall thickness will affect the rate of degradation of poly(L-lactic acid) (PLLA) foams in vitro, where thicker pore walls and larger pore size contributed to faster degradation via an autocatalytic effect (Lu et al., 2000a). The effect was also enhanced in vivo, where acidic degradation products remained within the pores and further accelerated the degradation reaction (Lu et al., 2000b).

Porosity and pore size/distribution will not only affect the scaffold's mechanical properties and rate of degradation, but also how seeded cells respond to the environment

(Petite et al., 2000). High porosity must also be accompanied with pore interconnectivity, as pores that are trapped within the scaffold are not accessible to cells and will reduce the scaffold's mechanical properties. Interconnected pores will also act as conduits for blood vessels to infiltrate and form a well-vascularized network within the scaffold, which is a necessary step toward the regeneration of tissues such as bone (Petite et al., 2000). A highly porous scaffold has a high surface area to volume ratio, which provides sufficient space for cells to attach onto the scaffold's surfaces, enhances the rate of mass transport of oxygen and nutrients both to seeded cells, and aids in the removal of cell waste (Mikos and Temenoff, 2000; Yang et al., 2001). Different pore sizes have been shown to trigger diverse responses from the tissue (Rouwkema et al., 2008; Yang et al., 2001); for instance, pores larger than 300 μm were shown to be ideal for bone in-growth, whereas fibrovascular tissues required 500 μm or greater (Kuboki et al., 2001; Wake et al., 1994). These results indicate that a modular approach is required to regenerate different types of tissues. Nevertheless, while high porosity is an important factor for tissue regeneration, the mechanical integrity of the scaffolds can be negatively influenced (Karageorgiou and Kaplan, 2005).

In addition to soluble factors, surface characteristics such as hydrophobicity, charge, roughness, and stiffness will also impact the behavior of cells seeded on the scaffold (Chang and Wang, 2011). Without the presence of proteins, cells tend to adhere and proliferate better on moderately hydrophilic surfaces (i.e., high wettability) than on hydrophobic surfaces. One benefit of hydrophobic surfaces though is the ability for proteins to adsorb through hydrophobic interactions and thus serve as a surface for cells to bind and proliferate. Synthetic polymers that are widely used for scaffold fabrication such as PLGA and PCL are hydrophobic and thus are not ideal substrates for cell adhesion on their own, but with proteins adsorbed on the surface they make promising tissue-engineering scaffolding systems. Surface modification strategies such as plasma treatment and hydrophilic polymer coating have therefore been utilized to enhance cell–surface interaction (Arima and Iwata, 2007; Cui et al., 2009; Place et al., 2009). An increase in roughness has been shown to not only enhance cell adhesion by improving adsorption of cell adhesion-mediating proteins such as fibronectin, but also alter their functions such as proliferation, morphology, and matrix production (Hallab et al., 2001; Martin et al., 1995; Puckett et al., 2008; Saranya et al., 2011).

Surface coating of synthetic scaffolds is often required to enhance the cell–scaffold interaction, as they often lack the biological signals that are required for cell attachment. The coating process involves chemically treating the surface to functionalize it with active domains that could be used for modifications with bioactive molecules of choice, such as ECM components that promote cell adhesion (collagen, fibronectin, and laminin), minerals to drive osteoconduction and osteointegration (calcium phosphate-based minerals such as hydroxyapatite), and drug molecules (Wu et al., 2014; Yoo et al., 2009). Short peptide sequences that mimic the active domain of a specific protein, such as the popular arginine-glycine-aspartate (RGD) sequence, can be used instead of native ECM proteins which can have issues with stability during and after surface adsorption (Shin et al., 2003).

Cell function can also be affected by substrate stiffness. It has been shown that the microenvironment stiffness significantly affects the commitment and differentiation of mesenchymal stem cells (MSCs); softer matrices encourage the neurogenic or myogenic differentiation of MSCs, while stiffer substrates are known to exert a strong influence in supporting osteogenic differentiation (Engler et al., 2006). Other cell functions such as migration and proliferation are also affected by substrate stiffness (Breuls et al., 2008). Cell lineages have unique optimum conditions for proliferation and respond differently to microenvironmental stiffnesses; for instance, human dermal fibroblasts seeded on stiff substrates show higher degrees of organization in their actin cytoskeleton and slower migration speed (Dado and Levenberg, 2009; Ghosh et al., 2007).

Scaffold Applications

Cell Delivery

A widespread application of scaffolds is as a carrier for cell delivery. Although delivering cells in suspension has shown positive results in improving disease conditions such as osteoarthritis and myocardial infarction (Amado et al., 2005; Berry, 2006; Black et al., 2008; Koh et al., 2013), the technique suffers from low cell retention and poor integration of cells at the site of delivery (Chen et al., 2012). By providing an environment where cells can be seeded, tissue-engineering scaffolds provide a platform that can deliver such cell populations directly into the defect site. Surgical techniques that incorporate scaffold carriers such as matrix-assisted chondrocyte implantation (MACI) have proven to be a more effective alternative to direct delivery of cell suspension (Kon et al., 2009; Steinwachs, 2009).

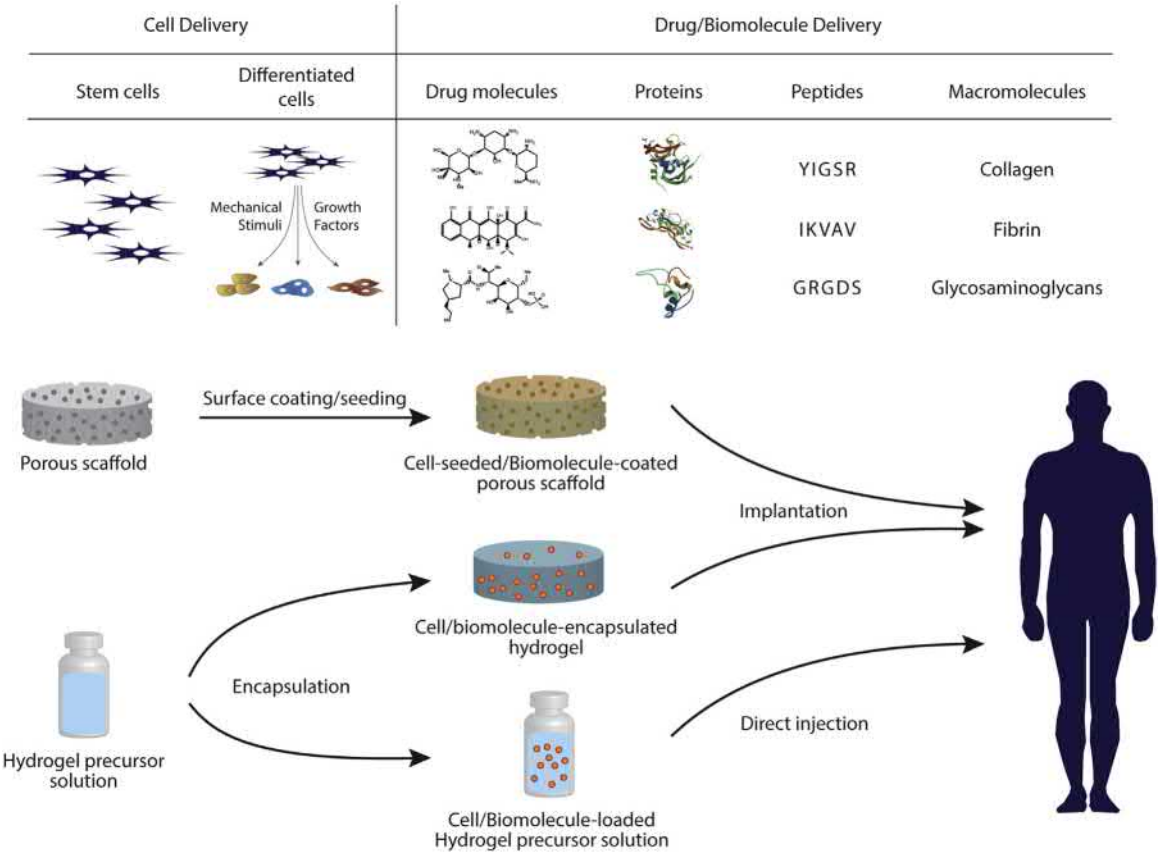
Cells, regardless of their origin, may be seeded onto a scaffold via a static or dynamic method (Marler et al., 1998). Static seeding involves a cell suspension being directly deposited onto the scaffold surface and gradually allowing the cells to coat the scaffold, whereas dynamic seeding utilizes any type of mechanical stimuli (e.g., stirring, shaking) to enhance the density and uniformity of cells on the surface of the scaffold. In addition to delivering cells on the surface of a 3D scaffold, cells may be incorporated within the bulk of a scaffold. Encapsulation refers to a technique where cell bodies are physically isolated from the surrounding environment while maintaining their activity and viability (Uludag et al., 2000). Hydrogels are utilized as the scaffold of choice for cell encapsulation, as they can provide a nontoxic, hydrated environment for encapsulated cells to survive and proliferate. Cells are loaded into the hydrogel precursor solution before undergoing gelation, after which the hydrogel

can be implanted. The hydrated environment allows for nutrients and signaling molecules from the body to diffuse into the hydrogel. Cells, in addition to being delivered in bulk hydrogels, can also be loaded into microspheres and delivered into the defect site when encapsulated in a bulk scaffold carrier. This method improves mass transfer of oxygen and other nutrients to the cells, thereby enhancing the viability of cells postimplantation (Hernández et al., 2010). Natural materials such as alginate and collagen (Chan et al., 2010; Tan and Takeuchi, 2007; Yu et al., 2010), as well as synthetic materials such as oligo(poly(ethylene glycol)fumarate) (OPF) (Park et al., 2005) have been used for the fabrication of cell-laden hydrogel microspheres (Fig. 2.6.3.1).

Another method of cell delivery involves direct injection of cell-laden hydrogel precursor solution into the body, where it will fill in the exact size and shape of the defect site and undergo gelation. These injectable systems allow for a minimally invasive delivery of cells to the site of interest, as they can be delivered using a syringe needle and thus bypass the need to perform an invasive surgery and suture the scaffold into place. Such gelation can take place either chemically or physically, depending on the material of the hydrogel. Injectable hydrogels that utilize chemical gelation often rely on free-radical initiators to start the reaction between polymer chains that have reactive groups (e.g., acrylates), or between the polymer chains and cross-linkers. Different combinations of initiators, such as ammonium persulfate/N,N,N′,N′-tetramethylethylenediamine (APS/TEMED) and APS/ascorbic acid, have been utilized to cross-link linear polymers with diacrylate-containing cross-linkers to form cell-laden hydrogels (Temenoff et al., 2003; Wang et al., 2006; Zhu and Ding, 2006). Photocross-linkable systems are a subset of chemically cross-linked hydrogels that require UV or visible light for activation. Polymers such as PEG that are otherwise not photocross-linkable can be modified with acrylate groups, after which they can be cross-linked under visible or UV light with the help of photoinitiators (Burdick and Anseth, 2002; Sawhney et al., 1993).

Chemically cross-linkable hydrogels that do not depend on free radical initiators have also been developed. For instance, supramolecular self-assembly between poly(ethylene oxide) (PEO) and α-cyclodextrins (α-CD) has been shown to result in the formation of a hydrogel that is injectable and biocompatible (Li et al., 2003). Click chemistry, which refers to reactions that can be performed in aqueous conditions and do not generate toxic byproducts, has also been utilized to develop injectable systems as cell carriers (Jiang et al., 2015a; Takahashi et al., 2013).

Injectable hydrogels that undergo physical gelation do not rely on initiators or other chemical interactions for hydrogel formation. Rather, they rely on changes in environmental cues such as temperature, pH, and ionic concentrations to undergo gelation. Thermogelling hydrogels



• **Figure 2.6.3.1** Scheme of the main applications of tissue-engineering scaffolds. (Protein structures downloaded from www.rcsb.org.)

are a subset of injectable materials that will undergo reversible gelation in response to temperature. One of the defining characteristics of these thermosensitive systems is their lower critical solution temperature (LCST), which is the temperature at which the system will undergo sol–gel transition. LCST can be tuned by adjusting the hydrophobicity of the polymer. Ensuring that the LCST is near body temperature is desirable for tissue-engineering applications (Kretlow et al., 2007).

Drug and Biomolecule Delivery

Delivering drugs and bioactive molecules using scaffolds allows for a sustained and localized delivery, thus minimizing complications related to systemic delivery such as poor localization of biomolecules at the target and low delivery efficiency stemming from short half-lives of biological molecules (Florence and Jani, 1994). When drugs and biomolecules are loaded inside a degradable scaffold, these molecules will be gradually released and delivered to the adjacent tissue as the scaffold undergoes degradation over time.

Drugs and biomolecules can be immobilized on scaffold surfaces via covalent conjugation or physical adsorption (Sokolsky-Papkov et al., 2007). Physical adsorption relies on noncovalent interactions between the substrate and the surface (e.g., ionic, hydrophobic, etc.), whereas covalent bonding requires reactive functional groups to be present on both the molecule of interest and the surface of the scaffold. This method often requires the surface to be treated with physical or chemical means to introduce such groups. Direct conjugation of proteins such as growth factors (GFs) also requires careful consideration when choosing which functional groups to modify, as poorly designed conjugation schemes can negatively affect their bioactivity by disrupting the native folding state or blocking the access to their active domains. In addition, conjugated factors will not be internalized by cells unless the surface undergoes erosion or degradation. Nevertheless, when well-executed, scaffolds covalently conjugated with GFs can show enhanced bioactivity over delivery of soluble GFs directly to the tissue. This method of delivery also enables more careful control of spatiotemporal distribution of factors on the surface of the scaffold and a longer duration of the signals than when the signals are encapsulated within the scaffolds (Tayalia and Mooney, 2009).

Drugs and biomolecules can also be encapsulated in the bulk space of the hydrogel during synthesis. Encapsulation into solid, porous scaffolds is possible but significantly more challenging than encapsulation in hydrogels due to the method of scaffold fabrication; for instance, synthesis of many porous synthetic scaffolds requires organic solvents and exposure to harsh conditions such as temperature and pressure, depending on which process is utilized to introduce pores into the scaffold (Tayalia and Mooney, 2009). As a result, most biomolecules are incorporated after the scaffold has been formed. Loading of drugs and biomolecules in hydrogels, on the other hand, can be done under mild conditions, as biomolecules can be mixed with the aqueous precursor solution and be encapsulated as the solution undergoes gelation. Such molecules can either be loaded into the bulk space of the hydrogel or covalently conjugated to the hydrogel backbone for a more controlled, sustained delivery that does not depend solely on diffusion. In addition, hydrogels can be designed so that they degrade in response to the physiological conditions of the surrounding environment and simultaneously release encapsulated biomolecules (Kost and Langer, 2012; Miyata et al., 2002). For instance, pH-sensitive hydrogels have been extensively developed and tested to control the release of GFs from the hydrogel (Garbern et al., 2010, 2011; Ishihara et al., 1984; Kim et al., 2009).

Scaffold Materials

Scaffold materials can range widely from synthetic scaffolds with little to no biochemical cues or factors incorporated to wholly biological systems possessing both innate and added bioactive factors to guide tissue growth (Deforest et al., 2009; Hubbell, 1995; Lutolf and Hubbell, 2005). As the field was initially being developed, the study of synthetic biomaterials benefited greatly from the wealth of information gained in the disciplines of chemical synthesis and materials processing, and the field has only continued to evolve and grow since. Classifying these polymers can be challenging, but a popular method is by categorizing polymers as either *polycondensation* or *polyaddition* polymers. This classification system, like all others, is imperfect but provides a clear picture of the polymer end-product and is helpful as it organizes systems based on the polymer structure (Odian, 2004). These two types of polymers include many important biomaterials including polyesters, polyurethanes, polyamides, and polyacrylates (Table 2.6.3.1).

Polycondensation Polymers

Polycondensation polymers are some of the most popular polymers used in biomaterials applications and include polyesters, polyethers, polyurethanes, and more. These polymers often possess functional groups within the polymer chain backbone (i.e., esters, ethers, amides, etc.) (Odian, 2004) and the polymerization methods used to form polycondensation polymers often involve the creation of low-molecular-weight byproducts; in biomaterials, these byproducts are most often water or alcohol-containing groups. The polymerizations used to create polycondensation polymers are characterized by a drastic monomer conversion at the beginning of the reactions due to the rapid formation of oligomers, followed by a steady growth into polymers until all monomers are consumed. The system reflects this monomer conversion with a gradual steady increase in polymer molecular weight over time. In polyester-forming condensations, often a carboxylic acid- or alcohol-containing group is the monomer and the system is usually acid-catalyzed. High temperatures and vacuum are often used to promote

TABLE 2.6.3.1 Polymerization Methods for Creating Synthetic Biocompatible Polymers

Polymerization Method	Characteristics	Example Polymers
Polymerizations producing polycondensation polymers	• Reaction exhibits rapid monomer conversion upon the start of the reaction • Polymer molecular weight increases steadily over time • Polymerizations often produce low-molecular-weight byproducts so can be performed under vacuum • Ring-opening polymerizations and click reactions are included	Poly(ε-caprolactone) (PCL), poly(glycerol sebacate) (PGS), polyurethane, polylactide (PLA), polyglycolide (PGA), poly(lactide-co-glycolide) (PLGA), poly(dimethylsiloxane) (PDMS), poly(propylene fumarate) (PPF)
Polymerizations producing polyaddition polymers	• Polymerization operates in distinct initiation, propagation, and termination steps • Reaction exhibits rapid polymer molecular weight growth upon initiation of the reaction • Monomer conversion progresses more steadily over time • Ionic polymerizations and free-radical polymerizations are included	Propylene fumarate dimethacrylate (PFDMA) and diacrylate (PPF-DA), poly(acrylamide), poly(ethylene glycol) (PEG), ethylene glycol dimethacrylate (EGDMA), butanediol dimethacrylate (BDMA)

the polymerization and facilitate the removal of byproducts. These condensation techniques have been used for decades and have produced condensation polymers such as poly(propylene fumarate) (PPF) (Peter et al., 1999a,b), poly(glycerol sebacate) (PGS) (Wang et al., 2002), and polyurethanes (Bachmann et al., 2001). Polyurethanes have been used for tissue-engineering applications such as electrospun scaffolds (Kishan and Cosgriff-Hernandez, 2017; Nezarati et al., 2013) and in shape-memory implants for embolic applications (Singhal et al., 2014).

Ring-Opening Polymerization

Ring-opening polymerization is a common tool used to produce linear polymers. It is commonly used to produce PCL (Dubois et al., 1991; Habibi et al., 2008; Hamitou et al., 1977), among other notable polyester biopolymers such as PLA, polyglycolide (PGA), and the copolymer PLGA (Gilding and Reed, 1979; Kaihara et al., 2007). Biodegradable sutures Dexon (PGA) and Vicryl (PLGA) are approved for use in humans by regulatory authorities and have been safely used for decades (Bourissou et al., 2004; Gilding and Reed, 1979). An extremely common biocompatible polymer, PEG, can be produced through the ring-opening polymerization of an epoxide ring (Herzberger et al., 2016). Poly(dimethylsiloxane) (PDMS) is a common polymer used in biological applications involving lithography which can also be produced through the ring-opening polymerization of cyclic siloxane groups (Rodriguez et al., 2007) and produces an optically transparent polymer product (Ersen and Sahin, 2017). Many of these ring-opening polymerizations are achieved through the initiation with an ionic group, or a coordination compound, the most common ones being Tin(II)-based (Gilding and Reed, 1979; Kaihara et al., 2007). Ring strain contributes to reactivity so three- and four-membered rings are most reactive with cyclohexane groups being relatively stable but still reactive given the correct conditions (Nuyken and Pask, 2013).

Click Reactions

Click reactions are a subset of chemical reactions that can be carried out in aqueous conditions, at physiological temperature, and without cytotoxic initiators (Deforest et al., 2009). These reactions are also highly specific and proceed in an orthogonal manner with high polymerization efficiency (Deforest et al., 2009; Tibbitt and Anseth, 2009). Click reactions encompass the well-known thiol-ene reaction, which allows highly controlled spatial and temporal regulation of materials through photoinitiation (Deforest et al., 2009). Click reactions can also be classified under the umbrella of polycondensation polymers. Although the formation of low-molecular-weight byproducts does not always occur, the reaction follows the general trend of polycondensation polymers such as rapid monomer conversion and a gradual increase in molecular weight, and the presence of functional groups in the polymer chain backbone. Extensive work has demonstrated the power of click chemistry in creating dynamic scaffolds that are responsive to both external stimuli (light, concentration gradient, mechanical stimulation, etc.) and to cells (Benoit et al., 2008; Brown et al., 2018; Burdick and Anseth, 2002; Kloxin et al., 2009; Sridhar et al., 2015). Additional work has been carried out to create biocompatible and bio-instructive scaffolding systems (Arakawa et al., 2017; Gramlich et al., 2013; Jivan et al., 2016, 2018; Nimmo et al., 2011).

Polyaddition Polymers

Unlike polycondensation, polyaddition reactions do not involve the formation of low-molecular-weight byproducts, and the polymer backbone does not often contain functional groups (Fried, 2014; Odian, 2004; Stevens, 1999). The reactions to form polyaddition polymers include ionic and free radical polymerizations. These reactions exhibit a rapid increase in the molecular weight almost immediately upon the initiation of the reaction while the monomer conversion progresses more steadily over time. Polyaddition reactions

operate in distinct initiation, propagation, and termination steps, each with their own kinetic rate and one growing reactive center that other monomers join as the polymerization progresses. Some of the most notable examples of polyaddition polymers are propylene fumarate dimethacrylate (PFDMA) and diacrylate (PF-DA), both biocompatible and mechanically robust bone tissue-engineering scaffolding systems (Moglia et al., 2014; Timmer et al., 2003).

Ionic Polymerization

Ionic polymerizations include both cationic and anionic reactions. Cationic polymerization systems are often initiated by a mineral acid, or a Lewis acid accompanied by a proton source, which becomes the electrophile needed to begin the reaction (Stevens, 1999). The method is attractive due to its ability to produce "living polymerizations," which has aided in the production of many commercially used block copolymers (Stevens, 1999) and branched copolymers (Iatrou et al., 2002). These systems are often induced through the addition of a metal initiator and begin with a nucleophilic addition to the monomer. The most notable biomaterial applications of anionic polymerizations are the creation of star polymers of PEO (Gnanou et al., 1988; Peppas et al., 1999).

Free Radical Polymerization

Free radical polymerization is a rapid, highly effective technique widely used in the industry to produce commercial polymers such as poly(methyl methacrylate) (PMMA) (Charnley, 1960; Turner et al., 1981), poly(acrylamide), and many acrylate and methacrylate terminated polyesters and polyethers (Matyjaszewski and Xia, 2001; Stevens, 1999). Initiators for free radical systems are diverse and include peroxides (Matyjaszewski and Xia, 2001), redox initiators (Hageman, 1985), azo groups (Braun, 2009), and photoinitiators (Hageman, 1985). Many peroxide initiators rely on temperature degradation to generate free radical species for initiation (Moglia et al., 2014), whereas redox systems can do so independent of temperature by including a reducing agent along with an oxidizing agent. Photoinitiators produce reactive species upon exposure to light of varying wavelengths depending on the compound (Hageman, 1985). Azo compounds decompose in a range of temperatures so, depending on the reaction requirements, a compatible azo initiator can be found (Braun, 2009). Some of the most notable work in free-radical polymerization has been the development of scaffolds consisting of polyester-based polymers, PPF (Peter et al., 1999a,b; Sikavitsas et al., 2001), ethylene glycol dimethacrylate (EGDMA), butanediol dimethacrylate (BDMA) (Moglia et al., 2014), and propylene fumarate dimethacrylate (PFDMA) (Moglia et al., 2014; Sears et al., 2017; Whitely et al., 2017).

Synthetic scaffolds offer a wealth of benefits to the field of tissue engineering. The work done in the polymer engineering and processing industry over the last several decades has benefited the field immensely and brought forth technologies for the creation of highly monodisperse and biocompatible polymers. The formation of polyaddition polymers with vinyl monomers through free-radical polymerization has opened the door for tissue-engineering scaffolds that can be created quickly to form robust scaffolding systems; polycondensation polymers have been harnessed to create biocompatible scaffolds such as PCL, PLA, and PGA and PLGA which are commonly used in biodegradable sutures (Bourissou et al., 2004; Gilding and Reed, 1979). The field has expanded immensely and is expected to continue expanding in the coming years.

Biological Polymers

Biological polymers have emerged as attractive materials for tissue engineering given their biocompatibility and biodegradability. Gelatin is a popular biological polymer that has been fabricated into a variety of scaffold systems; it is also highly biocompatible and contains the RGD peptide sequence known to promote cell adhesion (Liu et al., 2017). Gelatin has also been shown to demonstrate shear-thinning properties (Liu et al., 2017), which is very attractive for extrusion-based 3D printing applications. Alginate is another popular biopolymer that is cross-linked via ionic cross-linking around divalent cations, most commonly Ca^{2+} (Lee and Mooney, 2012). This cross-linking is reversible and has been harnessed to encapsulate single cells (Utech et al., 2015), and create stimuli-responsive drug-delivery systems (Huebsch et al., 2014). Glycosaminoglycans (GAGs) are another class of materials commonly used in tissue-engineering applications given their natural presence in the ECM. Hyaluronic acid has been used for a variety of tissue-engineering applications because of its natural presence in many wound-healing processes (Leach et al., 2003), as well as its ease for chemical modification and biodegradability (Hubbell, 1995; Leach et al., 2003; Van Vlierberghe et al., 2011). Once degraded, the polymer has been shown to promote angiogenesis (Leach et al., 2003). Sulfated GAGs such as chondroitin sulfate and heparan sulfate can also sequester GFs to promote cell growth and proliferation (Rinker et al., 2018; Van Vlierberghe et al., 2011).

Decellularized tissues are a class of biomaterials that has also been used to synthesize biological scaffolds. Once decellularized, these tissues retain many of the bio-instructive cues found in tissue that can promote native tissue integration and defect repair (Badylak, 2004; Badylak et al., 2011; Cheng et al., 2014). Scaffolds derived from decellularized tissues such as muscle (Cheng et al., 2014; Merritt et al., 2010a,b; Smoak et al., 2019), lung (Nichols et al., 2013), and heart (Ott et al., 2008) have been documented. Further processing the decellularized tissue (e.g., digestion with pepsin) for various applications such as electrospinning (Baiguera et al., 2014) and 3D printing (Pati et al., 2014) has also been explored.

Composites and Additives

Given the complexity of native tissue, composite and additive biomaterial systems for tissue engineering are popular options for encouraging regeneration (Temenoff and Mikos, 2000). Tissues such as bone and cartilage are particularly popular options for composite biomaterials (Temenoff and Mikos, 2000; Venkatesan and Kim, 2014). Hydroxyapatite (HA) is a

natural calcium phosphate mineral found in bone and enamel, used in bone tissue engineering. However, due to their brittleness, ceramics such as HA are often combined with polymers to create scaffolds with enhanced mechanical strength (Venkatesan and Kim, 2014). Polymers commonly used with HA for bone tissue engineering include collagen, gelatin, PLA, PLGA, PCL, and polyurethane. Composite scaffolds for cartilage often include cells and have been composed of polymers such as thrombin and fibrin, as well as alginate, hyaluronic acid, and oligo(poly(ethylene glycol) fumarate) (Park et al., 2007; Temenoff and Mikos, 2000). Another application of composite materials has been in neural tissue engineering. Composite fibers were used in neural regeneration applications by electrospinning human glial cell-derived neurotrophic factor (GDNF) inside a copolymer of ε-caprolactone and ethyl ethylene phosphate (Chew et al., 2007). Similarly, there have been other numerous documented examples of improved regenerative outcome for composite scaffolds incorporating transforming growth factor-β1 (TGF-β1) for cartilage repair, vascular endothelial growth factor (VEGF) for angiogenesis (Cao et al., 2009; Lee et al., 2011), and insulin-like growth factor 1 (IGF-1) for a variety of applications (Chen et al., 2009; Davis et al., 2006; Lee et al., 2011).

Scaffold Fabrication Techniques

Scaffolds are one of the three main components of the tissue-engineering strategy to repair, regenerate, and remodel living tissues after an injury or disease (O'Brien, 2011). Since the beginning of the tissue-engineering field, scaffolds have shown a key role since they provide a 3D solid support for the attachment, proliferation, migration, and differentiation of the cells. Furthermore, they can also serve as reservoirs for the controlled release of bioactive molecules or drugs that can drive the regeneration process (Nair and Laurencin, 2007). The field of tissue engineering has developed a wide range of processing techniques to fabricate porous scaffolds from one or more biodegradable polymers that are selected depending on the properties needed for the intended application (Table 2.6.3.2).

TABLE 2.6.3.2 Preparation Techniques for Tissue-Engineering Scaffolds, Requirements and Examples of Applications

Scaffold Fabrication Techniques	Requirements	Applications
Rapid prototyping	Must utilize inks that are easy to work with and possess desired mechanical properties	Create 3D structures from computer models. Stereolithograpy, selective laser sintering (SLS), inkjet bioprinting, extrusion printing, bioplotting. Often use amorphous and semicrystalline polymers such as PCL, PLA, and PLGA. Poly(vinyl alcohol) (PVA) and poly(propylene fumarate) (PPF) have also been used
Electrospinning/ electrospraying	Relies on an electric field to aid in the deposition of the polymer solution onto a collecting plate so choosing a suitable polymer and solvent carrier is required	Fabricate microparticles via electrospraying or fibrous mesh scaffolds via electrospinning. Have been used to generate scaffolds made from chitosan, gelatin, collagen, PCL, PLGA, polyurethanes, and more
Superstructure engineering	Depends on structural interactions to maintain scaffold integrity such as noncovalent, van der Waals, hydrophobic, ionic, magnetic, and electrostatic interactions so polymers must be chosen that promote these interactions	Generate complex structures built on noncovalent interactions. Allows for reversibility, and it also enables "self-healing" scaffolds to be created
Solvent casting, particulate/porogen leaching	Must select a porogen not soluble in the solvent that the polymer is being cast in. Selecting a porogen of adequate size that also allows for interconnectivity is important as well	Generate porosity in scaffolds. Salt leaching is the most common porosity-inducing method. Polymers such as sugar or paraffin have also been used as porogens
Freeze-drying	Must be able to withstand cold temperatures. The freezing rate impacts pore size with faster freezing rates producing homogeneous pore structures	Remove water and generate porosity when paired with annealing. Attractive for use with materials that are temperature sensitive at higher temperatures
Phase separation	Requires immiscible phases to be chosen, and consideration for compatibility of the phases with biological molecules must be considered	Create porous foams. Can also use thermally induced phase separation to create porous structures with high interconnectivity
Gas foaming	Requires the polymer to be able to be saturated with CO_2	Generate highly porous structures by foaming dissolved CO_2 gas. The CO_2 interacts strongly with carbonyl groups so PLA, PLGA, and PCL are commonly used. Can also be used to decellularize tissues

Rapid Prototyping

Rapid prototyping or solid free form fabrication refers to a series of techniques that use polymeric materials by printing layer-by-layer scaffolds from a 3D model created by computer (Peltola et al., 2008). Compared to traditional biofabrication techniques, rapid prototyping can recreate complex structures with high fidelity and reproducibility while minimizing material loss (Bittner et al., 2018). Additional advantages are the possibility to design patient-specific scaffolds and on-demand fabrication (Guvendiren et al., 2016). Among various rapid prototyping techniques, extrusion printing, stereolithography (SLA), selective laser sintering (SLS), digital light projection (DLS) and inkjet bioprinting have gained increased usage in fabricating tissue-engineered scaffolds in the last decade (Ozbolat and Hospodiuk, 2016; Roseti et al., 2017).

Extrusion printing is based on the melting of a polymeric admixture inside of a moving extruder arm and its deposition on a printing platform through a nozzle using pneumatic or mechanical dispersers (Zein et al., 2002). Extrusion printing has become an attractive platform for the preparation of highly precise porous scaffolds for tissue engineering because of its resolution, reproducibility, and fidelity to the predesigned model (An et al., 2015). In particular, extrusion printing has been shown to be suitable for the fabrication of porous scaffolds prepared with a wide range of compositions including thermoplastics and composite admixtures (Bittner et al., 2019; Diaz-Gomez et al., 2019). However, the incorporation of bioactive or heat-sensitive biomolecules in the aforementioned methods is limited due to the high temperatures and pressures involved in the extrusion process. A cell-friendly alternative to the high temperatures involved in the extrusion printing is direct ink writing or cold temperature 3D bioprinting. A wide range of natural polymers, including polysaccharides such as alginate or chitosan, and proteins such as collagen, gelatin, or elastin, among others, have been used as bioinks to prepare cell- or GF-laden scaffolds for tissue engineering (Chung et al., 2013; Das et al., 2015; Echave et al., 2017; Jammalamadaka and Tappa, 2018; Radhakrishnan et al., 2017).

SLA and DLS use a light beam or an image projection, respectively, to cure a polymer solution into a specific pattern with high resolution (Dean et al., 2012; Melchels et al., 2010). After each layer is cured, the platform moves up, and the process is repeated until the fabrication is completed. SLA has become an alternative to extrusion-related approaches since shear-stress mechanisms are not involved (Lin et al., 2013). However, the need for photoinitiators that are potentially cytotoxic limits the use of this approach for cell-laden tissue-engineering applications (Manapat et al., 2017). SLS is another layer-by-layer technology that uses a high-energy laser to fuse a thin layer of powder particles together. The resolution of the printed object is restricted by the precision of the laser to sinter the powder, and depends on the laser power and speed, layer thickness, and laser focusing radius, among others (Shirazi et al., 2015). SLS offers very precise control over the microstructure design and the obtained scaffolds usually hold high mechanical strength. The main drawbacks of this technique are the difficulty to alternate different materials in the construct and the need for powdered materials with good flow properties to homogeneously deposit each layer (Mazzoli, 2013).

Electrospinning/Electrospraying

Electrospinning is a widely used technique to prepare nano- and/or microfibrous structures from polymeric solutions using the action of an electric field (Lannutti et al., 2007; Pham et al., 2006). The diameter and morphology of the resulting fibers that mainly define scaffold porosity can be modified with the polymer concentration, the voltage applied, and the distance between the needle and the collector (Jiang et al., 2015b). Fiber diameter has a key role in the micro- and macroscopic properties of the electrospun scaffolds, including porosity and mechanical and biological properties (Sisson et al., 2010; Unnithan et al., 2015). A wide range of both natural and synthetic polymers as well as their blends have been used for electrospinning (Khajavi et al., 2016). In particular, core–shell coaxial electrospinning has been explored as a method to prepare nanofibrous scaffolds that encapsulate drugs or other bioactive molecules such as GFs in the core (Yoon et al., 2018; Zhang et al., 2013). Melt electrospinning is another variation of electrospinning, where the polymer is melted in a syringe or cartridge and ejected toward a collector by applying an electric field. This method of electrospinning does not require solvents and thus results in lower toxicity and fewer postprocessing steps compared to conventional electrospinning. Furthermore, when a movable collector plate is used, it is possible to fabricate intricate porous structures from a template created using a software (Brown et al., 2016; Hochleitner et al., 2015).

Superstructure Engineering

Self-assembly is considered a bottom-up autonomous arrangement of components into certain patterns or structures driven by short-distance interactions (noncovalent, van der Waals, hydrophobic interactions, ionic, magnetic, or electrostatic). Using self-assembly, it is possible to control the structure of the scaffolds at the molecular level to create highly complex structures that closely mimic the properties and architecture of the native tissues. Furthermore, since self-assembly is a reversible process, most of the scaffolds developed using this technique present unique self-healing properties that make them very attractive when used in locations that could present mechanical perturbations. Self-assembly scaffolds with diverse architectures have been developed using protein-based strategies such as chemically or biologically synthesized peptides. Self-assembly peptides are usually prepared as injectable hydrogels that self-assemble in situ as a result of pH or temperature (Hosseinkhani et al., 2013). The main advantages of using peptides for the preparation of self-assembly scaffolds are their high biocompatibility and biodegradability. Furthermore, slight modifications

in the peptide sequences result in macromolecular changes that affect the properties of the scaffold and can be used to tune the mechanical and functional properties of the resulting constructs (Habibi et al., 2016). However, since most of the compositions are hydrogels, their use is limited to soft tissues, which remains as a challenge along with cost and scalability (Dutta et al., 2017; Khan and Tanaka, 2017).

Solvent Casting, Particulate/Porogen Leaching

Solvent-casting particulate leaching (SCPL) is a simple and cost-effective method to prepare highly porous polymeric scaffolds. Insoluble porogens such as salts are dispersed in a polymer solution, and following a solvent evaporation step, a porogen–polymer composite is formed that is further washed to remove the porogen particles (Mikos et al., 1994). SCPL allows for the preparation of scaffolds with a porosity higher than 90% and pore size up to 500 μm (Prasad et al., 2017). Furthermore, it is relatively easy to control the pore architecture (pore size, interconnectivity, porosity) of the obtained scaffolds by the selection of adequate polymers, porogens, and their concentrations. Porogen leaching, however, has been reported to result in poor interconnectivity and heterogeneous pore shapes. Porogen–polymer blends such as sodium chloride and PEG have therefore been investigated to introduce a dual-leaching process, which could significantly increase the interconnectivity of pores while maintaining a homogeneous pore size distribution (Thadavirul et al., 2013). The main drawback of SCPL is the use of organic solvents that could lead to cytotoxicity and also limit the incorporation of bioactive molecules. Moreover, the mechanical properties of scaffolds prepared with this technique are below the requirements of load-bearing tissues (Janik and Marzec, 2015). In order to increase the mechanical properties of the scaffolds, gel casting has become an interesting alternative. A green strategy used to produce polymeric, ceramic, and composite porous scaffolds, gel casting consists of a preparation of an aqueous polymeric solution that is foamed and polymerized in situ through chemical reactions to prevent structure collapse. The obtained structures are dried and, if ceramic materials are used, sintered (Montanaro et al., 2018). Scaffolds produced using gel casting showed high interconnectivity and dense pore walls, with high mechanical strength and porosities over 90% (Baino et al., 2015; Siqueira et al., 2017).

Freeze-Drying

Freeze-drying is a simple approach for the preparation of highly porous polymeric scaffolds via freezing and sublimation of an aqueous or organic polymeric solution using low temperature and pressure. Since the process does not involve high temperatures, it allows heat-sensitive components to be included into the scaffold. The structure of the scaffold can be tuned by adjusting the polymer concentration and molecular weight, the viscosity of the polymer solution, and solvent type. Other processing parameters such as the cooling rate and the freezing temperature strongly affect the scaffolds' structural properties: fast cooling rates usually lead to more homogeneous pore structures, while lowering the freezing temperature decreases the mean pore size. Annealing (increasing the temperature of the frozen material to promote the growth of ice crystals) has also been described as a strategy to increase the mean pore size of scaffolds (Pawelec et al., 2014; Raeisdasteh Hokmabad et al., 2017). In general, freeze-drying only allows for the preparation of simple (planar) 3D structures, but complex structures have been successfully prepared by controlling the molds and the processing parameters (Brougham et al., 2017). Pore orientation can be defined by controlling the growth speed and orientation of the ice crystals, resulting in unidirectional porous scaffolds (Deville, 2010). Pore size can also be controlled by the polymer concentration and molecular weight (Qian and Zhang, 2011).

An alternative to freeze-drying is emulsion freeze-drying which has attracted attention due to its ability to prepare scaffolds with highly specific pore surface area. The method is based on the dissolution of a polymer solvent and its further emulsification by the addition of a nonsolvent. The obtained emulsion is poured into a mold and quenched at low temperature prior to freeze-drying to remove the solvent and nonsolvent (Sultana and Wang, 2008, 2012). PVA is an attractive polymer to be processed using these approaches since it physically cross-links when submitted to freeze/thawing, thus avoiding the use of potentially cytotoxic cross-linkers (Nie et al., 2012). The biodegradation rate of the scaffolds can also be controlled by modifying the ratio of polymers included in the composition (Sultana and Wang, 2012).

Phase Separation

Phase separation can be achieved with the addition of a nonsolvent, which yields scaffolds with heterogeneous pore structures. This option is less attractive for tissue engineering scaffolds that generally require uniform porous structures. A second approach is the thermally induced phase separation (TIPS) method, which is based on the decrease of thermodynamic stability of a polymeric solution with small changes in the temperature of the system resulting in a phase separation process which produces a polymer-rich phase and a polymer-lean phase. After the removal of the polymer-lean phase by evaporation or lyophilization, the polymer-rich phase becomes a highly interconnected porous structure with homogeneous pore size distributions (Lu et al., 2013; O'Brien, 2011). By controlling process variables such as polymer concentration and molecular weight, solvent/nonsolvent ratio, and the cooling path, it is possible to obtain scaffolds that have a wide range of morphologies and microporous structures. Since pores are formed in the paths created by the solvent extraction, high interconnectivity is easily achieved, which makes this technique very attractive for cell spreading and migration (Wei and Ma, 2004). Various synthetic and natural polymers have been processed alone or in combination with others to prepare highly porous scaffolds with controlled structures, including gradients (Mannella et al., 2015; Pavia et al., 2008).

Gas Foaming/Supercritical Fluid Processing

Gas foaming is a solvent-free method that uses the expansion effect of a gas to fabricate highly porous scaffolds. CO_2 is the most used gas since it is safe, reusable, and cost-efficient. CO_2 also reaches a supercritical state at mild temperature and pressure (31.1°C and 73.9 bar) (Picchioni, 2014). In this process, the polymer is saturated with CO_2, which reduces its glass transition temperature through a plasticizing effect. Once equilibrated, controlled depressurization results in the nucleation and expansion of the CO_2, forming pores in the material as it is evacuated (García-González et al., 2015). The size and density of the pores can be regulated by adjusting the temperature, pressure, and depressurization rate. Dual pore populations, generally in the nano- and microscale, can also be achieved by modification of the depressurization rate during the process (Ji et al., 2012). Blends of two or more materials can be used to control the foaming process or the porous micro- and macrostructure of the obtained scaffolds (Moghadam et al., 2017; Salerno et al., 2009). Due to its mild processing temperature, biological molecules such as GFs have been incorporated in polymeric scaffolds without affecting their biological activity (Diaz-Gomez et al., 2016; Hile et al., 2000).

Scaffold Characterization Techniques

Scaffold characterization involves the characterization of the material utilized to fabricate the scaffold and the bulk properties of the obtained constructs. Material characterizations involve methods to assess the purity and structure, such as nuclear magnetic resonance (NMR), mass spectrometry (MS), gas/liquid chromatography (GC/LC), and additional spectroscopic methods such as Raman and infrared. Gel permeation chromatography (GPC) is widely used to measure the molecular weight and polydispersity of synthesized polymers. Thermal properties of polymers are measured using differential scanning calorimetry (DSC) and thermogravimetric analyzer (TGA). DSC will quantify glass transition and melting temperatures (T_g and T_m, respectively) (Mikos et al., 1994), as well as LCST of thermoresponsive polymers; TGA will measure the thermal stability of a given polymer and is widely used to characterize ceramics.

Physical properties of synthesized scaffolds can be quantified via multiple methods. Microscopic techniques such as scanning electron microscopy (SEM) and atomic force microscopy (AFM) are frequently used to observe the surface morphology of a scaffold (Ma et al., 2007). Of the two techniques, AFM has a higher resolution and can accurately quantify nanoscale topographical details. SEM or simple light microscopy can be used also to measure the size and shape of microparticles. Mechanical properties such as compressive or tensile moduli can be quantified by directly placing the scaffold under appropriate stress and measuring the stress-strain curve. In the case of thermosensitive hydrogels, a thermomechanical analyzer (TMA) can be used to conduct mechanical testing under a temperature-controlled environment. The scaffold degradation rate can be measured over any period of time by weight loss after incubation in an environment that mimics in vivo or accelerated in vivo conditions. Drug release profiles from a bulk scaffold can be measured by using high-performance liquid chromatography (HPLC), which can measure the concentration of drugs that have been eluted from the scaffold to the surrounding media at specific time points (Haesslein et al., 2006; Shi et al., 2010). For applications that require cell encapsulation, biocompatibility can be measured indirectly by measuring the viability of encapsulated cells, or by culturing the cells with the leachable byproducts of the scaffold.

Standards for characterizing scaffolds and biomaterials for tissue-engineering applications have been developed by standards organizations such as ASTM and International Organization for Standardization (ISO) (Vo and Trachtenberg, 2014). In addition to characterization standards for scaffolds in vitro, methods of assessing constructs in vivo have been developed (Trachtenberg et al., 2015). These guides are application-specific and provide detailed guidelines on techniques and procedures that are required to test any given scaffold or biomaterial. Characterization techniques discussed in previous paragraphs should therefore be conducted on the designed scaffolds according to the established standards that correspond to the scaffolds' potential application. This will also be important for future clinical translation of such scaffolds (Table 2.6.3.3).

Cell-Incorporated Scaffolds

Biomaterial scaffolds are ideal carriers for cell delivery (Ricles et al., 2016; Truong et al., 2015). Research has shown that cell delivery alone results in cell death and low cell retention at the site of delivery (Chen et al., 2012; Ricles et al., 2016; Vo et al., 2016). However, when encapsulated within a biomaterial carrier, particularly those decorated with cell-specific or ECM-specific markers and factors, cell viability is improved and controlled differentiation may be induced (Na et al., 2007; Nguyen and West, 2002; Ricles et al., 2016). Hydrogels are a particularly popular biomaterial for cell encapsulation given their highly swollen nature, their ability to be patterned with moieties, and to allow the diffusion of oxygen and nutrients to cells within the scaffolds (Nguyen and West, 2002; Ricles et al., 2016; Truong et al., 2015; Vo et al., 2016). These cell-encapsulated systems may be injectable, allowing the cell-laden scaffold to fill the defect site (Ricles et al., 2016), or printed into their desired geometry (Billiet et al., 2014; Kolesky et al., 2014). Cell-laden scaffolds also allow for multiple cell types to be incorporated into a scaffold, which is important in mimicking the complexity of native tissue (Xu et al., 2013), including interfacial gradient units of tissue such as the osteochondral unit at the bone/cartilage interface (Mohan and Detamore, 2014; Yang et al., 2017).

Perfusion seeding is another technique for cell incorporation in the scaffolds (Zhao and Ma, 2005). Stem cells may be seeded onto scaffolds through perfusion-based methods and have been reported to maintain stemness in the case of MSCs (Zhao and

TABLE 2.6.3.3 Description of the Characterization Techniques for Tissue-Engineering Scaffolds

Polymer/Scaffold Property	Characterization Technique	Description
Chemical characterization	Nuclear magnetic resonance (NMR) spectroscopy	Provides highly specific characterization of polymer structure and molecular weight. Most commonly used NMR techniques are ^{1}H-NMR and ^{13}C-NMR with ^{1}H-NMR being the most common for polymers for tissue-engineering applications
	Fourier transform infrared (FTIR) spectroscopy	Is used to characterize scaffolds and polymers alike. Spectra possess unique fingerprint regions for common bonds such as amides, carbonyls, and more to characterize structures
	Gas/liquid chromatography (GC/LC)	Separates and analyzes polymers that can be vaporized without decomposing. Liquid chromatography (often high-performance liquid chromatography or HPLC) consists of a chromatography column and a detection tool such as a UV spectrometer that helps separate and identify products as they are eluted through the column
	Raman spectroscopy	Aids in the characterization and identification of polymers by looking at the spectra to identify fingerprint regions for common chemical bonds, similarly to FTIR
Mass/molecular weight characterization	Mass spectrometry (MS)	Ionizes the product and calculates molecular weight based on time of flight to a detector. Provides highly specific mass values
	Gel permeation chromatography (GPC)	Characterizes molecular weights based on well established PEG or PMMA standards. Can characterize hydrophilic and hydrophobic polymers. Can also be paired with mass spectrometry for added accuracy
Thermal properties characterization	Differential scanning calorimetry (DSC)	Determines the glass transition temperature (T_g) and the melting temperature (T_m) of the polymer
	Thermogravimetric analysis (TGA)	Determines the thermal stability of the polymer over a range of temperatures
Morphology/surface characterization	Scanning electron microscopy (SEM)	Aids in determining surface features of polymer scaffolds such as mesh size or porosity
	Atomic force microscopy (AFM)	Is used to image polymers and compounds at single-atom resolution. Can also be utilized to determine mechanical properties of scaffolds at single bond resolution
Mechanical properties characterization	Rheology	Measures mechanical properties for viscoelastic materials. Can determine the point of gelation for scaffolds
	Tensile testing	Is used to determine the tensile properties of a polymer or scaffold materials
	Compressive testing	Determines the compressive properties of a polymer or scaffold material

Ma, 2005). Perfusion-based seeding has also been used to vascularize scaffolds in 3D printed systems (Miller et al., 2012). Bioreactor culture is closely related and often follows perfusion-based seeding. This allows for the diffusion of nutrients to cells (Cartmell et al., 2003; Saini and Wick, 2003). It also allows the cells within the scaffold to be placed under shear forces during culture to maintain mechanical stimulation to improve viability (Cartmell et al., 2003), induce differentiation of bone cells (Gomes et al., 2003) and endothelial vascular cells (Yamamoto, 2004), and create better disease models in the case of Ewing sarcoma (Santoro et al., 2015). Tissues such as cartilage, bone, and heart valves require mechanical stimulation for their function (Cartmell et al., 2003; Hoerstrup et al., 2000; Saini and Wick, 2003), and engineered tissue quality is greatly enhanced for such tissues with mechanical stimulation via the shear forces seen in bioreactor culture (Bancroft et al., 2002; Holtorf et al., 2005a,b; Sikavitsas et al., 2003).

Conclusions

The field of materials development for tissue engineering has advanced greatly in recent years. Scaffolds can be created as carriers for cells, drugs, and bioactive factors for diverse tissue engineering, drug delivery, and wound-healing applications. These scaffolds are often biodegradable via ester hydrolysis or enzymatic degradation and can be composed of synthetic or natural polymers. Using a wide variety of fabrication techniques such as rapid prototyping, electrospinning, solvent casting/porogen leaching, gas foaming, and more, robust and porous scaffolds can be created for a variety of applications and their features and properties can be tailored depending on their intended application. Many challenges still remain in the field of materials development for tissue engineering, but ongoing work in the field shows promise for significant developments in the near future.

CASE STUDY: MATRIX-ASSISTED AUTOLOGOUS CHONDROCYTE TRANSPLANTATION (MACT)

Multiple reparative surgical techniques have been developed over the years to treat articular cartilage lesions. Microfracture, or marrow stimulation, refers to a technique where the subchondral bone beneath the defect is penetrated using a microneedle to allow the flow of blood and bone marrow into the site. The formation of a blood clot, which contains progenitor cells from the marrow, gradually leads to regeneration of the tissue. Another option available to patients is osteochondral autograft or allograft, where cartilage pieces from either low weight-bearing regions of the patient's (autograft) or a donor's (allograft) joints are harvested and transferred to the defect site. These surgical techniques, however, present certain challenges. For instance, microfracture has been shown to be linked with formation of fibrous cartilage,[1] osteochondral autograft with donor site morbidity,[2] and allograft with immune response and loss of cell viability.[2]

In the late 20th century, a cell-based approach to treating osteochondral defects was developed. This technique, called autologous chondrocyte implantation (ACI), involves small cartilage biopsies being taken from the patient to harvest chondrocytes that are then expanded in vitro and delivered directly into the defect site as a suspension.[3] Matrix-assisted autologous chondrocyte transplantation (MACT) is the second-generation ACI, where a type I/III collagen membrane is used as a cell-seeded scaffold to deliver in vitro-expanded autologous chondrocytes to the defect site.[4] The membrane is customized to fit the size of the defect site before being sealed in place using fibrin glue.

MACT also presents certain challenges. Expansion of chondrocytes in vitro has been shown to lead to dedifferentiation; studies have shown that when chondrocytes are cultured on a stiff, 2D substrate, they gradually lose the ability to produce type II collagen and glycosaminoglycans even after the first passage.[5] Cell expansion is also a time-consuming process, and the number of chondrocytes required for transplantation, and therefore the overall culture period, will depend on the size of the defect. Nevertheless, MACT is one of the first FDA-regulated tissue-engineered therapies for clinical usage.

Chapter Exercises

1. You and your team are designing a material that can offer three different degradation profiles both *in vitro* and *in vivo*. The tissue engineering scaffolds will be composed of blends of PLGA and PCL and will be porous.

   Given the following scaffold formulations, which would you recommend for (a) the fastest degradation profile, (b) intermediate degradation, and (c) slowest degradation, and why?
   - 25% PCL, 75% 50:50 PLGA
   - 50% PCL, 50% 50:50 PLGA
   - 75% PCL, 25% 50:50 PLGA

   Similarly, for the following formulations, which would you recommend for (a) the fastest degradation profile, (b) intermediate degradation, and (c) slowest degradation, and why?
   - 50% PCL, 50% 75:25 PLGA
   - 50% PCL, 50% 25:75 PLGA
   - 50% PCL, 50% 50:50 PLGA

2. A company wants to 3D print mesenchymal stem cells into a commercial tissue engineering scaffold system. Which 3D printing method would you recommend for them to use and why?
3. You are designing a tissue engineering scaffold for pancreatic islet cell regeneration. Which cell type would you choose for your scaffold and why? For the tissue engineering scaffold, would you choose (a) a hydrogel, (b) a calcium phosphate cement, or (c) an electrospun PCL mesh? Why?
4. You have an electrospun tissue engineering scaffold that you intend to use as a cancer model for Ewing Sarcoma to study the efficacy of chemotherapeutics in vitro. Which cell seeding method would you use to seed your scaffold? Why?
5. You have synthesized a new polyaddition polymer and need to characterize the chemical structure and molecular weight. Which characterization techniques would you use?
6. You and your team want to create a highly porous PCL scaffold with both nano- and microporosity, encapsulating growth factors that cannot be dissolved in an organic solvent. Which scaffold preparation method should you and your team choose and why?

Chapter Exercise Answers

1. Part 1:
   (a) 25% PCL, 75% 50:50 PLGA
   (b) 50% PCL, 50% 50:50 PLGA
   (c) 75% PCL, 25% 50:50 PLGA

   The greater the content of PCL, the slower the degradation profile as PCL is more hydrophobic and highly crystalline.

   Part 2:
   (a) 50% PCL, 50% 25:75 PLGA
   (b) 50% PCL, 50% 50:50 PLGA
   (c) 50% PCL, 50% 75:25 PLGA

   The greater the content of PLA, compared to PLGA, the slower the degradation rate given the increased hydrophobicity and crystallinity of PLA.

2. Extrusion based printing would be recommended as that system for 3D printing is compatible with many biological polymers, as well as crosslinking systems that do not require exposure to high temperatures and harsh initiators.
3. A variety of cell types could be chosen. Induced pluripotent stem cells (iPSCs) would be a good choice and a hydrogel would be the best material for the intended application given the material mechanical properties being the closest to native pancreatic tissue.
4. The best seeding method for the situation would be perfusion-based seeding of the Ewing Sarcoma cells. The system would also necessitate bioreactor culture in order to better recreate the in vivo environment when determining chemotherapeutic efficacy.
5. ^{1}H-NMR can be used to characterize the polymer chemical structure and either APC/GPC can be used to characterize the molecular weight.
6. Gas foaming would be a very good option as CO2 is readily soluble in PCL and gas foaming does not require heating the mixture to high temperatures that would denature or disrupt the bioactivity of any growth factors incorporated into the system.

2.6.4

Micromechanical Design Criteria for Tissue-Engineering Biomaterials

YING LEI, ZACHARY E. GOLDBLATT, KRISTEN L. BILLIAR

Biomedical Engineering Department, Worcester Polytechnic Institute, Worcester, MA, United States

Introduction

In the field of tissue engineering, cell–scaffold constructs are designed with the aim of promoting new tissue formation following injury or disease. Biomaterials used in tissue engineering were initially viewed as temporary mechanical supports for cell delivery that were designed to resist macroscopic loads, and growth factors were used to guide cell behavior, as depicted by the classic tissue engineering triad (Fig. 2.6.4.1A). However, it is becoming clear that attention needs to be paid to cell-scale mechanical properties and mechanical stimuli to guide regeneration and completely restore normal tissue form and function when implanted in vivo, as depicted by the tissue-engineering tetrahedron with mechanical stimuli at the apex (Fig. 2.6.4.1B).

Many tissues are mechanically active in vivo, bearing continuous or cyclical stress as well as stretch and/or compressive loading (e.g., heart valve and cartilage). Additionally, all tissues have hierarchical structures from submicron to millimeter scale. Tissue constructs mechanically preconditioned in bioreactors prior to in vivo implantation have greatly improved strength and stiffness (Waldman et al., 2003; McCulloch et al., 2004; Fehrenbacher et al., 2006; Isenberg et al., 2006). The bulk stiffness of a scaffold determines the load-bearing ability, whereas the micromechanical properties, such as local stiffness and topography, influence the forces transmitted to and generated by cells. In response to local mechanical cues, cells change their behaviors including attachment, proliferation, migration, and protein secretion, which in turn affect the mechanical and chemical properties of the surrounding environment (Fig. 2.6.4.1) (Shin et al., 2003; Lutolf and Hubbell, 2005). More information about cell–biomaterial interactions, including the effects of mechanical forces on cells and tissues, host reaction to biomaterials, as well as inflammation and wound healing can be found in Chapters 2.1.6–2.2.2.

There are myriad existing methods for fabricating scaffolds with particular mechanical features with the potential to control cell response. These methods are described in other chapters in this text: Chapter 1.4.6 Medical Fibers and Biotextiles, Chapter 1.4.7 Textured and Porous Materials, Chapter 1.4.8 Biomedical Applications of Additive Manufacturing, Chapter 2.6.2 Overview of Tissue Engineering Concepts and Applications, and Chapter 2.6.3 Tissue Engineering Scaffolds. The development of more recent techniques such as additive manufacturing and surface patterning will allow designers to manipulate the performance of cells through hierarchical design of scaffolds with precise control of the local stiffness and topography (Pan et al., 2017). To do this effectively, however, an understanding of the dynamic and reciprocal interactions that occur within the cell–extracellular matrix (ECM) microenvironment is needed.

In this chapter, we first introduce the fundamentals of micromechanical interactions between cells and biomaterials. Since different mechanical stimuli sensed by cells may trigger common intracellular signaling pathways, we emphasize mechanotransduction, the process by which mechanical signals are sensed and then transduced into changes in cellular biochemistry and gene expression (Ingber, 2006; Vogel and Sheetz, 2006). We then discuss the response of cells to various micromechanical features and how multiple stimuli interact to influence cell and tissue development in complex mechanical environments. Finally, we explore how our growing knowledge of micromechanical control of cell function and biomaterials science can be integrated to develop future biomaterials in order to best promote orderly tissue growth and restore normal function.

Cell–Matrix Interactions and Mechanotransduction

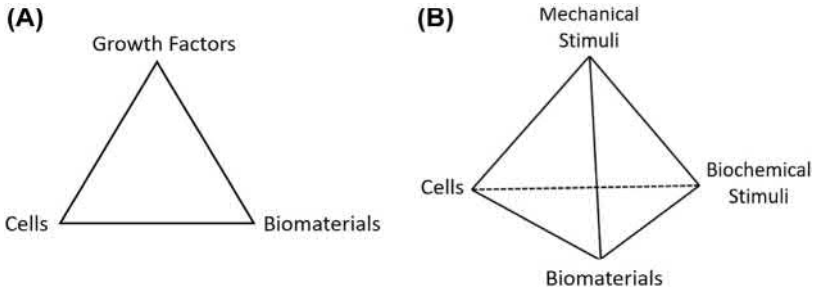
Cells sense and respond to micromechanical stimuli via a series of intracellular molecular processes collectively referred to as mechanotransduction (Fig. 2.6.4.2) (Martino et al.,

2018). Critical micromechanical stimuli in tissue scaffolds, including matrix stiffness and topography, and applied loads and deformations, are transmitted into the cells through transmembrane receptors. Here we focus on the role of focal adhesions, since they are the primary sites where cells bind to biomaterials, and are involved in the majority of cell–ECM micromechanical interactions (Ohashi et al., 2017).

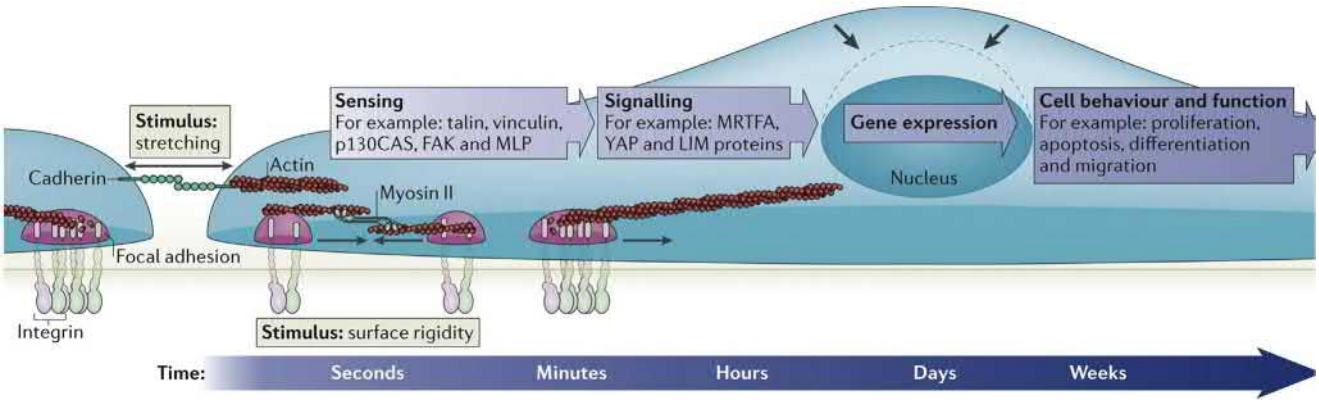
Focal Adhesion

Focal adhesions are large transmembrane protein complexes which physically connect the extracellular matrix to the cytoskeleton. They are composed of a transmembrane layer of integrins and intracellular layers of proteins that bind to cytoskeletal fibers, transduce forces, and trigger molecular pathways (Dupont, 2016). Integrins consist of α and β subunits, which unfold and separate when activated. The diversity of integrins may have profound influence on cell behavior, thus particular cell behavior can be manipulated by inducing a specific integrin subunit combination. For example, interaction between $\alpha_5\beta_1$-fibronectin bindings results in intracellular actin reorganization in mesenchymal stem cells (MSCs) and induces specific changes in shape and chondrocyte differentiation (Hao et al., 2015; Martino et al., 2018). In addition, integrin-binding molecules such as RGD tripeptide are widely used to enhance cell attachment on otherwise nonadhesive surfaces of biomaterials. More information about the use of surface-immobilized biomolecules to guide cell response is provided in Chapter 1.4.4.

The activation of integrins results from both external mechanical signals and internally generated forces, triggering outside-in and inside-out signaling, respectively (Seetharaman and Etienne Manneville, 2018). Signals sensed outside-in or inside-out may induce similar integrin activation and molecular pathways (Fig. 2.6.4.3), therefore it is important to consider the interplay between various micromechanical stimuli when designing biomaterials for tissue-engineering applications. In inside-out signaling, cells probe their surroundings by actively pulling on the extracellular matrix or scaffold via focal adhesions utilizing their cytoskeletal acto-myosin machinery (Gauthier et al., 2011; Ghassemi et al., 2012; Giannone et al., 2004). Depending upon the resistance of their surroundings when cells generate forces, integrins are activated or deactivated, stress fibers are reinforced or disassembled, and downstream effects such as changes in cell migration and differentiation are induced (Iskratsch et al., 2014). For instance, on soft substrates, cell shape will be more rounded with a low density of stress fibers, while stiffer substrates have increased cell spreading and stress fiber density. The differentiation of neurons from

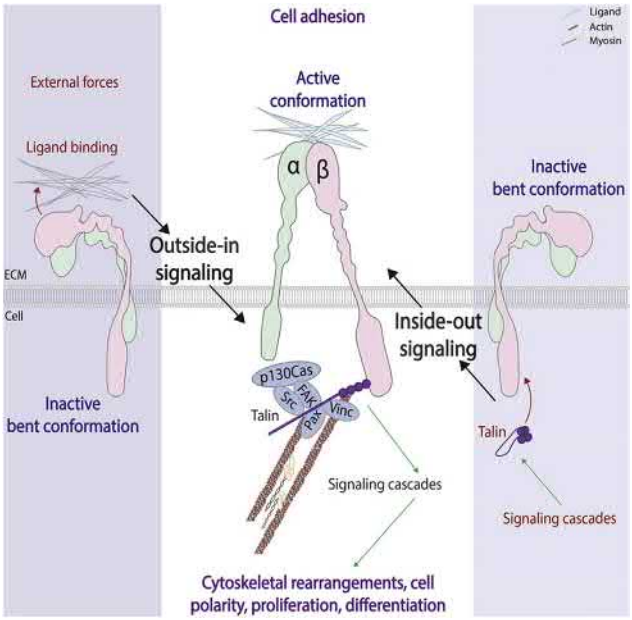


• **Figure 2.6.4.1** (A) The classic tissue-engineering triad viewing biomaterial scaffolds as bulk mechanical support for cells. (B) Updated tissue-engineering tetrahedron demonstrating more complex interplay between cells, media, materials, and mechanics. In particular, local micromechanical cues at the cell level significantly influence cell behaviors and tissue formation.



• **Figure 2.6.4.2** Schematic of cellular mechanical signaling at focal adhesions (integrins) and cell–cell contact (cadherins). Transmembrane protein complexes transduce external mechanical stimuli and transfer the signal via molecular signaling pathways to the nucleus and/or transfer forces through the cytoskeleton directly to the nucleus. The biochemical signals and nuclear deformation influence gene expression and thus cellular function. The timescale of these behavioral changes can range from milliseconds (stretching of mechanosensors) to weeks (tissue development) (Iskratsch et al., 2014).

MSCs requires a soft substrate (<5 kPa), resembling the pliability of brain tissue, whereas osteoblasts differentiate on stiffer substrates (>20 kPa), which resembles that of bone (Engler et al., 2006). In outside-in signaling, integrins are activated by external forces or stretching applied on their extracellular domains, with or without cellular myosin contractile force generation (Discher et al., 2005). Similar to inside-out signaling, integrin activation involves conformational changes to uncover scaffold binding sites and also creates new cytoskeletal binding sites for activator and adapter proteins such as talin and vinculin. Therefore, externally applied stretch may provide a similar mechanical input to cells as culturing them on a material. For instance, valvular interstitial cells (VICs) cultured on low-modulus gels that are cyclically stretched exhibit a large, spread morphology similar to those cultured statically on stiff gels (Fig. 2.6.4.4) (Quinlan et al., 2011).

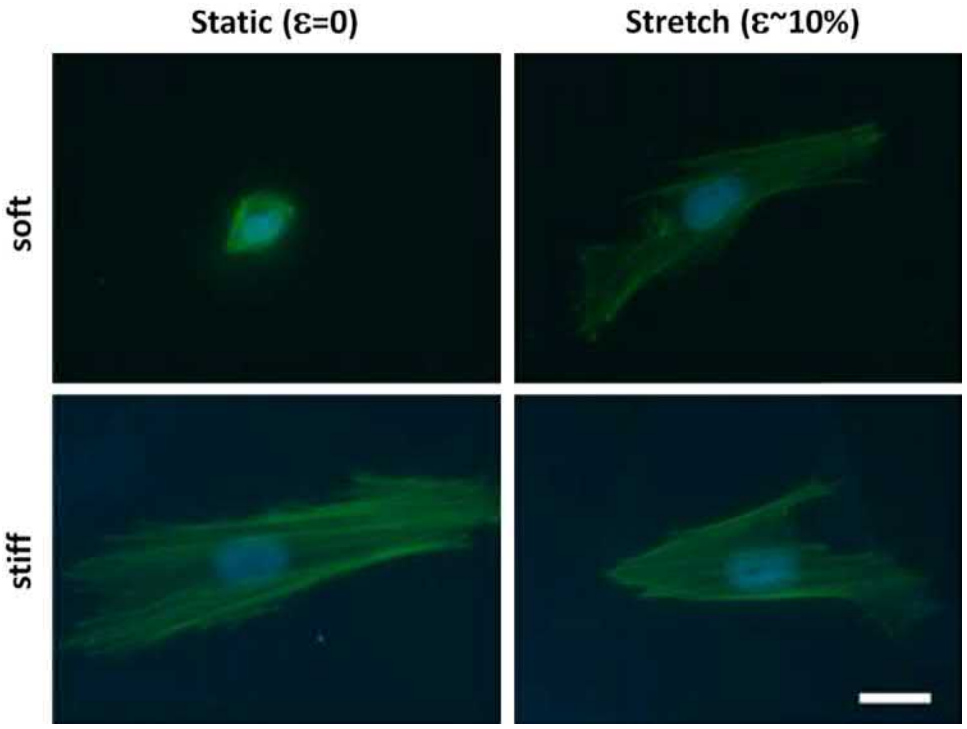


• **Figure 2.6.4.3** Activation of integrins. Subunits unfolding and separation may be induced by either externally applied forces or internally generated forces (Aiyelabegan, 2017).

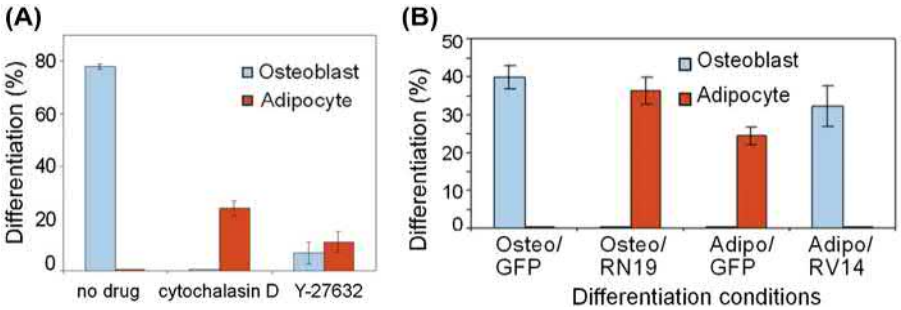
Roles of Focal Adhesion Maturation and Stress Fiber Formation in Mechanotransduction

Small nascent focal adhesions with less activated integrins can be stabilized to form larger, mature adhesions featuring a multilayered protein structure. Different degrees of protein clustering and focal adhesion maturation are determined by the spacing and availability of ECM adhesion sites. This sensitivity to focal adhesion (FA) spacing enables control of cell behaviors through arrangement of micro/nanomechanical characteristics in biomaterial design (Bachir et al., 2017; Ohashi et al., 2017; Sun et al., 2016). Chapter 1.4.5 provides more information about surface patterning techniques for guiding cell behavior.

Focal adhesions and stress fibers cooperate and stabilize each other in a mutual reinforcing loop. Stress fibers are



• **Figure 2.6.4.4** VICs stained for F-actin (green) and Hoechst (blue) cultured on low-modulus (top; "soft" 0.3 kPa) and high-modulus (bottom; "stiff" 50 kPa) gels under static (left) and cyclically stretched (right) conditions. After 6 h of 1-Hz cyclic stretch, cells on soft gels were able to elongate and spread out. Scale bar = 20 μm (Quinlan et al., 2011).



• **Figure 2.6.4.5** (A) Disruption of the cytoskeleton via cytochalasin D and inhibition of RhoA via Y-27,632 causes hMSCs to differentiate into adipocytes instead of osteoblasts. (B) Dominant negative RhoA (RhoA-N19) causes hMSCs in osteoblast differentiation media to form into adipocytes, while constitutively active RhoA (RhoA-V14) causes cells to differentiate into osteoblasts while in adipocyte differentiation media (McBeath et al., 2004).

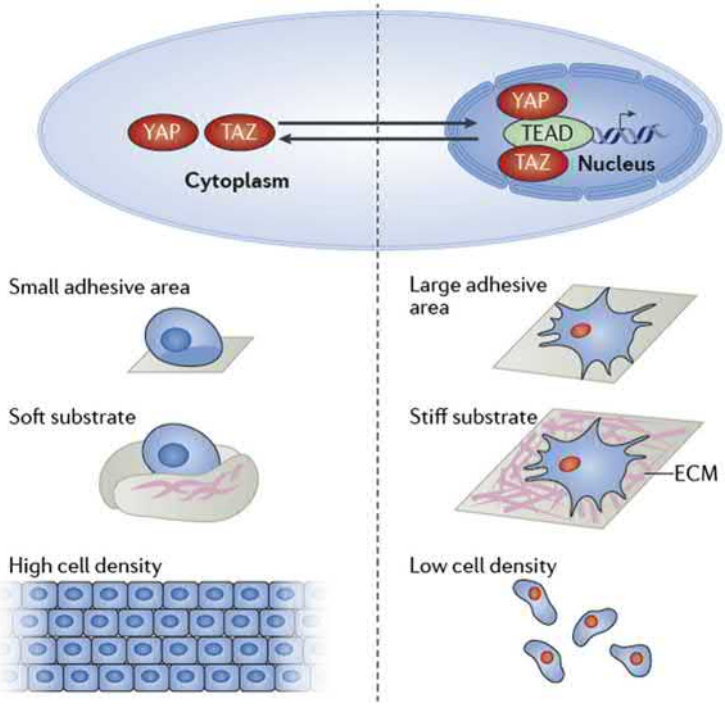
composed of actin filaments (F-actin) and nonmuscle myosin II, an ATP-driven motor protein. Stress fibers can generate contractile forces and pull on focal adhesions (Chen et al., 2010; Fabry et al., 2011). If the sensed external stimulus is strong enough, conformational unfolding of mechanosensitive molecules in focal adhesions can result in the exposure of binding sites that promote recruitment of myosin and stabilization of stress fibers. Contractile forces developed by stress fibers in turn stabilize and allow the maturation of focal adhesions to an increased size (Aiyelabegan and Esmaeil, 2017). Accordingly, focal adhesion maturation and stress fiber contraction are negatively affected when the mechanical stimulus is weak, e.g., when cells are seeded on soft scaffolds or the binding sites for focal adhesions are restricted (Dupont et al., 2011; Dupont, 2016; Martino et al., 2018). Focal adhesion maturation and stress fiber contraction also result in cell biophysical changes, such as cell spreading, elongation, increased cell prestress, and a reduction in the amount of globular actin (G-actin), as the free actin is polymerized into F-actin in stress fibers. These changes are associated with a variety of cell behaviors including cell division, proliferation, apoptosis, migration, and differentiation (Discher et al., 2005; O'Connor and Gomez, 2013).

Important Mechanotransduction Molecular Pathways for Design of Scaffolds

Numerous signaling pathways and mechanotransducers are involved in cell sensing and responding to mechanical stimuli applied at focal adhesions (Martino et al., 2018). While the underlying mechanisms are still an active area of investigation, attempts to design novel biomaterials capable of guiding cells' behavior by controlling the signaling pathways have shown great potential for tissue-engineering applications (Brusatin et al., 2019). Here, we introduce a few key signaling regulators of cell proliferation, differentiation, and other cell processes critical for modulating tissue repair and regeneration, which can be considered in the design of future biomaterials.

The Rho family of guanosine triphosphatases (GTPases) consists of small molecules that coordinate cytoskeletal reorganization. RhoA promotes myosin activity through the activation of Rho-associated protein kinase (ROCK) (Bardi et al., 2003). Activated by diverse biomechanical signals, RhoA/ROCK and downstream molecules lead to the interaction of myosin motors with F-actin, which is related to focal adhesion assembly, maturation, stress fiber formation, and contractile force generation (Davidson et al., 2010; Kovács et al., 2003). Human pluripotent stem cell-derived cardiomyocytes cultured on low-modulus, 4-kPa hydrogels lack activation of the RhoA/ROCK pathway and fail to form mature sarcomeres. In contrast, myofibril alignment to the cell long-axis is clearly observed in cells cultured on stiff substrates (16-kPa hydrogels and glass) in which activation of the RhoA/ROCK pathway occurs. Further, ROCK inhibition impairs sarcomeric alignment in these cells (Martewicz et al., 2017). Similarly, RhoA/ROCK activation elicited by culture of MSCs on stiff substrates generates myosin contractility, which generally results in increased osteogenic differentiation (Ambriz et al., 2018), whereas culturing on low-modulus substrates can inactivate RhoA/ROCK and induce differentiation into adipocytes. Inhibition of cellular tension with cytochalasin D, ROCK inhibitor Y-27,632, or by expression of a dominant-negative RhoA promotes adipogenesis on stiff (typically osteogenic) conditions, and overexpression of constitutively active ROCK restores osteogenic fate on soft (typically adipogenic) conditions (Fig. 2.6.4.5) (Engler et al., 2006; McBeath et al., 2004; Sun et al., 2016).

Yes-associated protein (YAP) and transcriptional coactivator PDZ-binding motif (TAZ) are mechanosensitive transcriptional coregulators of proliferation, differentiation, and survival. As such, YAP/TAZ play important roles in controlling organ growth, stem cell self-renewal, and cell differentiation. YAP/TAZ are activated by stabilization of F-actin and high levels of cytoskeletal tension coordinated by RhoA/ROCK (Galli et al., 2015; Stein et al., 2015). Therefore, YAP/TAZ are affected by very diverse biomechanical signals such as local stress, geometries of individual cells and whole tissues, and stiffness and topology of the ECM substrate (Fig. 2.6.4.6) (Aragona et al., 2013; Dupont et al., 2011). YAP/TAZ shuttle between the cytoplasm and nucleus and interact with DNA-binding transcription factors which contribute to the regulation of gene expression when accumulating in the nucleus. YAP/TAZ are localized in the cytoplasm in cells experiencing low levels of mechanical signaling, such as rounded cells attached to a soft ECM



• **Figure 2.6.4.6** Schematics of different mechanical stimuli (geometry, matrix, density) effects on YAP/TAZ nuclear localization and activity. YAP and TAZ are activated and localized to the nucleus under higher stress conditions (right panels), and are deactivated and localized in the cytosol when under low-stress conditions (left panels) (Panciera et al., 2017).

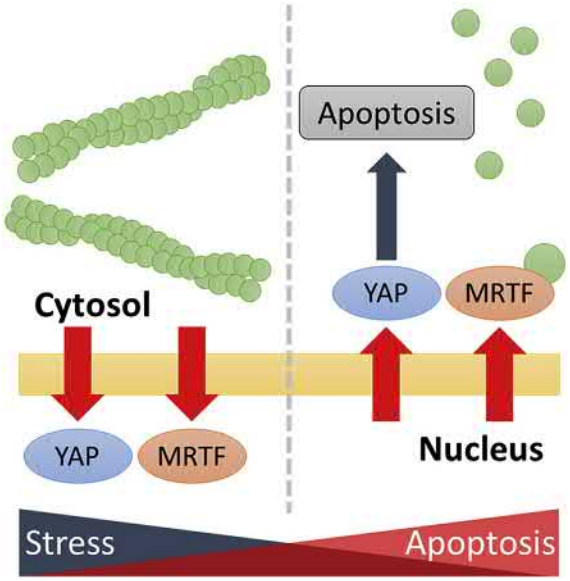
or to a small adhesive area that restricts their spreading (Hao et al., 2014). Conversely, YAP/TAZ are localized to the nucleus in cells perceiving high mechanical signaling, such as cells cultured on rigid substrates or experiencing deformation and cytoskeletal tension (Totaro et al., 2017). When YAP/TAZ is knocked down, cells grown on a stiff matrix exhibit a phenotype similar to that of cells grown on a soft matrix. On the other hand, with overexpression of YAP/TAZ, cells grown on a soft matrix behave as if they are on a stiff matrix (Galli et al., 2015). For tissue engineering applications, scaffolds could be designed to modulate YAP/TAZ activation, e.g., by allowing cell spreading or generation of high intracellular tension to induce cell proliferation when cell growth is desired, or to restrict cell spreading and trigger apoptosis when cell growth is undesirable (Liu et al., 2016; Morikawa et al., 2015; Xin et al., 2013).

Myocardin-related transcription factor A (MRTF-A) is another mechanosensitive transcriptional regulator that coordinates cell growth, organ development, and wound healing (Yu-Wai-Man et al., 2017). Similar to YAP/TAZ, MRTF-A is mediated by Rho signaling and polymerization of F-actin (Sun et al., 2016). MRTF-A is deactivated and localized to the cytosol when bound to G-actin. When mechanical force-induced actin polymerization reduces the cellular concentration of G-actin, MRTF-A dissociates from G-actin and translocates into the nucleus, resulting in stimulation of the transcription factor and serum response factor, which promotes myogenic differentiation and cytoskeletal reorganization. Notably, MRTF-A regulates the transcription of alpha smooth muscle actin (α-SMA), a key marker of the activated myofibroblast phenotype responsible for contractile force generation and enhanced ECM protein secretion (Hautmann et al., 1999; O'Connor and Gomez, 2013; Miralles et al., 2003). MRTF-A localizes to the nucleus in cells that are permitted to spread and have higher cytoskeletal tension (Hautmann et al., 1999). Pharmacological inhibition of cytoskeletal tension or MRTF-A signaling blocks the phenotype transfer to myofibroblasts in spread cells (O'Connor and Gomez, 2013). Increased cell stress can also be applied externally by cyclic stretch leading to cell proliferation, apoptosis, and differentiation markers, even for cells cultured on soft substrates; this response can be mediated by MRTF-A and YAP (Dutta et al., 2018; Cui et al., 2015). The mechanisms of micromechanical activation of molecular pathways are very complicated and highly interrelated. We present a unifying hypothesis relating cell stress, F/G-actin, nuclear localization of YAP and MRTF-A, and apoptosis (Fig. 2.6.4.7).

Direct Transmission of Forces to the Nucleus

While the majority of research on the mechanisms of mechanotransduction concentrates on identifying mechanotransducers at the cell membrane and the downstream biochemical pathways, recent studies demonstrate that forces transmitted directly to the nucleus or other organelles via the cytoskeleton also play a role in mechanotransduction (Driscoll et al., 2015). The nucleoskeleton is connected to cytoplasmic F-actin structures through nuclear lamina, a network of lamin and lamin-binding proteins underlying the inner nuclear envelope. Since peripheral DNA and chromatin are anchored to the nuclear lamina, mechanical signals can be transduced from the cell surface into the nucleus, modulating nuclear structure and gene

transcription. Stretching the nuclear envelope also increases in-plane membrane tension and loosens lipid packing, which promotes hydrophobic protein–lipid interactions (Enyedi and Niethammer, 2017). Neelam et al. showed that the application of mechanical forces on integrin receptors at the cell membrane is followed shortly after by nuclear structural reorganization and deformation in the direction of the pulling force and then chromatin reorganization (Booth-Gauthier et al., 2012; Dickinson et al., 2015). In addition, actin fibers are physically connected to the microtubule network, which is involved in crucial biological processes, such as intracellular trafficking, mitotic spindle formation, and cell polarity (Fletcher and Mullins, 2010). When being stretched, dividing cells display an alignment of the mitotic spindle parallel to the applied force, with a polarization of dynamic subcortical actin structures that correlate with spindle movements (Fink et al., 2011).



• **Figure 2.6.4.7** Schematic of stress effects on YAP and MRTF-A pathways in the cell. Polymerization of F-actin from G-actin (*green circles*) promotes YAP and MRTF nuclear localization and cell proliferation in response to high cell stress (left), while G-actin promotes nuclear exclusion of YAP and cell apoptosis in response to low cell stress (right).

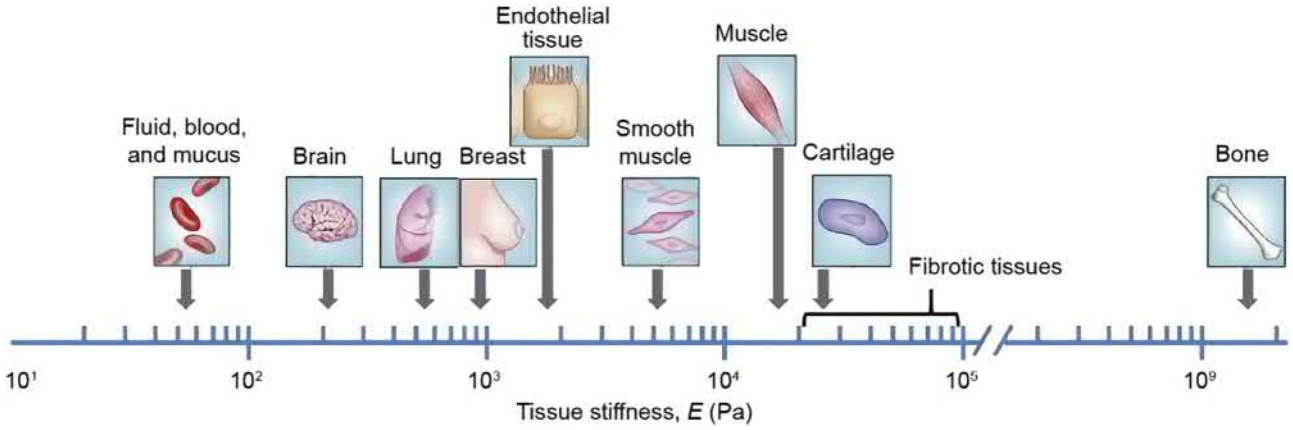
Aforementioned knowledge regarding cells–ECM interaction and mechanotransduction enables directing cell behaviors and tissue growth via tuning the microstructure and local properties of scaffolds. Although the native mechanical environment and features of scaffolds that influence their performance are very complicated, when designing biomaterials it is paramount to consider their ability to induce mature focal adhesions, cytoskeleton remodeling, and contractile force generation. For verification, signaling regulating proteins such as RhoA/ROCK, YAP/TAZ, and MRTF-A could be tracked as indicators of cell functions when investigating the performance of designed biomaterials.

Design Considerations for Scaffolds to Regulate Tissue Development

There are multiple mechanical cues, including local stiffness and topography, which biomaterial designers can alter to modulate cell response. Further, fiber diameter, alignment, and porosity are additional parameters that can be modulated to guide cell behavior for fibrous scaffolds. For tissues mainly composed of cells with minimal ECM, e.g., muscle and epithelium, the effects of cell–cell contact and transmission of forces also need to be considered. In addition, newly formed engineered tissues may be conditioned in bioreactors to promote tissue growth, thus outside-in signaling due to external forces and stretch provides an additional design parameter. In this section, we discuss each of these mechanical design parameters individually and highlight interactions between the mechanical cues.

Local Stiffness

Stiffness describes the resistance offered by an elastic body to deformation in response to an applied force. It depends on the elastic modulus (a material property) and geometry of the scaffold (a structural property). The bulk elastic modulus determines the overall mechanical deformation of a scaffold under an applied loading. At the cell level, local modulus is a powerful cue that directs cell attachment, growth,



• **Figure 2.6.4.8** Stiffness of various human tissues in the body. The levels of stiffness change the mechanical properties of the cells (Yang et al., 2017).

migration, and differentiation. The elastic modulus of native tissues ranges from 10^2 to 10^{10} Pa (Fig. 2.6.4.8). Generally, the designed scaffold stiffness of a particular tissue should be comparable to the native tissue, since a stiffness mismatch may induce undesirable cell behavior or differentiation. For example, a hallmark study by Engler and colleagues demonstrated that matrix modulus directs MSC fate, with low- (0.1–1 kPa), medium- (8–17 kPa), and high- (25–40 kPa) modulus collagen-coated polyacrylamide substrates favoring neurogenic, myogenic, or osteogenic differentiation, respectively (Yang et al., 2017). Quinlin et al. revealed that culture of fibroblastic cells on collagen-coated polyacrylamide substrates of increasing moduli results in more pronounced expression of αSMA-positive stress fibers, indicating a graded phenotypic change from fibroblast to myofibroblast phenotype with an increase in local stiffness (Fig. 2.6.4.9) (Quinlan and Billiar, 2012; Rudnicki et al., 2013).

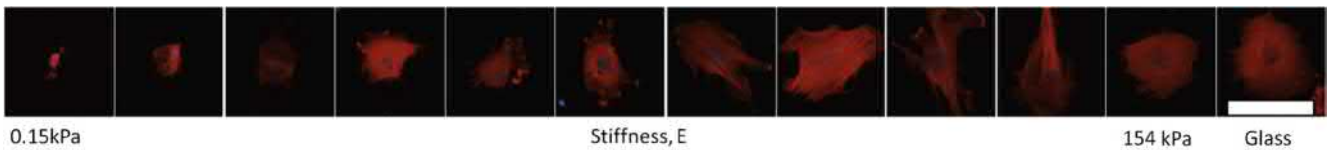
In addition, tissue growth can be guided on a scaffold to mimic the healing process of damaged tissues which involves increasing stiffness of the surrounding ECM. This local stiffening may lead to enhanced migration, proliferation, and/or progenitor-like properties. A large number of in vitro studies have confirmed that with an increase in substrate stiffness, various types of cells, including endothelial cells, airway smooth muscle cells, and dermal fibroblasts, exhibit enhanced cell adhesion, enlarged cell spreading with defined actin organization, increased cellular contractility, decreased migration speed, and enhanced proliferation (Hao et al., 2015; Razinia et al., 2017; Reilly and Engler, 2010; Shkumatov et al., 2015; Yeh et al., 2012; Yim and Sheetz, 2012).

With advanced techniques, not just the magnitude but also the local patterns of stiffness can be manipulated to allow the design of specific conditions that direct cell organization, alignment, and migration (Marklein and Burdick, 2009; Ambriz et al., 2018; Yang et al., 2017). Sochol and colleagues investigated endothelial cells cultured on microposts with a gradient of stiffness magnitudes, and found they preferentially migrate toward stiffer microposts, with a migration speed proportional to the gradient strength (Sochol et al., 2011). Lin and colleagues cultured muscle cells on a surface with alternating soft and stiff strips of hydrogel structures and showed that cells preferentially attach to stiff regions when the strip width is narrow and comparable to cell size (~100 μm), while cells randomly orient and spread for larger strip widths (~200 μm) (Yin et al., 2018) (Fig. 2.6.4.10). Anseth's group developed substrates with different elastic moduli and organized/disorganized stiffness patterns on an even smaller, subcellular scale. Similar to valvular interstitial cell activation to the myofibroblast phenotype on high-modulus substrates, they showed that MSCs cultured on substrates with a higher percentage of stiff regions are also activated. Moreover, MSCs cultured on substrates with a spatially disorganized pattern are less activated, have smaller focal adhesions, less α-SMA organization into stress fibers, and higher proliferation compared to those cultured on substrates with an organized pattern (Yang et al., 2016; Ma et al., 2017).

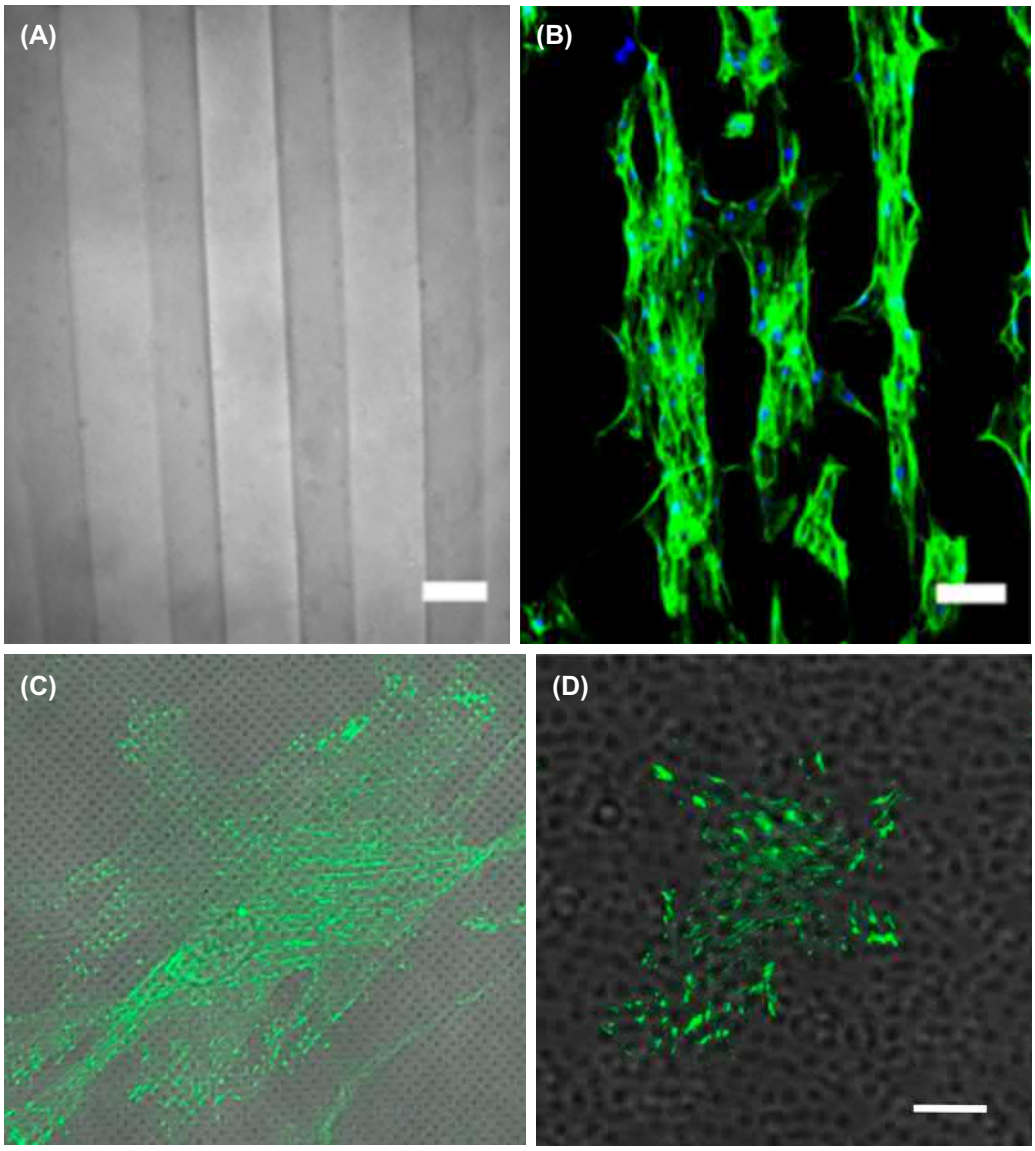
Surface Topography

It is virtually impossible to duplicate the complicated tissue-specific and multiscale topography of native tissues, yet specific micro- and nano-patterned designs are emerging as powerful tools to control cell behavior on engineered scaffolds. There are multiple parameters of surface topography that can be controlled including shape, dimension (feature size, spacing, and height), and periodicity. Each parameter has profound influence on cell behavior from cell adhesion and spreading to proliferation and differentiation (Nguyen et al., 2016). Chen and colleagues were among the first to demonstrate that local geometry is a fundamental mechanism that regulates cell response. By precisely controlling cell spreading while maintaining constant contact area, they demonstrated that proliferation and apoptosis are regulated by spread area rather than adhesion area (Liu et al., 2017).

It has also been demonstrated that cells can distinguish between micro- and nano-scale features. For instance, when MSCs are cultured on gratings of different width, they align and elongate along the grating axis, and show smaller and more elongated focal adhesions on nanogratings (250 nm width) compared to microgratings (10 μm width) or unpatterned surfaces (Yim et al., 2007). The size of surface patterns can also affect cell differentiation, as seen, adipogenic differentiation increases when MSCs are cultured on microgratings with 15-μm ridges, compared to 2-μm ridges that is enhanced osteogenic differentiation. The narrower ridges result in higher aspect ratio of cell shape and higher tension in the cytoskeleton (Abagnale et al., 2015). Cells can also sense gradients in topography. When fibroblasts are plated on grooves, cells migrate along the pattern orientation initially; however, within 2 h, cells show trends of migration toward areas with denser grooves (Kim et al., 2009). In addition, increased space between cell membrane protein-binding sites or random distribution of the binding sites result in compromised cell survival, migration, and



• **Figure 2.6.4.9** Substrate stiffness affects spreading and morphology of fibroblastic cells. Cells cultured on polyacrylamide gels ranging four orders of magnitude in modulus (150 Pa–150 kPa) plus glass exhibit increasing spread area and stress fibers with increasing stiffness. Cells were stained for α-SMA (red) and nuclei (blue). Scale bar is 100 μm (Quinlan and Billiar, 2012b).



• **Figure 2.6.4.10** (A) Bright-field image of alternating soft (dark; ~5 kPa) and stiff (light; ~11 kPa) 2D stripe pattern. Scale bar = 100 μm. (B) Cells on stiffness-pattern substrate preferentially adhere and align on stiffer regions (Yin et al., 2018). Immunostaining of paxillin in MSCs on regularly (C) or randomized (D) patterned hydrogel with 75% stiff area. Scale bar = 30 μm (Yang et al., 2016).

differentiation capacity, since integrin clustering is abolished and cell adhesion weakened (Comisar et al., 2011; Park et al., 2007; Yang et al., 2016).

Fibrous Scaffolds

The native tissue matrix is conducive for cell communication, migration, and function, and researchers aim to mimic this environment in scaffolds (Carey et al., 2012; Paszek et al., 2005; Pupa et al., 2002; Stevens and George, 2005). In native ECM, cells attach to fibrous proteins including fibronectin, collagen, fibrin, and elastin. Cells can grab and pull on these fibers to change their shape or position. Fiber density, stiffness, alignment, and composition are all factors that can affect cell behavior, structure, and even stiffness (Hadjipanayi et al., 2009; Lu et al., 2012). For instance, cells cultured on stiffer fibrous materials, such as nanotubes, can exhibit enhanced adhesion, spreading, and higher cytoskeletal tension (Aghvami et al., 2016). Mechanically, longer fibers have high axial stiffness but buckle easily, having overall low compressive stiffness. Long-range forces are transmitted through the fibers and can be affected by fiber length, entanglement, and cross-linking level, which can then influence neighboring cells (Ma et al., 2013). We, and others, have demonstrated that cells can sense much further in fibrous scaffolds compared to two-dimensional continuum materials (e.g., polyethylene glycol or polyacrylamide gels) (Ma et al., 2013; Rudnicki et al., 2013). In addition, fibrous biomaterials have nonlinear mechanical properties in that they stiffen under increased stretch. External or cell-generated stretch can also alter alignment of the fibers, thus biomaterial designers need to consider these complicated interactions between cells and fibrous scaffolds (Hall et al., 2016).

Multicellular Interactions

In multicellular systems, cells interact with both their extracellular environment as well as neighboring cells. Cell–cell contact allows direct connections via adherens junctions and transfer of mechanical stimuli through transmembrane proteins including cadherins. It is becoming increasingly clear that focal adhesions and adherens junctions share signaling molecules including MRTF and YAP/TAZ proteins (Mui et al., 2016). Coordinated interplay between integrins and cadherins also leads to a spatial distribution of molecular signals and forces, which guide diverse cell behaviors (Cirka et al., 2017; He et al., 2015; Li et al., 2009). Mooney and colleagues have shown that for MSC differentiation, higher stiffness alone can promote expression of early protein markers of osteogenesis, yet multicellular aggregation is necessary for mature osteogenesis with calcium deposition (Mao et al., 2016). Additionally, we have demonstrated that cells near the edges of 2D cell clusters have higher generated traction forces, increased stiffness, increased proliferation rate, and gene localization of mechanosensitive proteins compared to central cells (Cirka et al., 2017). Similarly, when cultured on confined protein islands, MSCs differentiate into an osteogenic phenotype at edges and adipogenic differentiation occurs in the central region (Nelson et al., 2005; Ruiz and Chen, 2008). As revealed in these studies, cell–cell contact has profound effects on altering the mechanical environment of engineered cell clusters. Accordingly, it can influence cell–scaffold interactions in engineered tissues.

Moreover, within a tissue-engineered scaffold, cells communicate with one another through chemical means. Nearby cells can sense biomolecules that are released from neighboring cells via paracrine signaling in addition to physical forces that are transduced through a fibrous scaffold. Both types of signals can cause changes in cell behavior that would not occur if the cells were isolated. Studies show that coculturing cells help better mimic the in vivo environment by regulating cellular function, behavior, development, and creating native niche conditions (Bogdanowicz and Lu, 2016; Wu et al., 2010).

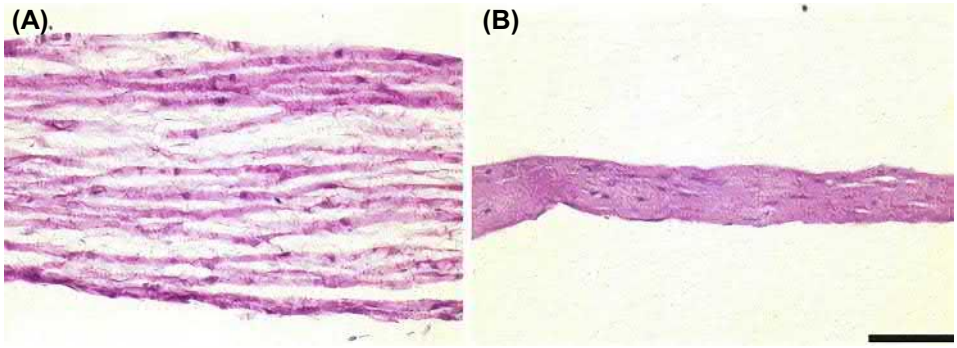
Mechanical Stimulation

Once placed in the body, scaffolds and the cells within are subjected to complex mechanical forces and deformations. The effects of shear stress induced by flow are discussed in Chapter 2.1.6; here, we focus on the response of cells and tissues to cyclic stretch. Cyclic stretch has pronounced effects on cell–biomaterial interactions, and mechanical conditioning can be employed to improve the strength and stiffness of a construct. Cyclic stretch regimens have been used to induce increased production and maturation of collagen in engineered arteries, heart valves, ligaments, and skeletal muscle (Schmidt et al., 2016). A quantitative understanding of the effects of mechanical conditioning is necessary for designing tissue scaffolds functioning in vivo.

Cyclic stretch promotes stress fiber formation and F-action realignment in cells, which can generate specific changes in cellular shape, spreading, adhesion patterns, and differentiation. Typically parameters near physiological conditions (0.5–2 Hz, 2%–20% strain) are employed and the frequency, magnitude, duration, and direction of stretch are all important factors that translate into focal adhesion maturation and downstream signaling (Li et al., 2014). Regardless of cell type, cells cultured on compliant (but stiff) 2D substrates subjected to uniaxial, cyclic stretch generally show stretch-avoidance behavior, i.e., cells align perpendicular to the direction of principal cyclic strain (Li et al., 2014). In contrast, we have shown that cells cultured on low-stiffness substrates spread and orient at an intermediate angle (not completely perpendicular to stretch) (Cirka et al., 2015). Reorientation of cells cultured in 3D constructs is even more complicated, since ECM fibers in the fibrous scaffolds also provide strong contact guidance for cells (Lei and Ferdous, 2016). For example, stretching 3D tissues after reconstituted ECM fibers are well aligned due to cell contraction and boundary conditions does not induce cell realignment; whereas stretching immediately after casting the gel (without time for fiber alignment) results in a strong stretch-avoidance response and reorientation (Foolen et al., 2012; Li et al., 2014; Schmidt et al., 2016). The degree of stretch anisotropy is also an important parameter. Increasing anisotropy with biaxial strain results in increased cellular orientation and collagen fiber alignment along the principal directions of strain for VICs cultured in collagen gels (Gould et al., 2012).

Computational models and experimental observation have indicated that cells do not respond to stretch below a threshold frequency of 0.01 Hz (Tondon and Kaunas, 2014; Schmidt et al., 2016). Rahimi et al. reported that vascular smooth muscle cells were efficiently aligned by cyclic stretch at 1.25 Hz under short-term stimulation (12 h), while they oriented more uniformly under lower frequency (0.5 Hz) under long-term stimulation (24 h) (Li et al., 2014). Stretch amplitudes also play a considerable role in cell orientation. For instance, a 10%–24% (1 Hz) graded stretch resulted in graded vascular smooth muscle cell alignment ranging from a completely random orientation to a maximum alignment perpendicular to the stretch vector (Kakisis et al., 2004).

Compared to engineered tissues cultured under static conditions, engineered tissues conditioned under cyclic stretch generally have significantly increased viability of cells and ECM protein secretion, reduced volume, elevated matrix metalloproteinase activity, and mechanical properties more similar to native tissues (Lei et al., 2017; Seliktar et al., 2003). For collagen-based blood vessels, heart valves, cartilage, and ligaments, cyclic stretch has shown increased strength and stiffness compared to static controls (McMahon et al., 2008; Kensah et al., 2011). We have demonstrated that, when cyclic equibiaxial stretch (16% stretch at 0.2 Hz) is applied to fibroblast-populated fibrin gels for 8 days, stretched samples are approximately 10 times stronger, eightfold denser, and eight times thinner than statically cultured samples (Fig. 2.6.4.11). These changes are accompanied by a 15% increase in net collagen produced (Balestrini and Billiar, 2006).



• **Figure 2.6.4.11** Brightfield images of hematoxylin and eosin-stained sections of fibrin gels after 8 days in (A) static samples and (B) 16% cyclic stretch at 0.2 Hz for 6 h/day. Stretch induces fibroblasts to compact the gels which results in a denser matrix. Scale bar = 100 μm (Balestrini and Billiar, 2006).

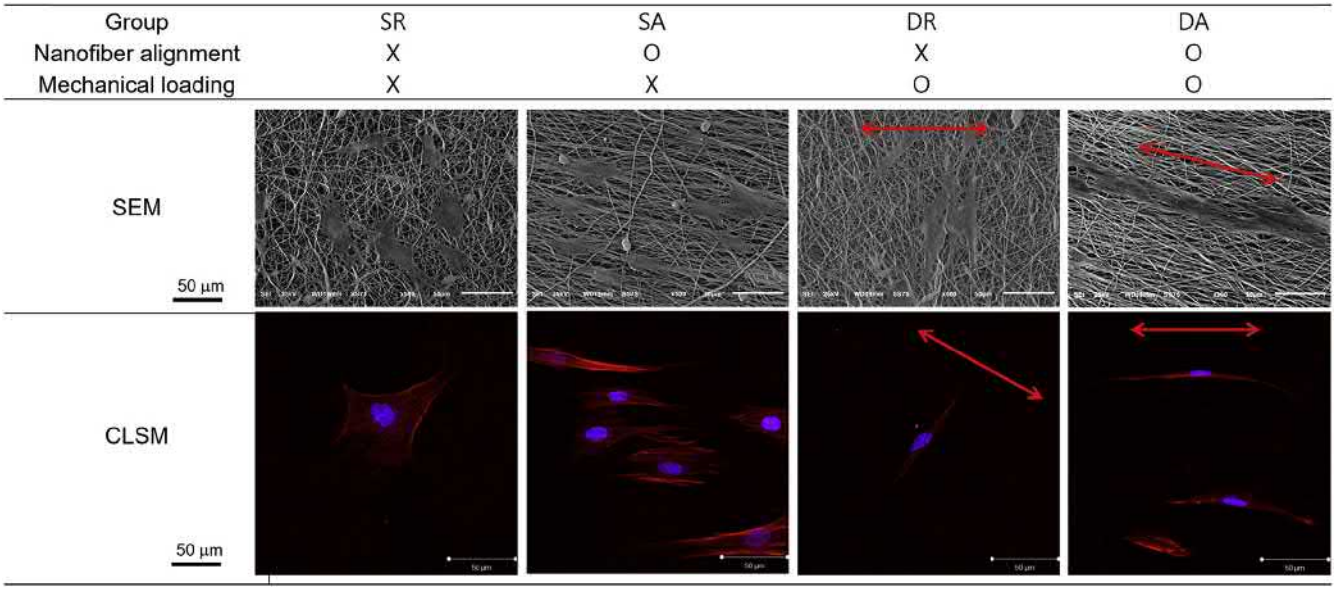
While cyclic stretch can stimulate cells to produce more collagen, this ability is limited by adaptation of the cells to the applied mechanical stimuli when the amplitude of stretch remains constant. In order to circumvent this adaptive effect, various stretching regimens have been employed including incrementally increasing strain amplitude and intermittent stretching (Courtney et al., 2006; Syedain and Tranquillo, 2009). For example, neonatal human dermal fibroblast-seeded fibrin gels were subjected to 2 weeks of constant amplitude (5% or 13.5% amplitude), intermittent (15 min at 5%, 6 h static, repeat), or incremental (5%–13.5% increment by ~1% every 24 h) cyclic stretching regimens. Results show that extracellular signal-regulated kinase (ERK1/2), which is necessary for stretch-induced collagen transcription, is maximal at 15 min and decayed by 1 h in constant-amplitude stretches (Schmidt et al., 2016). A 6 h static period was required before the fibroblasts were able to respond to a second onset of cyclic stretch (Rubbens et al., 2009). While both intermittent and incremental regimens reactivated ERK1/2, only incremental stretching increased collagen production compared to samples stretched with constant amplitude, resulting in a 37% increase in collagen per cell after 2 weeks. In contrast to this study, Paxton et al. found that intermittent stretching (10 min every 6 h) increased the percentage of collagen in their fibrin-based "sinews" approximately 20% over continuously stretched samples (Paxton et al., 2012; Syedain et al., 2011). These findings suggest that a regimen with small, frequent increments in strain amplitude might be optimal for promoting collagen production and tissue development.

Effects of Combined Mechanical Stimuli

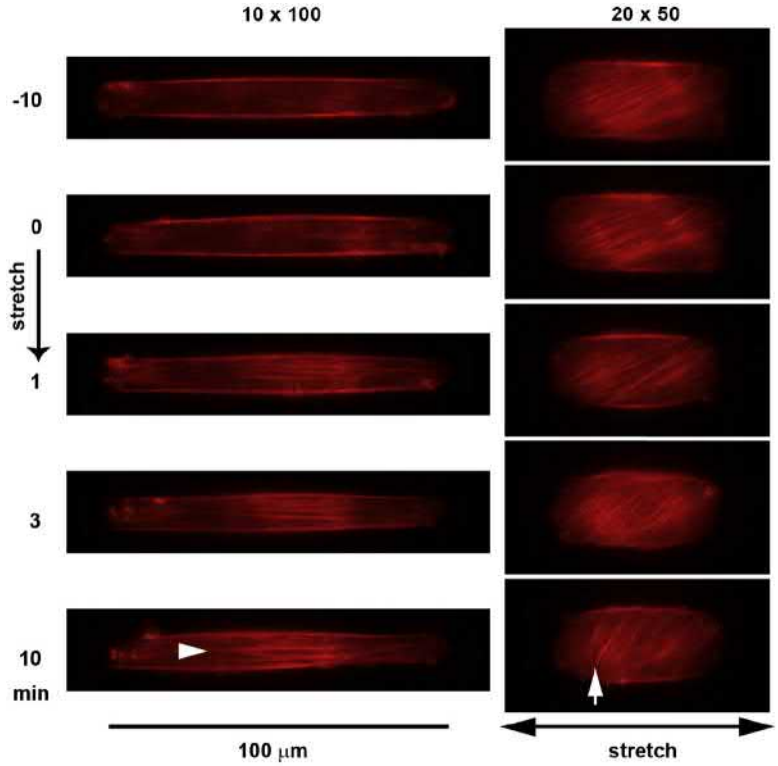
In living organisms, cells reside in a complex environment with multiscale topographic features, spatially heterogeneous mechanical cues, and dynamic stimulation provided by surrounding cells and ECM. Therefore, when designing scaffolds, it is necessary to consider the influence of these interrelated factors on cell behaviors and tissue growth. In a study of combined influence of stiffness and spread area, hepatic stellate cells differentiation into myofibroblasts was observed on large (1 mm diameter) islands with higher stiffness (23.8 ± 4.6 kPa), while they remained quiescent on low-modulus substrates (2.1 ± 0.7 kPa) or on small (50 μm diameter), stiff islands that prevented cell spreading (Guvendiren et al., 2014). For cells, stretch can trigger a marked increase of traction forces and apparent stiffness. Therefore, cells cultured on soft substrates under stretch may behave similarly to those cultured on stiffer substrates (Rosowski et al., 2018). For instance, we cultured fibroblastic cells under a wide range of combined levels of substrate stiffness and dynamic stretch. Substrate stiffness was adjusted from relatively soft (G' = 0.3 kPa) to stiff (G' = 50 kPa). On soft substrates, cells cultured statically exhibited a rounded morphology and were significantly smaller than on stiff substrates. After equibiaxial cyclic stretch, VICs spread similar to cells cultured on stiff substrates (Fig. 2.6.4.4). These results indicate that inhibition of spreading due to a lack of matrix stiffness surrounding a cell may be overcome by externally applied stretch, suggesting similar mechanotransduction mechanisms for sensing stiffness and stretch (Quinlan et al., 2011). Other studies show that MRTF-A or YAP are activated when cells sense cyclic stretch and stiff substrates, and cell internal prestress (stress fiber formation) also plays an important role in the localization of these markers (Cui et al., 2015; Cirka et al., 2015).

Topography strongly influences cell attachment, reorientation, and viability under stretch. Under static conditions, stem cells randomly spread on random nanofibers while cells are aligned on aligned nanofibers. Under uniaxial cyclic stretch conditions, cells on random nanofibers align perpendicular to the loading axis. Interestingly, cells on aligned nanofibers align along the loading axis, which is also parallel to the orientation of the nanofibers (Fig. 2.6.4.12). The cell elongation appears to be more substantial on aligned nanofibers under uniaxial stretch compared to the other conditions (Kim et al., 2016).

Wang et al. built an in vitro muscle model with combined mechanical stretch and geometrical control, and found that myoblasts with higher aspect ratio had higher viability under cyclic stretch. Given the same area, wider cells under stretch had most of their parallel actin filaments broken and disassembled, but had stable perpendicular central actin filaments; this is consistent with the published reports that uniaxial mechanical stretch induces actin filaments to reassemble and align along the perpendicular direction.



• **Figure 2.6.4.12** Top: SEM images show random or aligned orientation of nanofibers. Bottom: Fluorescent images reveal that cells preferentially align along the orientation of aligned fibers. Following cyclic stretch, cells align perpendicular to direction of stretch on random oriented fibers. However, on oriented fibers, cells align parallel to stretch along the direction of the fiber alignment. F-actin (red) and DAPI (blue) were stained and red arrows indicate the direction of stretch (Kim et al., 2016).



• **Figure 2.6.4.13** Stained F-actin (red) shows reassembly of actin fibers over time in response to stretch. In thin, elongated cells (left), F-actin reassembled parallel to the direction of stretch, while in shorter, wider cells (right), F-actin reassembled perpendicular to the direction of stretch (Wang et al., 2014).

Interestingly for thinner cells, there was new parallel F-actin assembly during stretch (Fig. 2.6.4.13). Although this cannot be explained by current experiment models or theories, this evidence might explain why myoblasts are destined to take the elongated geometry in vivo (Wang et al., 2014).

Implications for Future Materials Design

Biomaterials for tissue engineering include complex scaffolds with intricate porous and fibrous structures that resist macroscopic loads and support cell growth and migration

at the local scale. In the future, ideal biomaterials for tissue engineering are expected to provide even more precise control of cell behavior during tissue formation. Here we highlight a few promising directions.

(1) 3D printing devices and inks could achieve sub-μm scale and allow multiple materials to be printed simultaneously, reaching precise control over complex geometry, topography, and even local mechanical properties. For instance, in light-assisted bioprinting techniques, local stiffness of hydrogels can be manipulated by controlling oxygen permeation, inhibition, and ultraviolet exposure dosage, which alter the cross-linking density and stiffness of cured structures. The programmable stiffness spans nearly an order of magnitude (E ~2–15 kPa) within the physiologically relevant range. ECMs with programmed micromechanical environments can dictate 3D cellular organization, enabling in vitro tissue reconstruction. Chapter 1.4.8 provides additional information about additive manufacturing.

(2) The mechanical properties of scaffolds could be tuned in real time, providing higher flexibility in guidance of cell growth. Traditionally, hydrogels are normally degraded without control by hydrolytic or enzymatic mechanisms. For example, Khetan and colleagues reported that for covalently cross-linked hyaluronic acid hydrogels with equivalent stiffness (~4 kPa), enzymatic degradation permitted cell spreading, and favored osteogenic differentiation. In contrast, nondegradable hydrogels restricted cell migration and favored adipogenic differentiation (Marklein and Burdick, 2009). More information about degradation is provided in Chapter 1.3.2F;. More recently, Brown et al. synthesized biocompatible hydrogels that can be degraded via a radical addition-fragmentation chain transfer process, where a single photon initiates multiple events and amplifies the degradation process. The gel formation and photodegradation processes can be controlled in real time to study the cell response to multiple levels of stiffness (Brown et al., 2017). In addition, Yeh et al. developed a two-step cross-linking strategy that can increase the compressive modulus of polydimethylsiloxane up to 10-fold within minutes. With stiffening, cells displayed increased spreading and higher level of fibroblast activation (Yeh et al., 2017). More information about hydrogels is provided in Chapter 1.3.2E.

(3) Nonlinear biomaterials can better mimic properties of native ECM. Covalently cross-linked hydrogels are typically elastic, while native ECM is viscoelastic. Chaudhuri et al. observed increased cell spreading on soft, viscoelastic substrates compared to elastic gels with the same stiffness, and similar to that on stiffer, elastic substrates. MSC spreading, proliferation, and osteogenic differentiation were enhanced in rapidly relaxing hydrogels ($\tau_{1/2} = 70$ s) compared to elastic gels ($\tau_{1/2} = 3300$ s) (Quinlan et al., 2011; Chaudhuri, 2017).

Conclusion

Today, biomaterials are an indispensable tool in our efforts to repair and regenerate injured or diseased tissues and organs. Biomaterials are viewed as more than carriers for cell delivery and growth factors; they are now designed to mechanically interact with cells and promote tissue development as well as to restore function. The mechanical and structural features of developing tissues vary over space and time on the micrometer scale. Thus, biomaterials that allow precise spatiotemporal regulation of adhesive and micromechanical cues will have tremendous regenerative potential as they are designed to more faithfully recapitulate the dynamic cellular microenvironment characteristic of endogenous developmental processes.

HIGHLIGHTS OF THIS CHAPTER

Hierarchical Design

- Micromechanical properties of biomaterials have a profound influence on cell behaviors and tissue formation.
- It is promising to modulate cell–scaffold interactions by designing micro/nano-scaled features of biomaterials.
- Controllable mechanical properties include bulk stiffness, local stiffness, topography, and dynamic conditioning.

Mechanotransduction

- Relatively stiff substrate, large spreading area, and low cell density promote focal adhesion maturation.
- This maturation facilitates migration, proliferation, and differentiation into phenotypes with higher cell tension.
- Signaling proteins such as RhoA/ROCK and YAP/TAZ could be tracked in validation of biomaterial design.

Interplay of Mechanical Cues

- Cells in low-modulus scaffolds under stretch may have behaviors similar to those in stiffer scaffolds.
- Fibrous topography may dominate stretch in guiding cell alignment.
- Cell–cell contact allows force transfer in multicellular systems, resulting in complex distributions of stress dependent upon mechanically constrained shapes/boundaries.

3D Scaffolds

- Cells residing in 3D scaffolds have different behaviors compared to cells cultured on 2D substrates.
- Cells on collagen-coated membranes align perpendicularly to the direction of stretch, whereas those cultured within collagen gels align parallel with the direction of stretch.

Degradation

- Micromechanical cues (bulk and local stiffness, topography) change with degradation of biomaterials, which could direct ECM remodeling with external stimulation.
- Scaffolds need to properly direct extracellular matrix remodeling and cell force generation during neotissue formation.

Introduction

Tendons transmit muscle-generated mechanical forces to bone to enable skeletal movement. These tissues experience some of the highest mechanical loads in the body. When these loads exceed the load-bearing capacity of the tendon, permanent tissue damage occurs, leading to impaired function and mobility. Unfortunately, tendons possess a poor ability to regenerate after injury, leading to a significant medical problem. It is estimated that 77% (65.8 million) of all health care visits are musculoskeletal-related issues (Pollak, 2014). Acute tendon injuries alone have been reported to cost more than $30 billion per year (Chen et al., 2009).

Partial tendon ruptures, in which the gap between ruptured ends is minimal, have the capacity to heal. However, such healing often leads to the formation of fibrotic tissues that are biochemically and structurally abnormal and mechanically dysfunctional. Animal models have demonstrated that the mechanical properties of injured tendons are not recovered even after 12 months of healing (Woo et al., 2006). The poor healing ability of tendon is attributed to its low fibroblast (tenocyte) density and vascularity, which are needed for tissue synthesis and delivery of nutrients, respectively. When tendon ruptures lead to retraction of the tissue ends, surgical repair is commonly employed to either bridge the gap between ends or replace the injured tissue with an autograft or allograft (cadaveric grafts). Unfortunately, autografts are associated with donor site morbidity and pain. Moreover, for both autografts and allografts, their application has yet to achieve the stiffness, ductility, nonlinearity, and viscoelastic responses of native tendon, and failure often ensues. These challenges have led to the pursuit of engineered tendons that can fully restore the tendon tissue to its preinjured state.

An engineered tendon construct would ideally develop over time into a tissue that closely matches the dimensions, mechanical properties, biochemical composition, and microstructure of native tendon. A common approach is to incorporate stem cells into a biodegradable scaffold. This scaffold should have sufficient mechanical properties to support immediate or early return-to-load-bearing function in vivo, demonstrate dimensional stability in an aqueous environment, and degrade at a rate that matches new tissue formation. It should also possess a combination of material and biochemical properties that support cell viability in bulk and degraded forms and provide guidance cues to promote cell functions such as tenogenic differentiation and extracellular matrix (ECM) synthesis and organization. To satisfy these requirements, scaffolds for tendon tissue engineering are typically fabricated from polymers, rather than metals or ceramics. At the time of the writing of this chapter, the field of tendon tissue engineering is still working to design a scaffold that fulfills these multiple requirements to create mechanically and biologically functional tendon. One challenge that the field currently faces is that the physical and biochemical cues that can direct tendon cells toward these functions have not yet been fully elucidated; because this topic is beyond the scope of this chapter, we refer readers to review papers that discuss current approaches to address this need (Glass et al., 2014; Schiele et al., 2013; Nguyen et al., 2018; Huang et al., 2015; Edom-Vovard and Duprez, 2004; Okech and Kuo, 2016; Kuo and Tuan, 2003).

Here, we discuss considerations in designing and fabricating a scaffold that meets multiple requirements such as

supporting immediate or early return to tendon load-bearing function and providing guidance cues to promote tenogenic cell behaviors. Scaffold-specific considerations will be discussed in this chapter, including scaffold biomaterial choices, fabrication methods, and postfabrication modifications (e.g., crosslinking). These considerations individually and in combination have significant effects on scaffold mechanical properties and performance. We first introduce native adult tendon properties and function to provide readers with an understanding of the complexity of tendon tissues. We then discuss specific scaffold design goals, fabrication, and postfabrication methods that can be used with a variety of tendon scaffold biomaterials. We review specific scaffold design strategies that are current in the field, with focus on the most commonly used scaffold biomaterials, and end the chapter with perspectives on how to advance scaffold-based tendon tissue-engineering approaches.

Native Adult Tendon Properties

Mechanical Properties

Tendons exhibit nonlinear, anisotropic, and viscoelastic responses to tensile loads, with over 50% stress relaxation in 120 min (Kwan et al., 1993). Elastic modulus of adult human Achilles tendon is between 0.8 and 1.5 GPa based on in vitro measurements (Bennett et al., 1986), which is similar to in vivo ultrasound and reaction force-plate measurements (0.87 ± 0.2 GPa, Lichtwark and Wilson, 2005, and 1.16 ± 0.15 GPa, Maganaris and Paul, 2002, respectively). In vivo measurements estimate peak bulk tissue strains to be $8.3\% \pm 2.1\%$ (Lichtwark and Wilson, 2005) with 18% hysteresis (Maganaris and Paul, 2002). To date, graft tendon tissues and scaffolds have yet to achieve native mechanical properties and function. For example, cadaveric Achilles and patellar tendons typically have elastic moduli between 0.2 and 0.27 GPa (Penn et al., 2009). Thus there is a critical need for tendon replacements that can both possess the native mechanical properties of adult tendon and self-maintain a biologically healthy tissue over a lifetime.

Extracellular Matrix Composition and Molecular Arrangement

The highly complex and unique mechanical properties of tendon are attributed to their complex ECM composition and hierarchical arrangement. Tendon mechanical properties, such as ultimate tensile strength and elastic modulus, derive primarily from collagen type I fibrils, which account for at least 60% of tendon dry weight. These fibrils also associate with other proteins, including collagen types III, IV, V, VI, XII, and XIV, elastin, and small leucine-rich proteins such as decorin, biglycans, cartilage oligomeric matrix protein, and more (Banos et al., 2008; Nguyen et al., 2018). These ECM proteins facilitate collagen fibril organization, crosslink fibrillar collagens and elastin, enable gliding of fibril bundles and viscoelastic responses to load, and provide space for proprioceptive neural networks and vascular supply. Collagen type I molecules (~1 nm diameter) organize into parallel nanoscale fibrils, and then into parallel microscale fibers, both of which align along the major axis of tension. In the embryonic tendon, collagen fibril diameters range from 50 to 100 nm (Mcbride et al., 1988) and after maturation can reach as large as 280 nm in the adult (Silver et al., 2003), with a characteristic 67 nm lateral D-banding pattern coincident with molecular gaps (Raspanti and Guizzardi, 2002). The ideal goal of tendon tissue engineering would be to produce a tissue that is similar in composition and molecular arrangement. By comparison, current scaffold designs, as well as the tissues formed within these scaffolds, are composed of fewer ECM components and are comparatively simpler in microstructure.

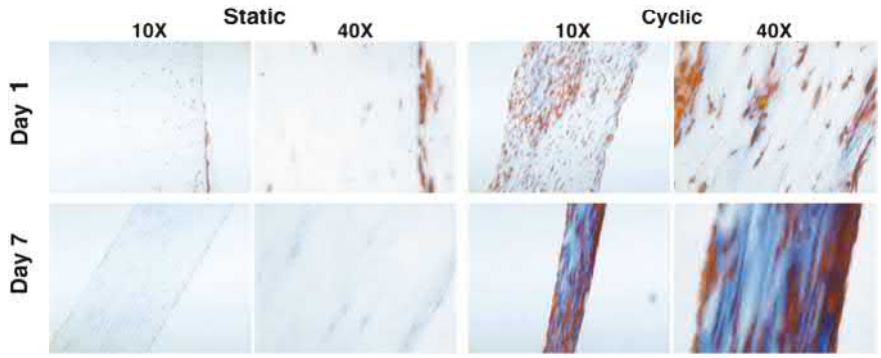
Tendon Cells

Tendon fibroblasts (tenocytes) arrange circumferentially around collagen fibers and are likely the cells primarily responsible for maintaining the ECM under homeostatic conditions. Tenocytes communicate with each other via gap junctions, including connexin 32 and 43 (McNeilly et al., 1996). Some studies have suggested that multipotent tendon-derived stem cells exist within tendon (Bi et al., 2007). Fibrocartilage cells are also detectable in regions of high compressive force, such as regions where tendons wrap around another skeletal structure (Benjamin et al., 2008). Although gene-based identification of tendon cells is likely incomplete, known markers of tendon cells include the transcription factors scleraxis (Scx) and mohawk (Schweitzer et al., 2001) (Mkx), the transmembrane protein tenomodulin (Tnmd) (Shukunami et al., 2006), and ECM glycoprotein tenascin-C (TN-C) (Chiquet-Ehrismann and Tucker, 2004). For more details, we refer readers to a comprehensive review on tendon ECM molecules and respective functions (Nguyen et al., 2018)

Scaffold Design Goals

Early scaffold designs for tendon tissue engineering were relatively simplistic. Adult stem cells were seeded within scaffolds composed of collagen type I, the primary ECM component of adult tendon, and placed under cyclic uniaxial tensile loads similar to those experienced during walking or running (Kuo and Tuan, 2008; Awad et al., 2000). The idea was that culturing cells within an adult tendon-like microenvironment would biochemically and mechanically encourage adult stem cells to behave tenogenically. However, while collagen content increased (Fig. 2.6.5.1) and mechanical properties improved over time, the constructs remained relatively weak compared to native tendon tissue both in vitro and in vivo. Nevertheless, the promise of tendon tissue engineering was established by these seminal studies and the field has since evolved to produce more complex scaffold designs, as discussed throughout this chapter.

Over the years, scaffold design has become increasingly sophisticated in attempting to capture the complexity of



• **Figure 2.6.5.1** Histology of mesenchymal stem cell-seeded collagen constructs harvested after 1 and 7 days of static and cyclic loading. Longitudinal 5-μm-thick sections histologically stained with Mallory's trichrome. A higher level of matrix staining is seen consistently in constructs subjected to cyclic loading. (Figures adapted from Kuo, C.K., Tuan, R.S., 2008. Mechanoactive tenogenic differentiation of human mesenchymal stem cells. Tissue Eng. A 14, 1615–1627.)

tendon tissue. Some approaches aim to control engineered microstructures at multiple length scales to more closely mimic the hierarchical structures of collagen fibers and fibrils. Other approaches incorporate bound and soluble biological cues to promote tenogenic gene expression and ECM deposition by stem cells. Such design criteria have been incorporated into scaffolds that also aim to enable immediate or early return to load-bearing function. This chapter reviews current scaffold designing approaches, which can be categorized as the following: (1) achieving immediate or early return to load-bearing function, and (2) instructing tenogenic cell behaviors via scaffold physical features (mechanical properties, topography) or the presence of biological (soluble or bound) factors.

Immediate or Early Return to Load-Bearing Function

Because tendon possesses unique mechanical properties that enable transfer of forces generated by muscle to bone to facilitate skeletal movements, an important design goal for tendon scaffolds has been to enable immediate or early return to load-bearing function. Material properties, which include elastic modulus and failure strength, are intrinsic to a tissue and reflect its quality. Functional properties, which include stiffness and failure load, are dependent on tissue dimension and size and can be achieved in the absence of the material properties of healthy tendon. Scaffold designs have aimed to recapitulate either healthy tendon material properties or functional properties. Arguments can be made to support either strategy, and examples of both are highlighted in later sections of the chapter. However, it is possible that a scaffold achieves mechanical function but does not present a biochemical composition and structure that promotes cell tenogenic behavior. Therefore the important biological cues needed to support a healthy tissue in the long term might be lacking. Another important consideration that has not yet been a main focus of scaffold designs is that material and functional properties of tendons may vary between those of different anatomical sites, as they have different geometries and functional requirements. Tendon cells isolated from tendons of the axial versus limb skeleton express ECM genes differently in response to the same tendon-specific growth factors (Brown et al., 2014), suggesting different profiles of ECM proteins are deposited by tendon cells in different parts of the body, perhaps related to their developmental origin.

Guidance Cues to Induce Tenogenic Cell Behaviors

Perhaps the most commonly used guidance cues are biological factors that promote specific cell functions, including differentiation, ECM synthesis and deposition, and tissue remodeling. Scaffolds can be designed to present a range of bioactive molecules that are covalently bound within or coated onto the scaffold surface. These biological factors can be gradually released from the scaffold as it swells or degrades over time. Binding of soluble factors via transmembrane receptors can regulate cellular activities by transmitting signals, including activation of multiple intracellular signaling pathways as well as mechanical cues from the extracellular space into the cell. In addition, passage of molecules or ions into the cell can happen through channels or pores on the cell membrane to induce intracellular biological reactions.

Physical cues may also induce tenogenic cell behaviors. Adult tendon possesses a unique tissue architecture of collagen type I fibers that align parallel to one another along the primary axis of tension, with cells wrapping around these fibers. Based on this unique in vivo feature, some scaffolds aim to present cells with aligned nano- or microscale fibers or channels that mimic tendon tissue architecture at the cell length scales. The idea is that cells will arrange themselves similarly as they do in vivo, and that these topographical guidance cues will induce tenogenic cell behaviors.

Tissue mechanical properties have also been implicated as cell guidance cues in addition to enabling mechanical function. In this regard, nano- and microscale mechanical properties are important to consider, as whole tissue mechanical properties may not reflect the local mechanical microen-

vironment that cells experience (Marturano et al., 2013). For example, cells have been shown to sense and respond to local elastic moduli or stiffness (Marturano et al., 2016). Because mechanical forces are transmitted from the extracellular space to the intracellular space via integrin interactions with the ECM, nano- and microscale elastic moduli of the tissue are thought to be particularly relevant mechanical cues. Thus, as discussed in the later section "Polymer Selection and Scaffold Designs," some scaffolds designed to guide cell behavior have considered cell length-scale mechanical properties.

Fabrication Methods

Most polymers can be fabricated into scaffolds of different forms, including gels, fibers, and foams. The choice of fabrication method, combined with polymer selection (discussed in the next section), significantly influences scaffold mechanical properties, microstructure, swelling behavior, pore size and porosity, and degradation rate. Ideally, the fabrication method is compatible with the polymer (does not degrade the polymer), is nontoxic (especially if cells are incorporated during fabrication), and reproducibly forms a three-dimensional (3D) scaffold with specific dimensions and material properties without compromising biological activity, if any, of the polymer. During fabrication, biofactors or other scaffold materials may be added to deliver tenogenic factors or create a composite scaffold with tailored material properties. Commonly used fabrication methods include electrospinning, electrohydrodynamic jet printing, wet spinning, fiber extrusion, weaving, knitting, braiding, gelation, and freeze drying. Another approach is tissue decellularization, in which natural tissue is harvested from a donor and treated to remove cells. The remaining ECM scaffold, possibly reseeded with cells, is then implanted into the recipient. As discussed later, each fabrication method for a tendon tissue-engineering scaffold is associated with its own unique advantages and disadvantages. The basics of these technologies are reviewed in more detail in the following sections, and examples of tendon tissue-engineering scaffolds fabricated with these technologies are highlighted within the section "Polymer Selection and Scaffold Designs."

Spinning

Based on the aligned collagen fibrils and fibers of adult tendon, techniques such as electrospinning, electrohydrodynamic jet (E-jet) printing, wet spinning, and fiber extrusion have been used to create scaffolds with aligned fibers with a range of fiber diameters and degrees of alignment. Spinning techniques can produce nano- and microscale fibers by ejecting polymer solutions via syringes and needles or pipette tips onto a collector surface. The spinning process can be guided by gravity or electrostatics as in the case of electrospinning (Sahoo et al., 2006, 2010; Chainani et al., 2013; Manning et al., 2013; Rinoldi et al., 2019a,b; Oryan et al., 2014; Xu et al., 2014; Yang et al., 2014, 2016; Hakimi et al., 2015; Naghashzargar et al., 2015; Orr et al., 2015; Zhang et al., 2015; Banik et al., 2016; Deepthi et al., 2016; Domingues et al., 2016; Gelberman et al., 2016; Pauly et al., 2016; Baudequin et al., 2017; Rothrauff et al., 2017; Sharifi-Aghdam et al., 2017; Szczesny et al., 2017; Wu et al., 2017a; Peach et al., 2017; Liao et al., 2018; Schoenenberger et al., 2018; Sensini et al., 2018; Wang et al., 2018; Li et al., 2019; Sundaram et al., 2019). The use of a rotating mandrel to collect electrospun fibers can produce scaffolds with nano- and microscale-aligned fiber structures that can mimic the aligned fibers of native tendon. However, limitations of electrospinning include limited scaffold thickness (millimeters) and poor cell infiltration within scaffolds. Several methods have been used to improve cell infiltration in electrospun scaffolds, including selective removal of sacrificial fibers, ultrasonication, and laser radiation, but these approaches can negatively impact scaffold architecture (e.g., fiber alignment) and compromise mechanical properties (Baker et al., 2008; Lee et al., 2011; Joshi et al., 2013). Alternative approaches include stacking multilayered electrospun sheets or incorporating textile fabrication techniques such as braiding or weaving (Rothrauff et al., 2017). In addition, methods such as extrusion (e.g., wet spinning fibers into a methanol-based coagulation bath) (Funakoshi et al., 2005a,b; Shepherd et al., 2013; Majima et al., 2007; Yang et al., 2019) and E-jet printing (Wu et al., 2016, 2017c) have been explored to fabricate scaffolds with increased pore size and enhanced cell infiltration.

Textile Technologies

Different techniques in textile technologies such as weaving, knitting, and braiding have been used to fabricate scaffolds with high tensile strength and modulus for tendon tissue engineering. Additional advantages of scaffolds fabricated with these techniques include tunable scaffold parameters such as fiber size and organization, pore size and porosity, controlled mechanical properties, and cell infiltration and distribution within the scaffolds. Knitted scaffolds are composed of interconnected loops of yarns that can be arranged in vertical (warp knitting) and horizontal direction (weft knitting) (Chen et al., 2010, 2014; Ouyang et al., 2003; Sahoo et al., 2006, 2010; Shen et al., 2010; Teh et al., 2013; Deng et al., 2014; Musson et al., 2015; Zhang et al., 2015; Sharifi-Aghdam et al., 2017; Zheng et al., 2017; Tang et al., 2018). Knitting stitches and yarn material can be altered to control pore size and fiber alignment, which influence cell infiltration and scaffold mechanical properties. Woven scaffolds are typically composed of two sets of interlaced yarns: warp and weft (Younesi et al., 2014; Hakimi et al., 2015; Seo et al., 2016; Wu et al., 2017b). Weaving patterns such as plain, twill, and satin can be selected to tailor scaffold flexibility and topography. Woven scaffolds exhibit lower extensibility but maintain their structure and shape better than knitted scaffolds. Braided scaffolds consist of multiple sets of interlacing yarns that are intertwined together in an overlapping circular pattern (Kwon et al., 2014; Rothrauff et al.,

2017; Govoni et al., 2017; Cai et al., 2018; Pagan et al., 2019; Sandri et al., 2016; Funakoshi et al., 2005a). Braided scaffolds tend to possess a higher tensile strength compared to their knitted and woven counterparts. However, one of the limitations associated with woven and braided scaffolds is their low porosity, which can restrict nutrient distribution and cell infiltration.

Gelation

Hydrogel scaffolds are formed via gelation, a process in which polymer molecules are crosslinked to form a hydrophilic network (Ouyang et al., 2003; Majima et al., 2005, 2007; Kapacee et al., 2010; Shen et al., 2010; Manning et al., 2013; Breidenbach et al., 2015; Deepthi et al., 2016; Marturano et al., 2016; Yang et al., 2016; Govoni et al., 2017; Rothrauff et al., 2018; Sundaram et al., 2019; Farkash et al., 2019; Frauz et al., 2019; Rinoldi et al., 2019a,b). Gelation offers an advantage over the other methods in that cells can be incorporated during scaffold formation if nontoxic reagents are used. This allows cells to be encapsulated uniformly throughout the scaffold during formation, rather than seeded within the scaffold after formation. Additionally, the cell–polymer suspension can be injected into the injury site in vivo, after which the gel sets in the shape and size of the tissue defect. While hydrogels have traditionally been thought to be weaker than other scaffold types, the formation of interpenetrating polymer network (IPN) gels has elevated the potential to use hydrogels as tendon tissue-engineering scaffolds. IPN gels can be made of polymers that form independent and interlaced networks via ionic and covalent crosslinking (Sun et al., 2012; Darnell et al., 2013; Branco da Cunha et al., 2014; Vining et al., 2019; Park et al., 2019). IPN gel toughness can be increased significantly compared to single component hydrogel by combining a range of natural and synthetic polymers such as alginate and polyacrylamide (Sun et al., 2012; Darnell et al., 2013), collagen type I and alginate (Branco da Cunha et al., 2014), and gelatin and silk fibroin (Park et al., 2019).

Freeze Drying

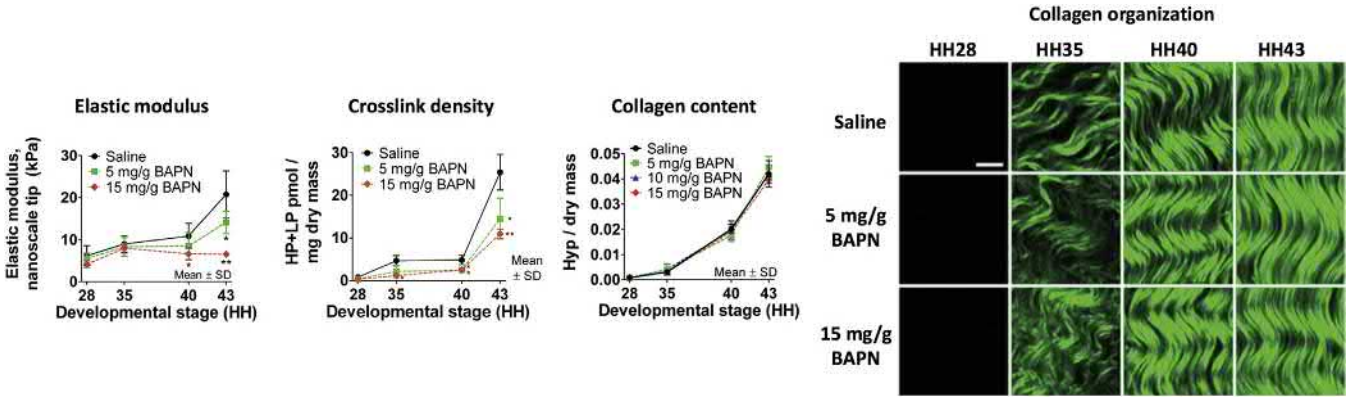
Freeze drying, often after gelation, can be used to create a highly porous sponge. Freeze drying has been used to fabricate highly porous scaffolds for tendon tissue engineering (Bagnaninchi et al., 2007; Caliari and Harley, 2011, 2013; Caliari et al., 2011, 2012; Hortensius and Harley, 2013; Bellini et al., 2016; Sandri et al., 2016; Mozdzen et al., 2016, 2017; Grier et al., 2017; Hortensius et al., 2018; Kirk et al., 2013). This method generally involves freezing a polymer solution at very low temperature, often between −10 and −80°C, and removing ice crystals through sublimation under low pressure. Notable advantages include the exclusion of organic solvents during fabrication and the formation of scaffolds with a high degree of porosity. In turn, porosity will affect mechanical properties, cell infiltration, nutrient and waste exchange, and susceptibility to degradation by enzymes or hydrolysis. Control over pore size can also be achieved by varying freezing rate and final freezing/cooling temperature (Haugh et al., 2010; O'Brien et al., 2004, 2005). However, it might be difficult to use freeze drying to fabricate scaffolds that possess hierarchical structure and comparable mechanical properties similar to native tendon tissue.

Decellularization

Decellularized matrices from human or animal tissues have been used as scaffolds in tendon tissue engineering. These offer the potential of preserving the biochemical composition and structural properties of native tendon tissue. Decellularization can be achieved via chemical (e.g., sodium dodecyl sulfate, Triton X-100), physical (e.g., freezing in liquid nitrogen), and enzymatic (e.g., trypsin treatment) processes. After in vitro decellularization and prior to in vivo implantation, several studies have seeded cells into these matrices and cultured them under tenogenic conditions such as mechanical loading and growth factor supplementation to promote cell differentiation and new tissue formation (Yin et al., 2013; Megerle et al., 2016; Ning et al., 2017; Xie et al., 2019). Another approach is the extraction of matrix-derived bioactive components via the preparation of a solubilized extract from decellularized tendon/ligament tissues, which have been found to exhibit protenogenic activities (Yang et al., 2013a, 2017; Rothrauff et al., 2018). Common challenges associated with using decellularized matrix as scaffold include the risk of eliciting inflammatory responses from the host body and inadequate mechanical properties to support immediate return to tendon's load-bearing function (Malcarney et al., 2005; Zheng et al., 2005).

Postfabrication Modifications

Crosslinking is routinely used to form polymer networks and thereby produce a 3D scaffold, or to reinforce the strength and stability of an existing polymer network of a scaffold after it has already been fabricated. In both scenarios, a higher crosslink density typically leads to higher failure strength and elastic modulus. Recent discoveries have shown that these mechanisms are utilized by nature to regulate embryonic tendon mechanical properties as well. Lysyl-oxidase (LOX) is an enzyme that converts lysine residues of collagen molecules into aldehydes, which then spontaneously react to form crosslinks between collagen molecules. Studies with chick embryo tendons reveal that elastic modulus and LOX-mediated crosslink density increase with similar trends from early to late stages of embryonic development (Fig. 2.6.5.2) (Marturano et al., 2013, 2014). Inhibition of LOX activity during development reduces both LOX-mediated crosslink density and elastic modulus of developing tendon proportionately, without affecting collagen organization or content, demonstrating that LOX-mediated crosslinking of collagen is



• **Figure 2.6.5.2** Elastic modulus, lysyl-oxidase (LOX)-mediated crosslink (*HP*, hydroxylysyl pyridinoline; *LP*, lysyl pyridinoline) density, and total collagen content (represented by hydroxyproline [Hyp] content) each increases in chick embryonic tendon during normal embryonic development from HH35 to HH43 (saline groups). Inhibition of LOX activity via β-aminopropionitrile (BAPN) treatment significantly reduced modulus and crosslink density but had no effect on collagen content or organization. Scale bar = 10 μm. (Figures adapted from Marturano, J.E., Arena, J.D., Schiller, Z.A., Georgakoudi, I., Kuo, C.K., 2013. Characterization of mechanical and biochemical properties of developing embryonic tendon. Proc. Natl. Acad. Sci. USA 110, 6370–6375 and Marturano, J.E., Xylas, J.F., Sridharan, G.V., Georgakoudi, I., Kuo, C.K., 2014. Lysyl oxidase-mediated collagen crosslinks may be assessed as markers of functional properties of tendon tissue formation. Acta Biomater. 10, 1370–1379.)

critical for embryonic tendon development (Fig. 2.6.5.2) (Pan et al., 2018; Marturano et al., 2013, 2014). While LOX has not been implemented in scaffold technologies for tendon tissue engineering, other synthetic and natural crosslinkers have been utilized, as discussed later.

After fabrication, scaffold material properties can be further enhanced via crosslinking. Specifically, crosslinking of the adjacent polymer chains can reinforce polymer networks, thereby increasing elastic modulus and/or failure strength and resistance to swelling in an aqueous environment in vivo or in vitro. Crosslinking can also decrease susceptibility to degradation by reducing pore size and limiting diffusion of enzymes or water into the polymer network. Current crosslinking strategies in tendon tissue-engineering scaffolds include the use of synthetic and natural crosslinking reagents to create covalent bonds between polymer chains. Synthetic crosslinkers include 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide (EDC), glutaraldehyde (GA), and 1,4-butanediol-diglycidyl ether (BDDGE), whereas natural crosslinking reagents include plant extracts of *Myrica rubra* and genipin. An advantage of natural crosslinking approaches is that they are typically gentler and have little to no toxicity compared to synthetic approaches. While not yet applied as a crosslinking agent to scaffolds in tendon tissue engineering, animal-derived enzymes (e.g., LOX) can also mediate the formation of covalent bonds between collagen and elastin molecules. In many cases, these covalent crosslinks are created when the synthetic or natural crosslinking reagent is applied to the scaffold. In other synthetic approaches, the polymers can be chemically modified with reactive functional groups prior to scaffold fabrication, in which case crosslinking of the polymer chains within the fabricated scaffold is induced by the application of heat, pressure, or light.

EDC, one of the most commonly used synthetic crosslinkers, is a water-soluble carbodiimide crosslinker that activates carboxyl groups on polymer chains, which then spontaneously conjugate with primary amines. *N*-Hydroxysuccinimide (NHS) is commonly added to enhance the efficiency of the EDC crosslinking reaction. EDC has been widely used to crosslink collagen scaffolds for tendon tissue engineering (Caliari et al., 2011, 2012; Caliari and Harley, 2011, 2013; Grier et al., 2017; Sensini et al., 2018; Shepherd et al., 2013; Kirk et al., 2013). EDC/NHS crosslinking improves scaffold mechanical properties and maintains their structure over a longer time compared to noncrosslinked scaffolds. However, scaffold porosity can be negatively affected. GA is a synthetic and water-soluble dialdehyde that crosslinks amine or hydroxyl groups in polymers. GA crosslinking has been used with collagen type I–nanocarbon composite fibers to achieve similar structural and mechanical properties to native tendon fascicles (Green et al., 2017). In BDDGE crosslinking, the epoxide groups of BDDGE react to create ester bonds with the carboxylic groups of polymers such as collagen (Lohre et al., 1992; Zeeman et al., 1999). BDDGE crosslinking has been used to slow the degradation rate of elastin–collagen composite scaffolds for tendon tissue engineering (Sandri et al., 2016). In these various systems, these synthetic covalent crosslinkers are typically applied after scaffold fabrication but before cell seeding and in vivo implantation. Due to nonspecific reactivity, harsh reaction conditions, and unwanted toxicity associated with synthetic crosslinkers, extensive washing of crosslinked scaffolds is needed to remove potentially cytotoxic chemical residuals before cell seeding. While mechanical properties of the scaffolds approaching that of tendon can be achieved with these synthetic crosslinkers, their associated cytotoxicity remains a limitation as it is difficult to eliminate entirely even after extensive washing.

Another synthetic crosslinking strategy is to apply heat or light to create covalent crosslinks. Dehydrothermal (DHT) treatment uses high temperature (>90°C) and vacuum conditions to induce condensation reactions between amine groups and carboxylic acid or hydroxyl groups of polymers. While DHT treatment has been utilized to crosslink different types of collagen-based scaffolds for tendon tissue engineering, a limitation is that it cannot be applied to cell-seeded scaffolds (Caliari et al., 2011, 2012; Caliari and Harley, 2011, 2013; Chen et al., 2010; Mozdzen et al., 2016). In ultraviolet (UV) light-induced crosslinking, UV radiation is used to activate a photoinitiator that, in turn, produces reactive molecules such as radicals or ions that react with the functional groups of polymer chains to create covalent crosslinks. Studies have used UV light to crosslink methacrylated gelatin (Rothrauff et al., 2018; Yang et al., 2016; Rinoldi et al., 2019b) and collagen (Oryan et al., 2014) in different types of scaffold for tendon tissue engineering. For example, methacrylated gelatin crosslinking improved scaffold maximum load and elastic modulus while maintaining cell viability similar to noncrosslinked scaffolds (Yang et al., 2016). In this and other studies, cells have been seeded in the scaffold prior to UV crosslinking, and are minimally affected by short-term UV treatments. However, at longer exposure times, UV radiation can be toxic to cells and result in heterogeneous crosslinking (Mironi-Harpaz et al., 2012). Furthermore, even though DHT and UV radiation crosslinking do not require the addition of toxic chemical reagents, polymer molecule integrity could be negatively impacted by UV light and harsh reaction conditions of high temperature and low pressure. For this reason, a visible light-mediated photocrosslinking procedure was developed for the production of a gelatin-based hydrogel, with significant improvement in cell viability (Lin et al., 2013, 2014), which has recently been applied in combination with electrospun polymeric nanofibers to form a composite tissue-engineering scaffold (Sun et al., 2019).

To overcome chemical toxicity and harsh reaction conditions associated with synthetic crosslinkers, naturally occurring crosslinking agents have been tried as well (Zeugolis et al., 2010; Fessel et al., 2012a,b, 2014; Mathew et al., 2013; Younesi et al., 2014). *M. rubra* extract, a plant-derived crosslinking agent, has been shown to react and covalently crosslink collagen scaffolds by binding to amino groups on adjacent collagen molecules (Liao et al., 2004). *M. rubra* extract crosslinking in collagen scaffolds was shown to improve mechanical properties and increase denaturation temperature compared to noncrosslinked scaffolds (Zeugolis et al., 2010). Genipin, derived from the fruits of *Gardenia jasminoides* and *Genipa americana*, is another natural crosslinking agent that has been used with collagen-based scaffolds in tendon tissue engineering (Fessel et al., 2012a,b; Mathew et al., 2013; Younesi et al., 2014). It has been proposed that genipin reacts with amine groups of polymers such as collagen, gelatin, and silk to form monomeric or oligomeric crosslinks (Butler et al., 2003). Studies have shown that genipin crosslinked collagen-based scaffolds can possess comparable mechanical properties to that of native tendon tissue and also support expression of tendon markers by seeded cells (Mathew et al., 2013; Younesi et al., 2014). Genipin also appears to be less cytotoxic than synthetic crosslinkers (Liang et al., 2004; Wang et al., 2016; Huang et al., 1998; Sung et al., 1999), although the time required to achieve a significant degree of crosslinking is generally considerably longer than that for chemical crosslinkers, such as those already discussed. It has also been reported that when genipin crosslinking was used to enhance the mechanical properties of tendon explant, higher dosages were shown to reduce cell viability (Fessel et al., 2014).

Delivery of Bioactive Molecules (e.g., Drugs and Growth Factors)

Delivery of bioactive molecules via scaffolds has been used to influence cellular activities, including expression of tendon markers and synthesis of ECM proteins (Sahoo et al., 2010; Shen et al., 2010; Hortensius et al., 2018; Govoni et al., 2017; Ramos et al., 2019; Manning et al., 2013; Min et al., 2016). The delivered bioactive molecules often include growth factors that are involved in adult tendon healing and homeostasis. Methods to deliver bioactive molecules via scaffolds generally fall into four systems: diffusion controlled, degradation controlled, cleavage controlled, and swelling controlled (Langer and Peppas, 1981, 2003). In a diffusion-controlled system, bioactive molecules encapsulated at high concentration within a polymer scaffold gradually diffuse out of the scaffold and into the surrounding environment. The diffusion-based release profile can be regulated by controlling the geometry and physicochemical parameters of the scaffold. In degradation-controlled release, bioactive molecules leave the scaffold either as the surface of the scaffold erodes (surface erosion) or as the entire scaffold degrades (bulk erosion). In a cleavage-controlled system, bioactive molecules are attached to the scaffold via covalent bonds so that the release of the molecules can be regulated by the enzymatic cleavage or hydrolysis of the covalent bond between the bioactive molecule and scaffold. In a swelling-controlled system, entrapped bioactive molecules diffuse through the scaffold and into the surrounding environment as the scaffold swells with corresponding increase in pore size. Scaffolds can be designed to release bioactive molecules via one or a combination of these release systems.

Drug delivery via scaffold degradation has been used in tendon tissue engineering with scaffolds fabricated by electrospinning, gelation, freeze drying, and more (Sahoo et al., 2010; Shen et al., 2010; Hortensius et al., 2018; Govoni et al., 2017; Ramos et al., 2019). For example, hydrolysis-induced bulk degradation of poly(lactic-*co*-glycolic acid) (PLGA) electrospun fibers enabled release of encapsulated basic fibroblast growth factor (bFGF) to enhance tendon marker expression and mechanical properties of repaired tendons compared to no-bFGF controls (Sahoo et al., 2010). Proteinase degradation of the collagen component of

implanted silk–collagen sponges led to the release of stromal cell-derived factor 1 alpha to promote tendon ECM production and enhance tendon repair (Shen et al., 2010). PLGA microcarriers encapsulating human growth differentiation factor 5 (hGDF-5) and embedded within a fibrin hydrogel showed continuous release of hGDF-5 and upregulation of tendon marker expression for 25 days in vitro (Govoni et al., 2017). In this case, the release kinetics of hGDF-5 were governed by hydrolytic degradation of PLGA microcarriers and proteinase degradation of the fibrin scaffold.

Degradation-controlled and cleavage-controlled systems have been combined with heparin affinity-controlled release to deliver bioactive molecules from tendon tissue-engineering scaffolds (Manning et al., 2013; Min et al., 2016). Heparin is a naturally occurring glycosaminoglycan (GAG), originally discovered in liver, that is known to bind various proteins via electrostatic interactions. The transient affinity of heparin to proteins allows slow release of bioactive molecules via diffusion from scaffolds (Sakiyama-Elbert and Hubbell, 2000; Vulic and Shoichet, 2014). For example, heparin-binding peptides were covalently crosslinked to fibrin scaffolds to immobilize soluble heparin that was ionically bound to platelet-derived growth factor BB (PDGF-BB) (Manning et al., 2013). The release of PDGF-BB from the fibrin scaffolds was controlled by a number of mechanisms. PDGF-BB dissociated from heparin and slowly diffused through the fibrin scaffold into the surrounding environment. PDGF-BB release was additionally controlled by enzymatic degradation of the fibrin scaffold by plasmin and degradation of heparin by heparinase. Another study reported the release of PDGF-BB from poly(ε-caprolactone) (PCL) scaffolds for tendon repair in vivo (Min et al., 2016). In this system, PDGF-BB was ionically bound to heparin, which was hydrogen bonded to the pluronic F127 component of a hybrid PCL–pluronic F127 scaffold (Min et al., 2016). The degradation of heparin by heparinase and hydrolysis of PCL enabled the sustained release of PDGF-BB over 42 days in vitro (Min et al., 2016). In both studies, delivery of PDGF-BB with scaffolds enhanced structural and mechanical properties of repaired tendon in vivo (Min et al., 2016; Manning et al., 2013).

Polymer Selection and Scaffold Designs

Biodegradable scaffolds for tendon tissue engineering are usually composed of synthetic and/or natural polymers, the latter of which may be mammalian derived or plant derived. The choice of polymers can influence the rate of scaffold degradation. Ideally, scaffold degradation rate should match the rate of new tissue synthesis so that the implant continuously offers adequate mechanical support for function and dimensional support for the newly forming tissue. Once implanted, the scaffold should be load bearing and able to return the patient to function while maintaining its shape and support for anabolic cell functions. Ideally, after a period of time, perhaps weeks or months, the implanted scaffold will be entirely replaced by new ECM generated by encapsulated or recruited cells. An animal-derived polymer may be desired for its peptide sequences that act as biological cues and cell adhesion sites. However, rapid degradation by mammalian enzymes in vivo may compromise the use of animal-derived natural polymers in load-bearing sites. Therefore either plant-derived natural polymers or synthetic polymers that are "invisible" to enzymes in vivo may be advantageous. On the other hand, while synthetic materials can be chemically modified to better control scaffold properties, many synthetic materials are susceptible to rapid hydrolysis. Some strategies have involved engineered hybrid scaffolds to utilize the advantages of both mammalian-derived polymers and plant-based or synthetic polymers to more fully control cell adhesion and various material properties. Other strategies involve chemical functionalization of polymers so that the resulting scaffold possesses specific properties. For instance, synthetic or plant-based polymers that would not typically be degraded in vivo by enzymes can be chemically modified to contain sites recognizable by matrix metalloproteinases (Yang et al., 2012; West and Hubbell, 1999; Patterson and Hubbell, 2010). Synthetic or plant-based polymers that lack cell recognition sites for binding can be chemically functionalized with peptide sequences that promote cell adhesion. Additionally, polymer scaffolds can be doped with other materials to enhance mechanical properties.

Natural Plant- and Animal-Derived Polymers

Alginates

Alginate is a polysaccharide commonly derived from seaweed and a natural copolymer of beta-D-mannuronic acid and alpha-L-guluronic acid monomers. Alginate is an attractive biomaterial for biomedical applications because of its abundance in source and noncytotoxicity (Cottrell, 1980). Alginate has been fabricated into hydrogels and wet-spun scaffolds for tendon tissue engineering. To form a hydrogel, multivalent ions, usually calcium ions, can be reacted with the carboxylic acid groups to form crosslinks between guluronic acid monomers. Gelation occurs upon the formation of "egg-box" structures, which are composed of calcium ion–crosslinked guluronic acid monomer blocks. Methods to slowly release calcium ions, thereby allowing gelation at a controlled rate, have enabled the formation of alginate gels with controlled shape, mechanical properties, swelling behavior, and diffusivity (Kuo and Ma, 2001, 2008). These gels are now commonly used in tissue-engineering studies for tendon and other soft connective tissues (Schiele et al., 2015; Marturano et al., 2016; Korecki et al., 2009).

A distinct advantage of alginate is its invisibility to mammalian enzymes and cells, due to its lack of peptide sequences that mammalian proteins recognize. Taking advantage of their "invisibility" to cells, alginate gels have been used to coat partially lacerated flexor tendon in a rabbit model, thereby leveraging their antiadhesive property to prevent

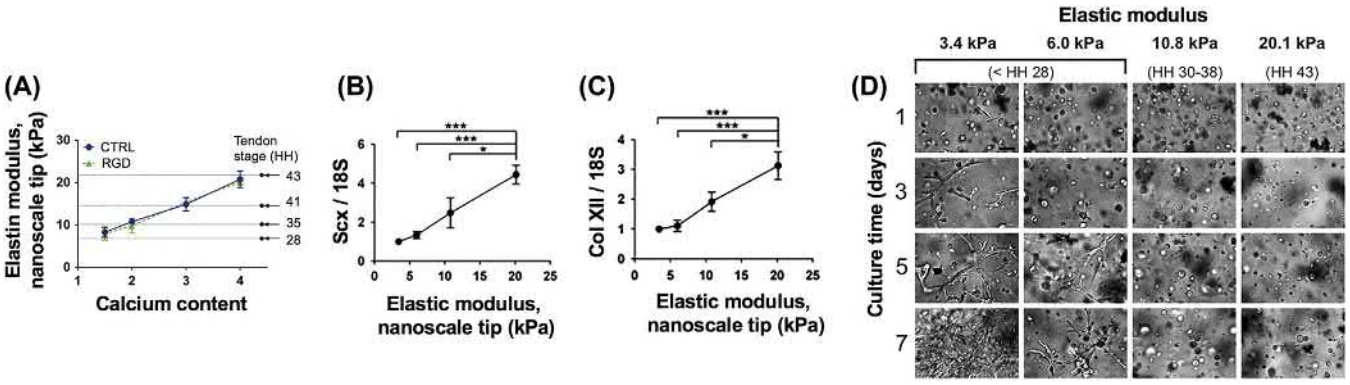
peritendinous adhesion (Namba et al., 2007). In another study, alginate coating of a hybrid scaffold composed of chitosan–collagen hydrogel and electrospun poly(L-lactic acid) (PLLA) nanofibers significantly reduced protein adsorption at the scaffold surface without affecting cell attachment and infiltration up to 7 days in vitro (Deepthi et al., 2016).

Another advantage of alginate is that it forms a hydrogel under gentle, nontoxic, ionic crosslinking conditions, and thus cells can be encapsulated during gelation. Furthermore, alginate lacks cell-binding sites within its polymer chain, but the polymer can be chemically functionalized with specific peptide sequences to enable specific cell-binding interactions (Schiele et al., 2015; Marturano et al., 2016; Rowley et al., 1999). For instance, functionalization of alginate with peptides containing arginyl-glycyl-aspartic acid, a cell-adhesion epitope of many ECM components, including fibronectin, enables tendon cell attachment and spreading within alginate hydrogel, whereas cells remain round in the nonfunctionalized hydrogels (Marturano et al., 2016). Alginate can also be combined with other polymers to which cells will adhere (Majima et al., 2005, 2007; Deepthi et al., 2016). For instance, a significantly higher degree of cell attachment was observed in chitosan–alginate scaffolds compared to alginate-only scaffolds (Majima et al., 2005, 2007).

Alginate hydrogels are also attractive because their material properties are highly tunable. Elastic modulus and strength of alginate hydrogels can be precisely controlled by changing crosslink density (calcium ion) and polymer concentration (alginate) (Kuo and Ma, 2001, 2008). This has enabled studies of stem cell responses to tenogenic microenvironments. In particular, alginate hydrogels were fabricated to possess cell length-scale (nanoscale) elastic moduli of native embryonic tendon at each stage of development (Marturano et al., 2016) (Fig. 2.6.5.3A). Embryonic tendon progenitor cells seeded within these gels exhibited stiffness-dependent cell morphology and tendon marker expression levels (Fig. 2.6.5.3B–D). This exciting observation demonstrated the ability to fabricate alginate scaffolds with specific mechanical properties, and showed that embryonic tendon progenitor cells are responsive to the changes in tendon stiffness throughout development (Marturano et al., 2016). Furthermore, these findings suggested that embryonically informed scaffolds can promote stem cell tenogenesis. While this ionically crosslinked alginate scaffold alone would not be suitable for load-bearing applications in vivo, it would be possible to infiltrate the alginate hydrogel within the pores of a load-bearing scaffold. This composite scaffold could then promote tenogenic cell differentiation while acting as a load-bearing structure for tendon repair or replacement. Another possibility to use alginate in a load-bearing scaffold application is to form IPN hydrogels composed of alginate and other polymers. For example, IPN hydrogels of ionically crosslinked alginate and covalently crosslinked polyacrylamide were shown to possess failure stress more than 40 times higher than alginate gels alone (Darnell et al., 2013; Sun et al., 2012).

Cellulose

Cellulose is a plant-derived polysaccharide that consists of chains of glucose monomers. Cellulose is abundantly available and commonly considered nontoxic (Gibson et al., 2010, Gibson 2012). However, like other plant-derived polymers, cellulose lacks mammalian cell recognition sites and is not biodegradable in the human body. Cellulose has been less commonly used as a biomaterial for tendon tissue-engineering scaffolds compared to other naturally derived polymers. Cellulose has primarily been used to reinforce



• **Figure 2.6.5.3** Effects of hydrogel elastic modulus on tendon progenitor cells (TPCs). (A) Hydrogels were fabricated to present chick embryonic tendon elastic modulus of different developmental stages from HH28 to HH43. Gene expression levels of scleraxis (B) and collagen type XII (C) were significantly higher in chick embryo TPCs that were cultured in stiffer gels that represented later embryonic-stage tendons. $^{*}P<.05$; $^{**}P<.01$; $^{***}P<.001$. (D) Representative brightfield images of arginyl-glycyl-aspartic acid (RGD)-functionalized alginate gels seeded with TPCs and cultured for 7 days. Gels with nanoscale elastic moduli from 3.4 to 20.1 kPa represented embryonic tendon from HH 28 to HH 43. Cells were more spread out in softer gels (representing younger embryonic tendons) and more round in stiffer gels (representing older embryonic tendons). Scale bar = 50 μm. (Figures adapted from Marturano, J.E., Schiele, N.R., Schiller, Z.A., Galassi, T.V., Stoppato, M., Kuo, C.K., 2016. Embryonically inspired scaffolds regulate tenogenically differentiating cells. J. Biomech. 49, 3281–3288.)

tendon scaffolds to achieve higher tensile strength and elastic modulus (Mathew et al., 2012, 2013; Domingues et al., 2016; Li et al., 2019).

Scaffolds made from both natural (e.g., collagen, chitosan) and synthetic (e.g., PCL) polymers have been reinforced with cellulose to enhance their mechanical strength and toughness (Mathew et al., 2012, 2013; Domingues et al., 2016; Li et al., 2019). Incorporation of cellulose increased tensile strength, strain, and elastic modulus of genipin crosslinked collagen–cellulose nanocomposites to within a comparable range to native tendon tissue (Mathew et al., 2012, 2013). Furthermore, seeded human ligament cells remained viable and proliferated within the hybrid scaffold (Mathew et al., 2013). In another study, incorporation of cellulose nanocrystals significantly enhanced the mechanical properties of electrospun PCL–chitosan composite scaffolds (Domingues et al., 2016). The cellulose-reinforced scaffolds were shown to possess a similar range of mechanical properties to that of native tendon (tensile strength in the range of 5–100 MPa and elastic modulus of 20–1200 MPa), while also supporting human tendon cell attachment and proliferation (Domingues et al., 2016). Incorporation of cellulose into electrospun nanofiber scaffolds that were then made into helical yarns resulted in high extensibility and toughness, exhibiting potential for use as a tendon tissue-engineering scaffold (Li et al., 2019).

Chitin/Chitosan

Chitin is a natural polysaccharide that can be found in the exoskeleton of crustaceans. Chitosan, a deacetylated derivative of chitin, is hydrophilic and cationic in nature and contains structural similarity to GAGs (Kumar et al., 2004; Muzzarelli, 1986). Chitosan scaffolds offer several advantages, including low immunogenicity and high degree of cell attachment (Madihally and Matthew, 1999; Funakoshi et al., 2005a). As a cationic polymer, chitosan is commonly combined with anionic polysaccharides like alginate to fabricate hybrid scaffolds that support cell adhesion (Park et al., 2000; Mizuno et al., 2003; Sechriest et al., 2000; Domard and Domard, 2001; Hirai et al., 1991; Funakoshi et al., 2005a,b; Zhang et al., 2015; Majima et al., 2005, 2007).

Chitosan scaffolds have been used to support porcine tendon cell proliferation and ECM deposition for more than 21 days in vitro (Bagnaninchi et al., 2007). Chitosan-coated alginate scaffolds have shown significant improvement in cell adhesion compared to alginate-only scaffolds (Majima et al., 2005, 2007). Coating electrospun PLLA scaffolds with chitosan increased cell proliferation and reduced protein adsorption compared to uncoated PLLA scaffolds (Sundaram et al., 2019). When combined with hyaluronic acid (HA), another natural polymer known for its biocompatibility, chitosan–HA hybrid scaffolds demonstrated a higher degree of cell attachment and proliferation along with enhanced material properties (Funakoshi et al., 2005a,b).

Although chitosan scaffolds can enable efficient cell attachment and create a suitable microenvironment for cell viability and proliferation, the use of chitosan scaffolds has not resulted in repaired tendons with comparable mechanical properties to native tissue (Zhang et al., 2015; Funakoshi et al., 2005a). While repaired tendon with braided hybrid chitosan–HA scaffold exhibited significantly higher tensile strength and tangent modulus than nonscaffold control, their material properties remained approximately sevenfold lower than intact tendons (Funakoshi et al., 2005a). Another study combined chitosan with both natural gelatin and synthetic PLLA and poly(ethylene oxide) (PEO) polymers to fabricate electrospun hybrid scaffolds with adequate mechanical strength and biocompatibility for rat Achilles tendon defect repair (Zhang et al., 2015). After 4 weeks of implantation in vivo, the scaffold-repaired tendons possessed a stiffness of ~70% of normal rat tendons.

Collagen

Collagen is the primary component of most connective tissues in mammals. The basic structure of collagen monomers is a triple helix formed from procollagen alpha chains, with the nonhelical N- and C-terminal sequences subsequently removed by specific peptidases. The triple helical collagen molecules then assemble into collagen fibrils extracellularly. The collagen fibrils then pack together to form collagen fibers, which then assemble to form fascicles. The fascicles then bundle together to comprise tendon. As tendon is mostly composed of collagen type I, collagen has been favored as a naturally occurring biomaterial for tendon tissue-engineering scaffolds. However, as an ECM protein, collagen is susceptible to proteolytic degradation. Additionally, because the collagen is commonly derived from animal sources, such as bovine skin, it is likely to elicit an immune response from the human recipient of the scaffold, particularly if the N- and C-terminal sequences have not been completely removed. Several important early studies used collagen type I gels as scaffolds for adult mesenchymal stem cell (MSC)-based tendon tissue-engineering efforts (Awad et al., 1999, 2000, 2003; Young et al., 1998; Kuo and Tuan, 2008; Yang et al., 2013a). However, the engineered tissues from collagen gels were exceedingly weak, thus precluding their use in early or immediate return to load-bearing function applications.

Fabrication methods such as textile technology and spinning have been adapted to produce collagen scaffolds with superior mechanical properties compared to collagen gels and to more closely mimic aspects of the native tendon architecture (Younesi et al., 2014; Yang et al., 2019; Zhang et al., 2018; Shepherd et al., 2013; Sandri et al., 2016). For example, one study fabricated scaffolds composed of collagen fibers with various orientations and examined the effects of fiber orientation on tenogenic differentiation of seeded bone marrow mesenchymal stem cells (BMSCs) in vitro and tendon regeneration in vivo (Yang et al., 2019). Microscale-aligned fiber scaffolds mimicked native tissue tendon structure more closely and upregulated expression

of tendon markers in vitro compared to randomly oriented fiber scaffolds. However, scaffold-repaired tendons only recovered 65% of the maximum load and stiffness of native tendon by 8 weeks after repair (Yang et al., 2019). Another study fabricated woven scaffolds from collagen yarns that were made by twisting three crosslinked collagen threads together (Younesi et al., 2014). Preimplantation, these scaffolds possessed similar stiffness to uninjured tendon tissue (Younesi et al., 2014). However, the strength of these fabricated scaffolds was only 60% of that of native tissue (Younesi et al., 2014).

Collagen has also been combined with GAGs to create porous collagen–GAG scaffolds with the goal of mimicking native tendon ECM composition and structure (Caliari et al., 2011, 2012; Grier et al., 2017; Hortensius et al., 2018; Mozdzen et al., 2016; Shepherd et al., 2013; Caliari and Harley, 2011, 2013). Controlling porosity of collagen–GAG scaffolds in turn controlled mechanical properties, nutrient and waste exchange, and susceptibility to degradation by enzymes or hydrolysis. Furthermore, when cells were seeded throughout the scaffold, they remained viable, proliferated with high metabolic activity, and expressed tendon markers (Caliari and Harley, 2011, 2013; Caliari et al., 2011, 2012; Grier et al., 2017). However, the collagen–GAG scaffolds possessed elastic modulus of at least an order of magnitude lower than native tendon tissue (Caliari et al., 2012; Dressler et al., 2006).

In addition to employing different fabrication methods, many studies have also improved mechanically weak collagen scaffolds by creating composites with silk fibroin (Chen et al., 2010, 2014; Zheng et al., 2017; Takezawa et al., 2007; Shen et al., 2010, 2012; Kwon et al., 2014; Tang et al., 2018). Tendons repaired with knitted silk–collagen sponge scaffolds achieved failure force up to 83% and stiffness up to 64% of control tendons (Chen et al., 2010, 2014). In another study, pores within knitted silk scaffolds were filled with silk–collagen sponge to fabricate tendon hybrid scaffolds (Tang et al., 2018). Scaffold-repaired tendon was shown to achieve up to ~60% of maximum load and elastic modulus of contralateral uninjured Achilles tendon after 20 weeks of implantation in vivo (Tang et al., 2018).

Gelatin

Gelatin is a denatured derivative of collagen, yet it retains the portion of amino acid sequences similar to collagen that are essential for cell adhesion and proliferation (Veis et al., 1961; Zeugolis et al., 2008). Gelatin scaffolds have been examined in the context of providing an environment to guide stem cell tenogenic behaviors and formation of neotendon tissue, as well as augmenting reconstruction of tendon defects in vivo (Yang et al., 2016; Rinoldi et al., 2019a; Visser et al., 2015; Rothrauff et al., 2018). Gelatin offers several advantages as a biomaterial for tendon tissue-engineering scaffolds, such as biocompatibility.

Several studies have used different techniques such as spinning and gelation to fabricate gelatin scaffolds that mimic native tendon structure and enhance expression of tendon markers of seeded cells (Yang et al., 2016; Rinoldi et al., 2019a; Visser et al., 2015). Gelatin was functionalized with methacrylate groups for photocrosslinking and coelectrospun with synthetic PCL polymer to fabricate scaffolds with aligned fibers (Yang et al., 2016). Seeded human adipose-derived stem cells cultured within these scaffolds and treated with transforming growth factor-β3 aligned along the fibers and upregulated expression of tendon markers such as Scx and TN-C (Yang et al., 2016). However, the maximum load and elastic modulus of these PCL–gelatin scaffolds were too low to support load-bearing function (Yang et al., 2016). Gelatin and alginate were used in a wet-spinning technique to fabricate 3D-aligned hydrogel yarns as scaffolds for tendon regeneration (Rinoldi et al., 2019a). The combination of structural (fiber alignment), mechanical (loading), and biochemical (bone morphogenetic protein 12) stimulation was shown to enhance human bone marrow MSC alignment and expression of different tendon markers compared to nontreated groups (Rinoldi et al., 2019a).

Silk

Silk fibroin is a widely used natural biomaterial in tendon tissue engineering. Silk fibroin is a protein produced by silkworms during cocoon production. Silk fibroin is made up of light (25 kDa) and heavy (350 kDa) chain units that are disulfide bonded together (Zhou et al., 2000). Silk fibroin proteins are linked by their sister sericin proteins, which can be removed from silk cocoon mass via boiling and degumming processes (Yamada et al., 2001). Degummed silk fibroin offers several advantages as a biomaterial, including the ability to retain its structural integrity in aqueous solutions and to be proteolytically degraded over time in vivo (Greenwald et al., 1994; Minoura et al., 1990). Silk fibroin is composed of amino acids (e.g., glycine) that can be recognized as binding sites for cells. Fibers made of silk fibroin have been reported to possess elastic modulus between 5 and 12 GPa, ultimate stress up to 500 MPa, and failure strain up to 26%, which are all within the comparable range to native tendon (Pérez-Rigueiro et al., 2000; Jiang et al., 2006; Greenwald et al., 1994).

Studies have used different fabrication methods to create scaffolds from degummed silk fibroin that can support tenogenic cell behavior and formation of tendon-like tissue (Teh et al., 2013; Pagan et al., 2019; Musson et al., 2015; Qiu et al., 2016). Sources of silk used in tendon regeneration scaffold include nonmulberry (produced from wild species of silkworm) and mulberry (produced by domesticated *Bombyx mori* silkworm). Knitted scaffolds fabricated from these two types of silk showed comparable support for tenocyte attachment and proliferation in vitro (Musson et al., 2015). In one study, knitting was combined with electrospinning to fabricate a hybrid silk scaffold that was used to examine the effects of mechanical loading and fiber alignment on tenogenesis of MSCs (Teh et al., 2013). Mechanical stimulation of MSCs seeded within the aligned hybrid scaffolds

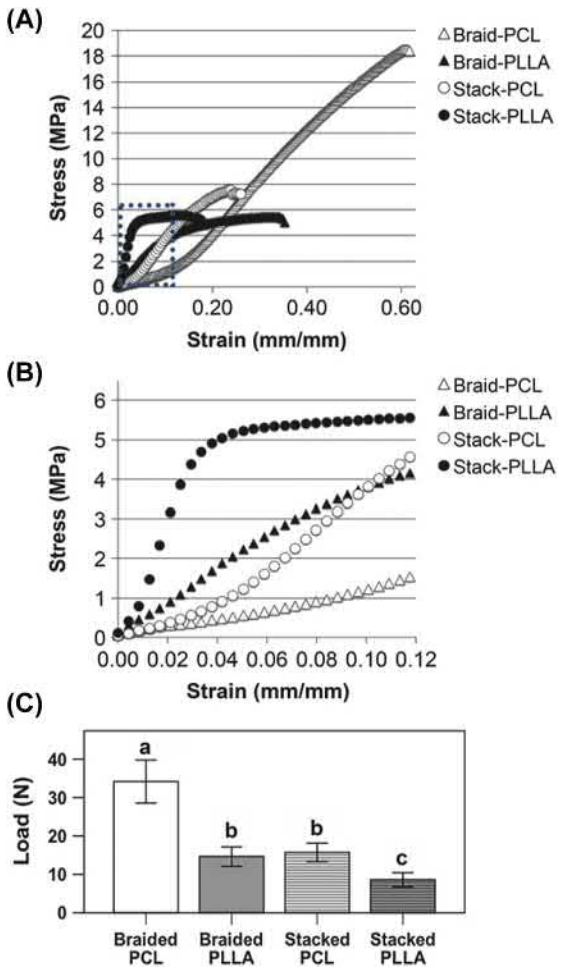
led to increased cell viability, higher expression of tendon markers (collagen types I and III, TN-C), and mechanical properties after 14 days of culture in vitro compared to randomly oriented scaffolds (Teh et al., 2013). A more recent study examined the mechanical properties of silkworm gut fiber braids that were made with different numbers of fibers and demonstrated the ability to achieve breaking force up to 330.5 N and elastic modulus up to 72 MPa, which were near the range of human anterior cruciate ligament (breaking force of 495–2160 N and elastic modulus of ~64 MPa) (Pagan et al., 2019). In addition, other studies have opted to combine silk with natural polymers such as collagen (see "Collagen" section) and synthetic polymers such as PLGA and PCL (see "Synthetic Polymers" section).

Synthetic Polymers

Poly(Glycolic Acid) and Poly(Lactic Acid)

Poly(glycolic acid) (PGA) and poly(lactic acid) (PLA) are two synthetic polyesters that have been Food and Drug Administration (FDA)-approved for a number of biomedical applications. Their approved status has made them especially attractive as biomaterials for tendon tissue engineering. PGA and PLA can be synthesized by ring opening polymerization of glycolide or lactide, respectively. The difference in molecular structure between PGA and PLA is that PLA possesses an additional methyl group that leads to distinct chemical and physical properties of the two polymers. The additional methyl group makes PLA more hydrophobic and resistant to hydrolytic degradation than PGA. The hydrophobicity of PLA also allows it to be dissolved in organic solvents such as tetrahydrofuran, acetonitrile, chlorinated solvents, and dioxane (Garlotta, 2001). Due to a higher degree of crystallinity, scaffolds made from PGA usually have higher modulus than PLA counterparts. Synthetic PGA and PLA polymers are degraded into glycolic acid and lactic acid, respectively, which are nontoxic in the body. However, these degradation products may reduce the pH locally, leading to inflammation (Liu et al., 2008). PLGA, a copolymer of PGA and PLA, has been used as biomaterial for tendon scaffold, as PLGA combines the advantages of both PGA and PLA, such as adequate mechanical properties and slow degradation rate (Ouyang et al., 2003; Sahoo et al., 2006; Gelberman et al., 2016).

PGA and PLA have each been used to fabricate tendon tissue-engineering scaffolds (Pietschmann et al., 2013; Wang et al., 2008; Cao et al., 2006; Liu et al., 2006; Wu et al., 2017a; Sato et al., 2000). For example, PLLA, a derivative of PLA, has been used to fabricate braided and stacked electrospun nanofibrous tendon scaffolds (Rothrauff et al., 2017). Within the range of physiological strain (0%–12%) of native ligament or tendon, stacked PLLA scaffolds exhibited ultimate stress and elastic modulus approaching those of native tendons (Fig. 2.6.5.4) (Rothrauff et al., 2017). Another study also showed that electrospun PLLA tendon scaffold could promote human adipose-derived MSC viability and expression of tendon markers (Wu et al., 2017a).



• **Figure 2.6.5.4** Mechanical properties of poly(ε-caprolactone) (PCL) and poly(L-lactic acid) (PLLA) scaffolds. (A) Averaged stress–strain curves of scaffolds. (B) Magnified stress–strain curves (box in [A]) within range of physiological strain of native tendon/ligament. (C) Maximum suture-retention strength of scaffolds; letters correspond to statistically equivalent groups, $P < .05$. (Figure adapted from Rothrauff, B.B., Lauro, B.B., Yang, G., Debski, R.E., Musahl, V., Tuan, R.S., 2017. Braided and stacked electrospun nanofibrous scaffolds for tendon and ligament tissue engineering. Tissue Eng. A 23, 378–389)

PGA and PLA have also been combined with other synthetic polymers to fabricate scaffolds with enhanced strength and toughness and to more closely mimic native tendon structure (Deng et al., 2014; Szczesny et al., 2017; Sahoo et al., 2006; Wu et al., 2017a). For instance, tendons repaired with hybrid scaffolds made of an inner component of PGA unwoven fibers and an outer component of knitted PGA:PLA (4:2 ratio) fibers achieved up to 60% tensile strength of uninjured tendon after 45 weeks of in vivo implantation (Deng et al., 2014). Using PEO sacrificial fibers and heat to control porosity, electrospun PLLA scaffolds were fabricated with fiber crimping pattern that aimed to mimic native tendon structure (Szczesny et al., 2017). Upregulated expression of tendon markers on crimped scaffolds were observed along with changes in cell morphology and nuclei strain transmission (Szczesny et al., 2017).

Natural polymers such as collagen and silk have been combined with PGA and PLA to improve hybrid scaffold biocompatibility while maintaining excellent scaffold mechanical properties (Bellini et al., 2016; Sensini et al., 2018; Xu et al., 2014; Yang et al., 2014; Zhang et al., 2015; Deepthi et al., 2016; Stoll et al., 2011; Liao et al., 2018). Scaffolds composed of electrospun PLLA–collagen type I nanofiber bundles have been fabricated to possess failure stress and elastic modulus within a comparable range of human tendons (Sensini et al., 2018). These scaffolds have supported fibroblast attachment and viability for up to 21 days in culture (Sensini et al., 2018). Another study combined synthetic poly(L-lactide-*co*-caprolactone) (PLLA-CL), a derivative of PLLA polymer, with collagen type I to fabricate electrospun hybrid scaffolds (Xu et al., 2014). Tendons repaired with these scaffolds possessed ultimate stress and elastic modulus up to 60% and 52%, respectively, of uninjured tendon after 12 weeks of implantation in vivo (Xu et al., 2014). In addition to collagen, silk fibroin has also been incorporated with PLLA-CL to fabricate hybrid scaffolds that possessed comparable tensile strength and elastic modulus to native tendon tissue (Yang et al., 2014).

Poly(ε-Caprolactone)

PCL, an aliphatic polyester that has also been FDA approved for multiple biomedical applications, is commonly used for tendon tissue-engineering scaffolds. PCL is synthesized by ring opening polymerization of ε-caprolactone. PCL is biodegradable and biocompatible as its degradation product caproic acid can be metabolized by the body. Hydrolytic degradation of PCL scaffolds happens slowly due to the hydrophobic chains of PCL. However, the hydrophobicity of PCL scaffolds can negatively affect diffusion rate of molecules and the absence of cell adhesion motifs on PCL chains can hinder cell attachment within scaffolds. The incorporation of hydrophilic or bioactive moieties and other polymers has been used to address limitations associated with molecule diffusion and cell attachment within PCL scaffolds.

PCL has been used to fabricate tendon tissue-engineering scaffolds with excellent mechanical properties (Croisier et al., 2012; Wu et al., 2016; Pauly et al., 2016; Banik et al., 2016; Wang et al., 2018; Rothrauff et al., 2017; Li et al., 2006). Electrospun PCL scaffolds were shown to possess greater strain to failure but lower elastic modulus than electrospun PGA and PLA scaffolds (Li et al., 2006). In addition, PCL scaffolds supported cell attachment and proliferation and maintained their structure in aqueous solution for up to 42 days in vitro (Li et al., 2006). Another study used E-jet printing combined with uniaxial stretching to fabricate hybrid PCL scaffolds with improved mechanical properties compared to electrospun PCL scaffolds (Wu et al., 2016). The hybrid scaffolds were composed of an outer portion made from E-jet printed PCL fiber mesh and an inner portion made from uniaxially stretched heat-sealed PCL tubes. These hybrid scaffolds enhanced seeded cell proliferation compared to electrospun scaffolds. In addition, these hybrid scaffolds possessed elastic modulus and ultimate stress that were within the range of human patellar tendon (~227 and ~50 MPa vs. 120–660 MPa and 40–65 MPa, respectively) (Wu et al., 2016). In another example, the nonlinear stress–strain curve characteristic of native tendon was mimicked using electrospun PCL fibers fabricated with a crisscrossed "Chinese-fingertrap" structure (Banik et al., 2016). When loaded under tension, the stress–strain curves of these scaffolds showed a toe and linear region similar to that of native tendon (Banik et al., 2016). More recently, hybrid core–shell scaffolds were fabricated to mimic the topography and microarchitecture of native tendon ECM while possessing mechanical properties similar to native tendon tissue (Wang et al., 2018). In particular, the scaffold possessed an elastic modulus of ~375 MPa, ultimate stress of ~56 MPa, and failure strain of ~47.5%, which were within the range of native human patellar tendon (elastic modulus of ~191–660 MPa, ultimate stress of ~26–95 MPa, and failure strain of ~13%–31%) (Wang et al., 2018).

Several studies have opted to combine PCL with other polymers to fabricate hybrid scaffolds with enhanced mechanical properties and biocompatibility (Wu et al., 2017b; Hakimi et al., 2015; Ramos et al., 2019; Yang et al., 2016; Rinoldi et al., 2019b; Chainani et al., 2013; Liao et al., 2018). For example, PLA was incorporated into PCL yarn to create woven scaffolds with comparable ultimate strain (~41%) to native human supraspinatus tendon (mean ultimate strain of ~36%) (Wu et al., 2017b; Nowotny et al., 2016). Another study fabricated multilayer hybrid scaffolds for tendon repair by combining electrospun polydioxanone (PDO) nanofibers and woven PDO layers with electrospun PCL sheets (Hakimi et al., 2015). These hybrid scaffolds were shown to possess failure load up to 85% of native human infraspinatus tendon (Hakimi et al., 2015; Bassett et al., 1990; Townsend et al., 1991). PCL scaffold biocompatibility can also be improved by incorporating different materials (Ramos et al., 2019; Yang et al., 2016; Rinoldi et al., 2019b; Chainani et al., 2013). For instance, the hydrophobicity of PCL scaffolds was reduced by incorporation of hydrophilic cellulose (Ramos et al., 2019). Methacrylated gelatin coating of PCL electrospun scaffolds improved cell attachment while also enhancing scaffold mechanical properties (Yang et al., 2016; Rinoldi et al., 2019b).

Other Synthetic Polymers

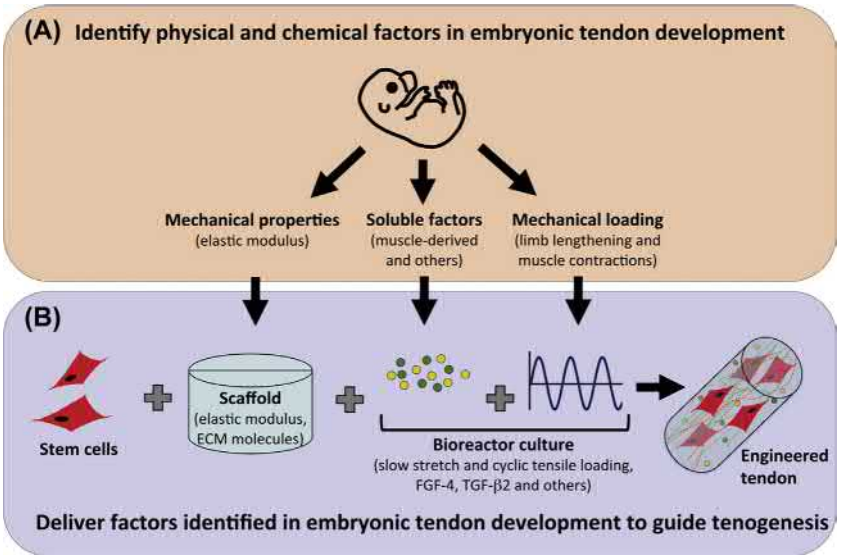
In addition to PGA, PLA, and PCL, other synthetic polymers such as poly(ethylene terephthalate) (PET) and polyhedral oligomeric silsesquioxane poly(carbonate-urea) urethane (POSS-PCU) have been used to fabricate tendon tissue-engineering scaffolds (Li et al., 2016; Cai et al., 2018; Alshomer et al., 2017). PET is a stable polyester containing aromatic groups that can be synthesized by the step-growth polymerization of ethylene glycol and terephthalic acid. PET scaffolds have been shown to possess high tensile strength (170–180 MPa) and elastic modulus (14,000 MPa) (Cziperle et al., 1992). PET has been used for surgical

sutures, vascular grafts, and artificial ligaments for primary anterior cruciate ligament reconstructive surgery (Maitz, 2015; Naim et al., 2011; Dhillon et al., 2010). However, the hydrophobicity of PET was reported to induce inflammation and thrombosis when implanted inside the body (Dhahri et al., 2011). More recently, PET was used to fabricate braided scaffolds for Achilles tendon repair in vivo (Cai et al., 2018). These PET scaffolds supported BMSC culture. BMSC-seeded PET scaffolds improved stiffness and failure load of repaired tendon and upregulated collagen expression compared to PET scaffolds alone (Cai et al., 2018). POSS-PCU is another synthetic polymer that has been used as biomaterial for tendon tissue-engineering scaffolds (Alshomer et al., 2017). POSS-PCU polymers are composed of poly(carbonate-urea) urethane backbones functionalized with polyhedral oligomeric silsesquioxane nanoparticles (Tan et al., 2013). POSS-PCU micropatterned substrates were fabricated as aligned hollow tubular structures to mimic the size and structure of native tendon fibers (Alshomer et al., 2017). Human tenocytes cultured on the micropatterned surfaces increased metabolism, alignment, and total collagen production with a higher degree of staining for tendon markers such as Scx and TN-C compared to POSS-PCU flat surfaces.

Future Directions: Developmental Biology-Inspired Strategies

In the past couple of decades, scaffolds for tendon tissue engineering have evolved from relatively simple cell-seeded collagen gels cultured under tension to complex composite materials with controlled multiscale architectures and mechanical properties. These scaffold designs have commonly strived to mimic adult tendon composition, microstructure, and mechanical properties. While the mechanical properties of these engineered structures have begun to approach those of native tendon, the tissues that form within these scaffolds still do not possess normal tendon tissue composition and material properties. Because tissue outcomes are governed by cells that reside within these scaffolds, efforts are ongoing to design scaffolds and culture systems that will provide tenogenic cues to cells within the scaffold and the surrounding tissues.

In recent years, rational approaches to guide stem cell differentiation based on developmental cues have started to emerge. The hypothesis behind these strategies is that the microenvironmental cues that induce stem cells to tenogenically differentiate and form new tendon during embryonic development will be effective signals to guide adult stem cell differentiation in a tissue-engineering system (Fig. 2.6.5.5) (Glass et al., 2014; Schiele et al., 2013; Nguyen et al., 2018; Okech and Kuo, 2016; Kuo and Tuan, 2003; Yang et al., 2013b). The promise of this approach has been demonstrated via a series of studies, some of which were briefly mentioned earlier in the chapter. In particular, the cell length-scale (microscale and nanoscale) elastic modulus of different-stage embryonic tendons were characterized by atomic force microscopy and shown to increase in a stage-specific manner during development (Marturano et al., 2013). To examine how these embryonic stage-specific tissue moduli influence tenogenesis during tendon development, hydrogel scaffolds were fabricated to present the cell length-scale modulus of each embryonic-stage tendon (Marturano



• **Figure 2.6.5.5** Developmental biology-inspired tissue-engineering strategies. (A) Characterize physical and chemical properties of developing embryonic tendon and its microenvironment. (B) Deliver these factors to stem cells via the scaffold (e.g., elastic modulus, bound extracellular matrix [ECM] molecules) and bioreactor culture (e.g., mechanical loading, soluble factors). Synergistic combinations of these cues may enhance and accelerate stem cell tenogenesis and neotissue formation. *FGF-4*, Fibroblast growth factor 4; *TGF-β2*, transforming growth factor beta2. (Figure adapted from Glass, Z.A., Schiele, N.R., Kuo, C.K., 2014. Informing tendon tissue engineering with embryonic development. J. Biomech. 47, 1964–1968.)

et al., 2016). Embryonic tendon progenitor cells cultured within these hydrogels exhibited unique morphology and tendon marker gene expression profile at each scaffold stiffness, reflecting a potential role for tissue stiffness in regulating tenogenesis during embryonic tendon development (Marturano et al., 2016). Importantly, it was also shown that when treated with growth factors and mechanical cues that are critical for embryonic tendon development, adult MSCs responded similarly as embryonic tendon progenitor cells to these cues (Brown et al., 2014, 2015). Based on these collective studies, an engineered scaffold that presents adult stem cells with tenogenic cues based on the embryonic microenvironment could be an effective tendon tissue-engineering approach. Considering a scaffold that mimics embryonic tissue mechanical properties will not fulfill adult tendon load-bearing requirements, it could be sensible to engineer a composite scaffold of at least two different polymers, whereas one scaffold component provides differentiation cues and the other component imparts load-bearing capacity to the construct.

Summary

As discussed in this chapter, strategies to design a scaffold for tendon tissue engineering have utilized a range of natural and synthetic materials, fabrication methods, and postfabrication modifications. Despite the plethora of options, the goal of engineering an ideal scaffold that provides mechanical function, presents critical biological cues to guide stem cell differentiation, and biodegrades in a controlled manner has not yet been achieved. Additional considerations include seeded cell type and density, in vitro culture conditions prior to implantation, size of implant, anatomical location, and more, all of which can significantly impact the scaffold design. As materials science technologies continue to advance, so has the understanding of the biology involved in normal tendon development. As both fields advance in parallel, it has become clear that for a scaffold design to succeed, it will need to play a role in directing cell behaviors at different stages of tenogenic differentiation, tissue formation, function, and eventually long-term stability. Thus depending on the specific needs and biology of the individual patient, there cannot be a "one-scaffold-fits-all" approach. Therefore well-defined goals and an understanding of both biomaterials properties and tendon biology will be critical to the success of a tendon tissue-engineering scaffold.

Bone Tissue Engineering

JUSTIN L. BROWN, CATO T. LAURENCIN

Department of Biomedical Engineering, The Pennsylvania State University, University Park, PA, United States

Introduction

The use of biocompatible polymeric materials for orthopedic applications, such as bone graft substitutes, has been under investigation since the 1940s (Blaine, 1946; Leveen and Barberio, 1949). By the 1970s the importance of attaining appropriate mechanical properties, an interconnected porosity, and a microstructure that promotes tissue ingrowth was realized (Hench et al., 1971). Research has highlighted the necessity for a subcellular dimension, or nanostructure, in synthetic bone grafts to promote the appropriate organization of bone cells in an effort to generate or regenerate bone tissue (Long et al., 2019; Ozdemir et al., 2019). This chapter begins with an overview of the biology of bone to provide a framework for what the application of biomaterials strives to recreate. The chapter then proceeds through a discussion of bone tissue engineering beginning with the natural bone grafts, moving through bone graft substitutes, and finishing with a discussion of bioreactors used in bone tissue engineering.

Bone Biology

Bones are vascularized and innervated organs that are composed of bone tissue, bone marrow, and a surrounding connective tissue called periosteum. Bones serve a number of functions such as support for muscles, protection of internal organs, production of blood, calcium homeostasis, acid/base buffering and transmission of sound (Bilezikian et al., 2008). Bone tissue is the rigid calcified portion of the bone organ and is critical for many of the functions.

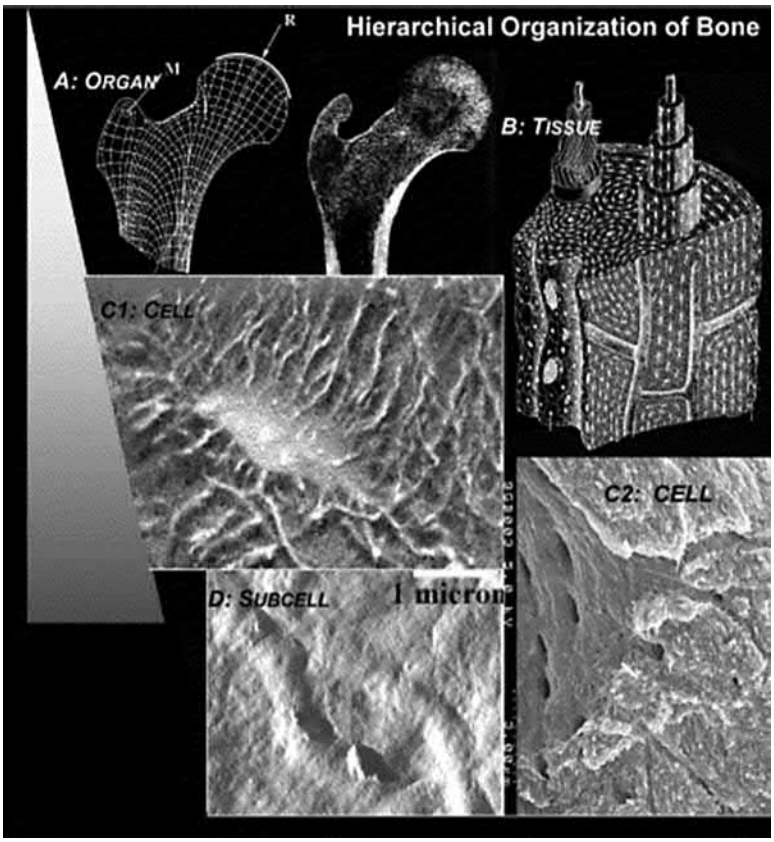
Types of Bone Tissue

Bone tissue is classified as either cortical bone or trabecular bone. Cortical bone is dense and highly mineralized bone tissue that is found on the peripheral regions of bone. Cortical bone is 80%–90% mineralized and constitutes 80% by mass of the bone tissue in the body. The high density of cortical bone makes it well suited for the mechanical and structural properties of bone. The thickness and density of cortical bone is loosely correlated to mechanical loading; however, many other variables are involved as well. Trabecular bone is found on the interior of bones adjacent to the marrow cavity. It is approximately 80% porous and exhibits less than 10% of the compressive strength and less than 5% of the compressive modulus of cortical bone. However, trabecular bone exhibits higher surface area than cortical bone and is considered more important for bone functions such as calcium homeostasis and acid/base regulation. Fig. 2.6.6.1 illustrates the hierarchical organization of bone, moving from the tissue level down to the subcellular level (Bilezikian et al., 2008; Pearson and Lieberman, 2004).

Cells Involved

Osteoblasts

There are several distinct cell types involved in the formation and remodeling of bone tissue. These cells are osteoblasts, bone lining cells, osteocytes, and osteoclasts. Osteoblasts are the workhorses of bone formation. Osteoblasts are fully differentiated cells derived from mesenchymal stem cells through a preosteoblast intermediate. The transition from mesenchymal stem cells to osteoblasts occurs through biochemical and cell:extracellular matrix (ECM) signaling. Osteoblasts are found at the surface of developing bone tissue and exhibit a cuboidal morphology. They actively secrete an unmineralized osteoid matrix at the location of newly forming bone. This osteoid matrix is the organic portion of bone ECM and is composed of primarily collagen type I, which makes up approximately 90% of the matrix. The remaining portion of the osteoid matrix is composed of proteoglycans and noncollagenous proteins such as osteopontin, osteocalcin, and osteonectin. The active production of the osteoid matrix as well as the presence of the membrane protein alkaline phosphatase distinguishes the osteoblast phenotype. The osteoid matrix around the osteoblast begins to calcify and approximately 20% of the buried osteoblasts



• **Figure 2.6.6.1** Hierarchical organization of bone. This figure provides a view of the organization of bone beginning with organ level (A) and moving to a depiction of the tissue level (B), which illustrates the network of osteocytes organized radially around Haversian canals. An individual osteocyte with the mineralized matrix removed is depicted in (C1) and clearly illustrates multiple processes extending away from the cell body; on the contrary, (C2) depicts the mineralized matrix without the cell and illustrates on the left-hand side the interior of the lacuna where the osteocyte cell body would reside and shows canals called canaliculi where the processes extending away from the osteocyte cell body ultimately connect with other osteocyte processes. Finally, (D) depicts the interior of canaliculi and shows the presence of striations created by collagen fibers that formed the initial framework for the mineralized matrix (Knothe Tate, 2003).

transition to osteocytes. The osteoblasts that do not transition to osteocytes undergo apoptosis (Franz-Odendaal et al., 2006).

Bone Lining Cells

Bone lining cells are found lining the surface of bone. Unlike osteoblasts on the bone surface, bone lining cells have a long, slender, and flat morphology. Bone lining cells were initially thought to be preosteoblasts; however, this is no longer thought to be the case. Instead, the current opinion is that osteoblasts that do not undergo apoptosis or differentiate to osteocytes become bone lining cells. Two of the key phenotypic differences between bone lining cells and osteoblasts are that bone lining cells express intercellular adhesion molecule 1 and they do not express osteocalcin (Everts et al., 2002). Research has shown that bone lining cells anchor hematopoietic stem cells and provide these stem cells with appropriate signals to keep them in an undifferentiated state (Kollet et al., 2006). The bone lining cells then play a crucial role in the transitions involved with bone remodeling by communicating through gap junctions with osteocytes deep in the bone matrix and promoting differentiation of hematopoietic stem cells into osteoclasts. Additionally, the bone lining cells are responsible for preparing the surface of the bone by removing nonmineralized collagen fibrils through the use of matrix metalloproteinases. After remodeling, the bone lining cells deposit a smooth layer of collagen over the bone surface (Kollet et al., 2006).

Osteocytes

Osteocytes are terminally differentiated cells derived from mature osteoblasts that have become encased within a calcified matrix. In the transformation from an osteoblast to an osteocyte, the expression of many of the proteins that constitute an osteoblast phenotype such as type I collagen, alkaline phosphatase, osteocalcin, and bone sialoprotein are no longer produced. Additionally, osteocytes create a network among themselves by extending many long processes to adjacent osteocytes. This network, the lacunar–canalicular network, is used for nutrient and waste transfer

as well as communication between the osteocytes via gap junctions.

The osteocyte cell body resides in the lacuna and the osteocyte's processes extend out through the canaliculi to adjacent osteocytes and Haversian canals. The Haversian canals supply vasculature to provide and remove nutrients. The concentric arrangement of the lacunar–canalicular network of osteocytes around a Haversian canal is referred to as the osteon. The organization of the osteocytes within bone is illustrated by Fig. 2.6.6.1. Additionally, osteocytes have been implicated as the primary mechanosensors in bone. The mechanotransduction that occurs in osteocytes is believed to be initiated by fluid flux within the canaliculi created by pressure gradients between lacunae when the bone is loaded. The mechanotransduction in osteocytes contributes to the recruitment of osteoblasts or osteoclasts depending on the loading condition (Franz-Odendaal et al., 2006; Goulet et al., 2008).

Osteoclasts

Osteoclasts, unlike the cells discussed thus far, are multinucleated cells derived from hematopoietic stem cells as opposed to mesenchymal stem cells. It has been established that hematopoietic stem cells anchored to bone lining cells are induced to differentiate into osteoclasts in response to osteocyte-bone lining cell signaling. The role of osteoclasts in bone metabolism is the resorption of bone. Initially, the osteoclast dissolves the mineralized portion of the bone matrix by secreting hydrochloric acid. After the mineral content is removed, the protein portion of the matrix is degraded by proteolytic enzymes. The resulting matrix fragments and ions created from matrix dissolution are transported through the osteoclast in vesicles that are emptied into the extracellular space on the basolateral side of the osteoclast (Kollet et al., 2006; Matsuo and Irie, 2008).

Bone Tissue Development

Calcified bone tissue is formed by two distinct modes of ossification, or calcification. These methods of ossification are classified as either intramembranous ossification or endochondral ossification. The method of ossification depends on the type of bone being formed. Intramembranous ossification is involved in the formation of flat and irregularly shaped bones, such as the cranial bones. Endochondral ossification is involved in the formation of long bones, bones that are longer than they are wide, such as the femur, humerus, and metacarpal (Bilezikian et al., 2008).

Intramembranous Ossification

Intramembranous ossification begins without a preexisting cartilage model. Instead, mesenchymal stem cells form clusters. The mesenchymal stem cells then differentiate to osteoblasts and the newly formed osteoblasts start to secrete an osteoid matrix. The osteoid matrix is calcified to form bone spicules. Osteoblasts trapped within the bone spicules either differentiate to osteocytes or undergo apoptosis. The bone spicules radiate outward from where the mesenchymal cluster originally formed. Eventually, spicules initiated by separate mesenchymal stem cell clusters join together to create a layer of calcified bone. Mesenchymal stem cells apical to the calcifying tissue differentiate to form the periosteum, whereas those basal to the calcifying tissue differentiate to osteoblasts, which form subsequent layers of calcified tissue. The resulting bone tissue is classified as woven bone. Woven bone is formed quickly and characterized by randomly oriented collagen fibrils; however, it is not as mechanically viable as lamellar bone. Woven bone will be remodeled over time through resorption and deposition by osteoclasts and osteoblasts to form lamellar bone (Bilezikian et al., 2008; Franz-Odendaal et al., 2006).

Endochondral Ossification

Endochondral ossification occurs in several steps, beginning with a preexisting cartilage template. The cartilage template begins calcification. As the cartilage template calcifies, the chondrocytes in the cartilage become hypertrophic and undergo apoptosis. Then, mesenchymal stem cells in the membrane surrounding the calcifying cartilage, periosteum, differentiate to osteoblasts. These osteoblasts lay down an osteoid matrix around the exterior of the cartilage template. At the same time a bud of cells originating from the periosteum invades the interior of the partially calcified cartilage template. This periosteal bud leads to vascularization and innervation of the developing bone. Additionally, the periosteal bud supplies mesenchymal and hematopoietic stem cells into the center of the cartilage template. The mesenchymal stem cells differentiate to osteoblasts and the hematopoietic stem cells differentiate to osteoclasts. These osteoblasts and osteoclasts remodel the partially calcified cartilage into woven bone, which ultimately becomes lamellar bone. Lamellar bone contains collagen fibrils that are arranged in parallel areas and exhibits greater strength as compared to woven bone (Bilezikian et al., 2008; Shapiro, 2008).

Bone Tissue Engineering

Strategies for bone tissue engineering often focus on the combination of the three key elements in tissue engineering: biomaterials, stem cells, and/or soluble factors. For example, a common tissue-engineering strategy involves fabricating biomaterials into porous scaffolds to facilitate cell growth and the eventual repair, restoration, or regeneration of the tissue (Langer and Vacanti, 1993). These biomaterial scaffolds can be used without any further modification in vivo. The next iteration in the application of biomaterial-focused tissue-engineering strategies involves culturing the biomaterial scaffold seeded with cells in vitro. The ultimate strategy for the in vitro use of a biomaterial scaffold involves seeding the scaffold and culturing in vitro to develop a replacement tissue that upon implantation functions exactly as the original host tissue.

Applying this tissue-engineering strategy, a paradigm for a successful bone graft emerges. This paradigm is that the graft or construct should be osteoconductive, osteoinductive, osteogenic, resorbable, or degradable and possess mechanical properties near to that of the implant site. Osteoconduction refers to the ability of a scaffold or implant to promote attachment of osteoblastic cells on the surface and throughout the interior of the scaffold or implant. In an in vitro setting, osteoconduction is exhibited by an ability to promote the attachment, migration, and proliferation of osteoblasts. Osteoinduction refers to the ability of a scaffold or implant to promote the differentiation of mesenchymal stem cells down an osteoblastic lineage ultimately leading to the formation of mineralized tissue. Osteoinduction can also be viewed as an ability to promote phenotype progression of an osteoblast from an early osteoblast to a mature osteoblast followed by differentiation to an osteocyte.

Osteogenicity refers to the ability of a scaffold or implant to promote de novo bone formation, which would occur in the absence of host cell invasion. For a scaffold to be osteogenic, cells would need to be seeded on the scaffold prior to implantation. The necessity of a bone tissue-engineering construct to be degradable arises from the fact that bone is constantly remodeling. A nonresorbable or nondegradable implant would impede the natural remodeling process of bone and extend the time it takes for the organ to return to natural function. Finally, the graft, scaffold, or implant should have mechanical properties that match that of the native bone tissue. The range for the mechanical properties depends on whether the bone tissue is cortical or trabecular. For trabecular bone the compressive strength varies from 4 to 12 MPa and the compressive modulus varies from 100 to 500 MPa. Cortical bone exhibits a compressive strength from 130 to 180 MPa and a compressive modulus from 12 to 18 GPa.

A problem with mechanical properties that exceed these ranges is stress shielding. Stress shielding results when the load on the bone is redistributed with the scaffold or implant being the load-bearing region and the surrounding bone being unloaded. The result of stress shielding is osteopenia of the bone surrounding the implant. To solve the bone tissue-engineering paradigm, there are presently a range of bone grafts and bone graft substitutes that fulfill all or some of the bone tissue-engineering paradigm (Kneser et al., 2006; Hutmacher, 2000).

Bone Grafts

Autograft

Bone grafts are pieces of bone that are harvested from the patient, a donor, or a cadaver and placed at the desired site of bone repair, regeneration, or restoration as needed. The long-standing, and considered "gold standard," bone graft solution to the bone tissue-engineering paradigm is an autograft. Autografts are sections or fragments of bone removed from one site on the patient, typically the iliac crest, and implanted to another site based on need. Since autografts originate with the patient they are readily incorporated at the implant site and rarely elicit any immune responses, which allows autografts to have excellent wound-healing properties. Autografts fulfill all four elements of the bone tissue-engineering paradigm, primarily because they consist of native bone tissue moved from one region of a patient's body to another region. However, autografts have a few drawbacks: there is often donor site morbidity indicated by necrosis and infection at the location of autograft harvest that may cause the patient more pain from the harvest site than the implant site. Additionally, autografts are limited in availability to the amount of tissue that can be harvested from the donor site. The problem of autograft bone tissue availability increases in cases where the need is the highest: those that involve osteoporotic, pediatric, or patients afflicted with bone cancer. It is these shortcomings plaguing the autograft that have increased the effort to find other bone graft substitutes (Greenwald et al., 2001).

Allograft

The next bone graft solution to the bone tissue-engineering paradigm is the allograft. Allografts are bone fragments obtained from donors or cadavers that are typically first frozen, irradiated, and/or lyophilized. These steps are implemented to reduce the likelihood of disease transmission. Allografts are readily available in an array of shapes and sizes. Since allografts originate from a donor or cadaver there is no additional surgical site on the patient, which removes complications such as donor site morbidity. However, the sterilization procedures performed on allograft bone tissue are not without consequence. In comparison to autografts, allografts are less osteoconductive, less osteoinductive, and are not osteogenic. Additionally, allografts that have been lyophilized exhibit much less mechanical integrity when compared to autografts. Due to allografts being nonnative tissue, they have been shown to occasionally produce an immune response, which requires allograft recipients to be placed on immunosuppressant drugs to prevent rejection of the allograft tissue. The complications that arise from autografts and allografts have fueled the search for bone graft substitutes (Greenwald et al., 2001).

Bone Graft Substitutes

Bone graft substitutes can offer solutions to the bone tissue-engineering paradigm and are based on the tissue-engineering concepts that arise from the definition of tissue engineering. These tissue-engineering principles lead to bone graft substitutes that can be classified as those based on biomaterials, cells, factors, or any combination of these.

Allograft-Based Substitutes

Biomaterial-based bone graft substitutes can be further subdivided into allografts, natural polymers, synthetic polymers, and ceramics. Allograft-based bone graft substitutes

are allograft bone tissue that has been thoroughly sterilized, decellularized, and demineralized. The methods by which manufacturers sterilize, decellularize, and demineralize the bone graft substitutes are carefully controlled to create a product that retains the collagen, noncollagenous proteins, and some of the growth factors present in the original bone tissue. The result is a demineralized bone matrix (DBM), which has been used in a variety of commercially available bone graft substitutes either as is or mixed with glycerol, hyaluronic acid, or calcium phosphates to improve the handling and performance characteristics of the product. Current efforts with allografts have produced technologies capable of processing DBM with computer-aided design and additive manufacturing leading to custom-shaped grafts (Grayson et al., 2010). There is evidence that supports improved osteoinduction with demineralization due to exposure of soluble factors that would be occluded in mineralized bone; however, DBM-based bone graft substitutes have limited osteoconductivity, no osteogenicity, and mechanical properties that are less than the desirable range (Peterson et al., 2004; Schwartz et al., 2007).

Natural Polymer-Based Substitutes

Natural polymers are gaining interest among the research community for bone tissue-engineering applications and additionally there are commercial bone graft substitutes derived from natural polymers available. The most prevalent natural polymer for bone graft substitutes is collagen. One example of a commercial collagen product is PlatFORM CM from Zimmer Biomet. PlatFORM CM is a collagen microfiber matrix that has been coated with β-tricalcium phosphate. The typical use of collagen graft substitutes involves coating it with bone marrow aspirate prior to implantation. By supplying the matrix with bone marrow aspirate there are progenitor cells present on the matrix, which makes it osteogenic in addition to being osteoconductive (Neen et al., 2006). In addition to collagen, fibrin and chitosan are two other natural polymers that are being investigated for bone tissue-engineering applications. The structures created by these polymers are typically fibers or foams. These structures provide excellent osteoconduction; however, osteoinduction, osteogenicity and mechanical properties are less than that provided by autograft tissue (Khan et al., 2008; Wahl and Czernuszka, 2006).

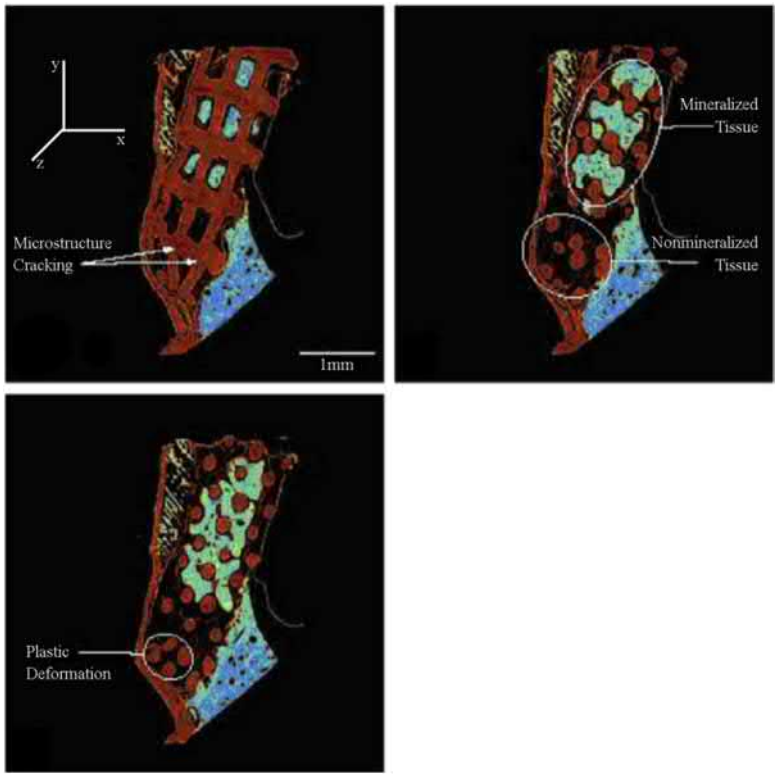
Synthetic Polymer-Based Substitutes

Synthetic polymer solutions for bone tissue-engineering applications are varied and abundant in current research. The use of synthetic polymers provides control over the surface chemistry, degradation kinetics, and geometry in much finer detail than can be accomplished with natural polymers. Clinically, a limited number of synthetic polymers are Food and Drug Administration (FDA) approved for use in nonlife-threatening applications, such as bone graft substitutes. These include the poly(α-hydroxy esters): poly(lactide), poly(glycolide), poly(lactide-*co*-glycolide), and poly(caprolactone). Fig. 2.6.6.2 illustrates a lattice structure made of poly(caprolactone) rods that has been implanted into a pig and imaged 3 months postimplantation with microcomputed tomography to demonstrate where new bone formation is occurring, which is not adjacent to existing bone tissue (Jones et al., 2004).

The mechanical properties of the construct are not documented and the cracking and plastic deformation visible after 3 months indicates the material may not be mechanically viable. The first porous bone tissue-engineering constructs fabricated from poly(α-hydroxy esters) were foams created by various porogen leaching techniques. The porogen in these foams is typically a substance that readily dissolves in water such as gelatin, salt, or sugar (Mooney et al., 1996). These scaffolds are created by dissolution of the poly(α-hydroxy esters) in an organic solvent. The dissolved polymer is then mixed with the porogen and cast. After the solvent has evaporated the construct is immersed in water to remove the porogen. This technique can produce scaffolds that are highly porous.

The primary issue with porogen leaching is the increase in porosity, which is directly correlated with a decrease in mechanical integrity. Additionally, at low porosities, which are more robust mechanically, the polymer surrounds each individual porogen resulting in poor interconnectivity among the pores (Mooney et al., 1996; Rezwan et al., 2006). The sintered microsphere scaffold fabricated from poly(α-hydroxy esters) succeeded the scaffolds created with porogen leaching and also addressed several of the problems with scaffolds created by porogen leaching. The maximum porosity achievable by the sintered microsphere scaffold is only around 45% based on random packing of spheres; however, the interconnectivity of the porosity is 100%, which was a dramatic improvement over the scaffolds fabricated with porogen leaching (Borden et al., 2002). More recently, microscale scaffolds have been fabricated with a very specific architecture from poly(α-hydroxy esters) by using solid freeform fabrication techniques. Solid freeform fabrication uses computer-aided design to build structures layer by layer through techniques such as stereolithography, selective laser sintering, and 3D printing (Hutmacher et al., 2004).

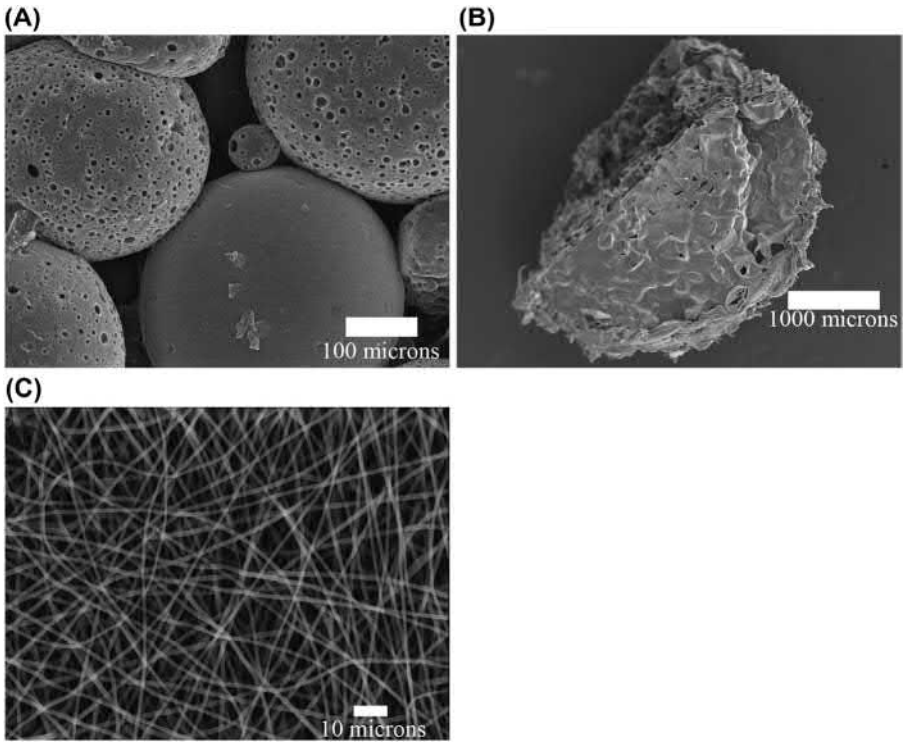
All of the scaffolds created with the foregoing microscale technologies provide similar performance. The mechanical integrity of the scaffolds can be fabricated into a range that suits bone tissue applications; the scaffolds degrade in a controllable manner based on the selection of the poly(α-hydroxy esters) and they are all osteoconductive. However, for the preparation of microscale structures, each of the techniques is limited to a resolution an order of magnitude larger than a cell, and the resulting materials are not osteoinductive nor are they osteogenic without supplementing the structure with growth factors or osteoblastic cells. The research community has moved to examine scaffolds composed of poly(α-hydroxy esters) that exhibit a subcellular dimension. These scaffolds are almost invariably fiber based



• **Figure 2.6.6.2** Representation obtained of a synthetic bone graft after 3 months in vivo using micro-computed tomography . The synthetic bone graft is a simple polycaprolactone (PCL) scaffold (red), with nonmineralized tissue (black), and mineralized tissue (blue green). The native bone is visible in the lower right corner of each image. The three images are different sections separated by 280 μm. The PCL scaffold was made by a rapid prototyping process and consists of a simple 3D lattice of connected rods. Also visible in the series of images are two defects caused by either degradation of the PCL, which the authors note that after 3 months has caused the diameters of the rods to shrink from 500 to 300 μm, or caused by excessive loading on the scaffold, compromising the material prior to degradation (Jones et al., 2004).

and are made either with electrospinning, phase separation for crystalline polymers, or precipitation in a nonsolvent of a continuous fiber stream from a polymer solution. The diameter of these fiber scaffolds can vary from 50 nm to several micrometers (Smith and Ma, 2004). The subcellular dimension provided by nano- and microfibers has illustrated improved osteoconductivity as compared to the supercellular dimension of the microstructures covered previously. Additionally, there is some evidence that nanofibers may promote osteoinduction; however, the gains that nano- and microfibers make with osteoconduction and osteoinduction are compromised by the mechanical properties under compression of the nano- and microfiber structures (Ozdemir et al., 2019; Kjelstrup-Hansen et al., 2006).

The next degree of control being explored for bone tissue-engineering constructs involves moving away from the FDA-approved poly(α-hydroxy esters) and onto other biodegradable polymers that provide better degradation by-products, or improving the osteoconductivity of polymers through the incorporation of integrin-binding peptides, such as RGD, within the synthetic polymer structure. A noted drawback of poly(α-hydroxy esters) is that they degrade into carboxylic acids, which can be inflammatory (Bostman and Pihlajamaki, 1998). An additional drawback to the usage of poly(α-hydroxy esters) is that they undergo bulk degradation, which results in the sudden failure of the scaffold. Similar to the poly(α-hydroxy esters), poly(propylene fumarate) is a polyester that can be used to fabricate similar scaffolds to the poly(α-hydroxy esters) and also shares the same problems with bulk degradation and acidic degradation products. Poly[(amino acid ester)phosphazenes] address the negative degradation products found with poly(α-hydroxy esters) and have recently been investigated for bone tissue-engineering applications. Poly[(amino acid ester)phosphazenes] degrade into amino acids, which are easier for the body to metabolize, and a buffer solution consisting of ammonia and phosphate, which prevents any change in the pH potentially brought about by the increase in the concentration of amino acids. Poly[(amino acid ester)phosphazenes] have also exhibited the more favorable surface erosion degradation mechanism (Allcock et al., 1994). Additionally, poly[(amino acid ester)phosphazenes] are suitable for many of the fabrication procedures discussed previously such as sintered microsphere scaffolds, porogen leaching scaffolds, and electrospun nanofibers (Brown et al., 2010; Kumbar et al., 2006). The scaffolds fabricated from poly[(amino acid ester)phosphazenes] have exhibited osteoconduction, but studies investigating the osteoinductivity and mechanical properties have yet to be reported. Fig. 2.6.6.3



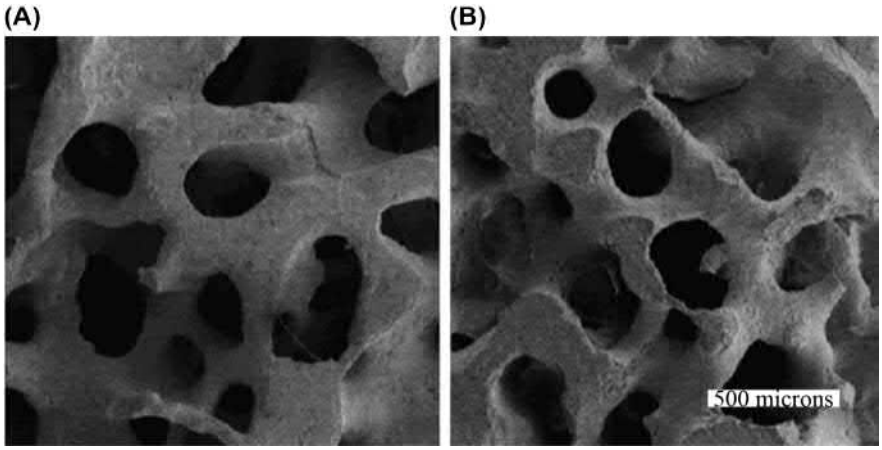
• **Figure 2.6.6.3** Scanning electron micrographs of three scaffold architectures fabricated from poly[(amino acid ester)phosphazenes]. (A) Sintered microsphere scaffold composed of poly[bis(ethyl alaninato)phosphazene]. (B) Scaffold made from leaching salt from poly[(ethyl alaninato-*co*-methylphenoxy)phosphazene]. (C) Nanofibers created by electrospinning poly[bis(methylphenoxy)phosphazene] (Nair et al., 2004). Images (A) and (B) are previously unpublished.

provides representative images of sintered microsphere scaffolds, porogen leaching scaffolds, and electrospun nanofiber scaffolds created with degradable polyphosphazenes. Finally, polyanhydrides are polymers that may surface erode similar to polyphosphazenes; however, little research has been performed investigating porous polyanhydride scaffolds for bone tissue engineering (Muggli et al., 1999).

Ceramic-Based Substitutes

Ceramic-based biomaterials are prevalent and widespread as bone graft substitutes. These ceramic biomaterial bone graft substitutes are made primarily from calcium phosphates, calcium sulfate, and Bioglass, which is a glass formulation containing a lower amount of silicon dioxide and higher amounts of sodium oxide and calcium oxide as compared to conventional glass. This specific glass formulation is bioactive and undergoes dissolution in the body. Calcium phosphate bone graft substitutes are usually either tricalcium phosphate or hydroxyapatite, which is the primary mineral in bone. One example of a commercially available hydroxyapatite-based bone graft substitute is Pro-Osteon from Zimmer Biomet. The Pro-Osteon bone graft substitute begins as natural coral, which is primarily calcium carbonate. The coral is then treated with a hydrothermal process in the presence of ammonium phosphate to convert the calcium carbonate structure to hydroxyapatite (Ben-Nissan, 2003). The resulting structure exhibits a pore structure similar to trabecular bone. Fig. 2.6.6.4 is a depiction of the resulting coralline hydroxyapatite resulting from the foregoing hydrothermal process. All of the hydroxyapatite-based ceramic bone graft substitutes are slowly resorbed by the body as the bone surrounding the implant remodels. Hydroxyapatite-based ceramic bone graft substitutes are also osteoconductive; however, the porous hydroxyapatite bone graft substitutes typically have compressive strength and moduli that fall below the range of trabecular bone.

Whether hydroxyapatite-based biomaterials are osteoinductive is a controversial topic. Osteoinduction appears to occur with hydroxyapatite and other calcium phosphate-based biomaterials. Initially, the osteoinductivity of hydroxyapatite and other calcium phosphates was believed to be a property of the ceramic itself. However, recent evidence suggests that it is a property of the microstructure of the material, which would be similar to results observed with polymer scaffolds (Li et al., 2008). Two calcium phosphate structures, one composed of hydroxyapatite and the other of a blend with 85% hydroxyapatite and 15% tricalcium phosphate, were fabricated into similar macrostructures; however, the hydroxyapatite/tricalcium phosphate structure also had a subcellular microstructure and was found to be more osteoinductive than the hydroxyapatite with no subcellular microstructure (Yuan et al., 2002). Additionally, an examination of several distinct calcium phosphates



• **Figure 2.6.6.4** Electron micrograph of coral prior to conversion to hydroxyapatite (A) and after hydrothermal conversion to coralline hydroxyapatite (B) (Ben-Nissan, 2003).

with different chemical and crystal structures fabricated into similar macrostructures illustrated no significant difference in the expression of phenotype markers (Wang et al., 2004). An additional type of calcium salt is calcium sulfate; however, there is minimal compelling information regarding the osteoconductivity and osteoinductivity of calcium sulfate, and it may be immunogenic.

Of the ceramic-based bone graft substitutes, those fabricated from Bioglass are the most intriguing. Bioglass was developed in the late 1960s and has been shown to fit the bone tissue-engineering paradigm better than the other ceramics covered. Porous scaffolds have been fabricated from Bioglass in a number of ways, such as foam replacement techniques where a polyurethane foam is coated with a Bioglass slurry and then the foam is burned out leaving a Bioglass scaffold, or sintering Bioglass fibers to form porous mats (Biocompatibility and bone, 2009; Brown et al., 2008). These Bioglass fiber mats have been shown to be osteoconductive and promote phenotype progression of preosteoblast cells, which suggests they may be osteoinductive. The compressive strength and modulus of these Bioglass fiber rafts are in the range of trabecular bone and they exhibit adequate porosity of around 44% (Brown et al., 2008).

Cell-Based Substitutes

Cell-based strategies for bone tissue engineering, similar to biomaterial-based strategies for bone tissue engineering, fall into several categories. These are transplantation of autogenous progenitor cells, transplantation of autogenous progenitor cells that have been expanded and/or differentiated in culture prior to implantation, transplantation of genetically modified cells, and transplantation of ex vivo generated tissue. The simplest of these strategies is the transplantation of autogenous stem cells. Typically, this is performed by aspirating bone marrow and placing the aspirate at the defect or surgical site either unmodified or centrifuged to remove red blood cells and hematopoietic cells, including monocytes, from the bone marrow. The transplantation of autogenous stem cells provides osteogenic potential to the defect, but does not provide osteoconductivity, osteoinductivity, or mechanical strength (Connolly et al., 1989).

The second method involves culturing the stem cells extracted from the bone marrow in culture. This can increase the number of progenitor cells available to implant, but it also comes with risks. The added time in culture in vitro increases the likelihood of bacteria contaminating the progenitor cell population. Successful expansion of the progenitor cells in vitro can ultimately improve the healing at the defect or surgical site. Similar to the nonexpanded cells, progenitor cells expanded in vitro prior to implantation are osteogenic but not osteoconductive, osteoinductive, or mechanically viable.

The third strategy for cell-based bone tissue engineering is the use of genetically modified cells. This is similar to the use of in vitro expanded autogenous progenitor cells, except the progenitor cells have been treated with an adenovirus or other vector to express a protein of interest. For bone tissue, often the progenitor cells will be transfected to express bone morphogenetic protein 2 (BMP-2). BMP-2 expressing progenitor cells enable the cell-based construct to be osteoinductive as well as osteogenic; however, the construct would still not improve in regard to osteoinductivity or mechanical viability (Cui et al., 2006).

The final strategy for cell-based bone tissue engineering is the most ambitious and the least clinically relevant at present. This is the in vitro culture of autogenous, embryonic, or inducible pluripotent stem cells with the aid of a bioreactor to ultimately produce a viable piece of bone tissue ex vivo. The major limitation in this strategy is material transport in developing tissue, since the issue of developing a vascularized construct has not been solved. If successful the ex vivo formation of bone tissue would meet all four criteria outlined in the bone tissue-engineering paradigm.

Growth Factor-Based Substitutes

The next strategy for bone tissue engineering is based on the use of factors. Two factors that have been shown to be

TABLE 2.6.6.1 Summary of the Properties Illustrated by the Different Types of Noncomposite Bone Graft Substitutes and How They Relate to the Desirable Characteristics of an Ideal Bone Graft Substitute

	Osteoconductive	Osteoinductive	Osteogenic	Mechanical Match
Allograft based	Yes	Yes	No	No
Microscale biomaterials	Yes	No	No	Yes, within the range of trabecular bone
Nanoscale biomaterials	Yes	Potentially. Supported by evidence with nanofibers made by self-assembly or phase separation.	No	No
Ceramics	Yes	Potentially. Supported by evidence for Bioglass.	No	Yes, range from less than trabecular bone to more than cortical bone depending on porosity
Cells	No	No	Yes	No
Growth factors	No	Yes	No	No

effective in a clinical setting and are approved by the FDA are recombinant human bone morphogenetic proteins 2 and 7 (rhBMP-2, rhBMP-7). Bone morphogenetic proteins are part of the transforming growth factor-β super-family and have been shown to exhibit osteoinductive potential. Between the two rhBMPs, rhBMP-2 has been shown to be more osteoinductive than rhBMP-7 (Khosla et al., 2008). Due to the soluble nature of both rhBMPs, they are often packaged with a carrier, often as simple as a collagen sponge. RhBMP-2 combined with a collagen sponge has been shown to perform better in spinal fusions than the "gold standard" autograft. In addition to spinal fusions, rhBMP-2 combined with a collagen sponge has illustrated effectiveness in fracture healing (Geiger et al., 2003). The primary limitation to the usage of rhBMPs in bone tissue-engineering applications is that they often cost a significant amount more than comparable procedures and consequently the usage of rhBMPs is primarily only in high-risk cases where all other options have been exhausted.

Composite Substitutes

The final strategy for bone tissue engineering is based on composites that combine two or more of the elements detailed earlier. The goal of creating composites is to combine the benefits of each component. Table 2.6.6.1 summarizes how the different bone tissue-engineering strategies correlate to the bone tissue-engineering paradigm. A common composite encountered consists of a biomaterial structure seeded with osteoblasts or osteoblastic cells. This is typically accomplished by either seeding of the biomaterial structure with osteoblast progenitor cells ex vivo just prior to implantation in vivo, or seeding of the biomaterial structure with osteoblasts or osteoblast progenitor cells followed by culture in vitro for several days to weeks prior to implantation.

An example of this technique that is presently used clinically is seeding Grafton DBM with bone marrow aspirate from the patient ex vivo followed by implantation of the Grafton DBM/bone marrow aspirate composite at the desired surgical site. This composite combines the osteogenic potential of the progenitor cells in the bone marrow aspirate with the osteoinductive and osteoconductive properties of the Grafton DBM and has shown to be comparable to an autograft in formation of bone at the surgical site (Lindsey et al., 2006).

Another example of a cell/biomaterial composite involves seeding a porous polymer scaffold created by additive manufacturing of poly(caprolactone) with fibroblasts transfected to express bone morphogenetic protein-7 (BMP-7) (Williams et al., 2005). The additive manufactured poly(caprolactone) scaffold provides a structure with millimeter-scale features that is mechanically adequate and osteoconductive, and the incorporation of the BMP-7-expressing fibroblasts makes the composite construct osteoinductive. However, the fibroblasts are not expected to differentiate to osteoblasts and consequently this composite is not osteogenic. A second example of composite scaffolds for bone tissue engineering involves the incorporation of a ceramic calcium phosphate with a polymer scaffold. This can be accomplished through several different methods such as suspension of calcium phosphate particles with the polymer phase prior to processing to form a scaffold, spontaneous formation of calcium phosphates within the polymer phase during processing, and coating of calcium phosphates on the surface of a biomaterial scaffold through soaking in simulated body fluid. For example, a composite created by incorporation of calcium phosphates with the polymer phase during processing is illustrated by electrospinning a slurry of β-tricalcium phosphate particles in dissolved poly(caprolactone) to create a scaffold consisting of nanofibers exhibiting β-tricalcium phosphate particles on the surface of the fibers. The incorporation of the β-tricalcium phosphate particles improves the mechanical properties of the nanofiber scaffold and may also improve the osteoinductivity of the scaffold; however,

an improvement in the osteoinductivity of the nanofiber/β-tricalcium phosphate composite has not been illustrated (Erisken et al., 2008).

A third example of a composite scaffold for bone tissue engineering involves the incorporation of growth factors with a polymer or ceramic scaffold. This concept was utilized when cross-linked poly(vinyl pyridine) microspheres containing either rhBMP-2 or rhBMP-7 were suspended in a poly(lactide-*co*-glycolide) (PLGA) foam. The concentration of the poly(vinyl pyridine) and the degree of cross-linking allowed for the staged release of rhBMP-2 and rhBMP-7. The rhBMP-2 was entrapped in lower concentration and less cross-linked microspheres and was released more rapidly than the rhBMP-7. The effect of this rhBMP microsphere-loaded PLGA foam was to increase the differentiation of bone marrow-derived mesenchymal stem cells in vitro as compared to the PLGA foam loaded with control microspheres not containing any rhBMPs. The results of this investigation are typical for what is expected by including BMPs in scaffolds and provides a strategy for making an osteoconductive scaffold osteoinductive as well (Basmanav et al., 2008). A critical issue with constructs containing growth factors, which is shared by growth factor strategies in general, is that they are prohibitively expensive for developing medical strategies to treat typically nonlife-threatening injuries. The foregoing examples of strategies for composite structures for bone tissue engineering represent only a small portion of the composite structures that have been investigated; however, these examples do provide an accurate representation of the desired outcomes in preparing composite structures for bone tissue engineering.

Porosity in Bone Graft Substitutes

An important characteristic of a successful biomaterial-based bone graft substitute that promotes all the features of the bone tissue-engineering paradigm involves the pore structure of the scaffold or construct. Without an adequate pore structure, migration into the scaffold is restricted, which subsequently limits the potential of the scaffold to be osteoconductive, osteoinductive, and osteogenic. The pore structure of the scaffold, both pore diameter and porosity, is a critical component in allowing cellular migration.

The concept of pore structure and cellular migration is similar across cell lines and as such this discussion focuses primarily on the characteristic dimension of the scaffold and the subsequent requirements to promote cell migration into the scaffold. For microscale scaffolds fabricated through techniques such as 3D printing/additive manufacturing, microsphere sintering, gas foaming, and particulate leaching the critical design aspects involve maintaining interconnected pores and pore diameters above 40 μm (Karageorgiou and Kaplan, 2005). An interconnected porosity is necessary to facilitate migration of cells throughout the scaffold as well as maintaining a supply of nutrients and removal of waste from the cells on the scaffold interior. It was found that scaffolds with large, 100–300 μm, pore diameters facilitated faster migration throughout the scaffold; however, despite the decreased rate of migration the lower, 40 μm, pore diameter scaffolds achieved the same level of cellular penetration as did those with the larger pore diameters (Karageorgiou and Kaplan, 2005).

When the characteristic dimension of the scaffold shrinks to the nanoscale these same concepts do not apply. No longer does pore diameter appear to be as influential, since nanofiber scaffolds fabricated from self-assembly and thermally induced phase separation have illustrated cell invasion into and throughout the interior of the scaffold despite pore diameters ranging from 300 nm to 10 μm (Brown et al., 2010; Silva et al., 2004). Two characteristics shared by both of these scaffold architectures are that they illustrate porosities greater than 95% and the fibers are randomly oriented in three dimensions. Likewise, electrospun nanofibers, which typically exhibit total porosities ranging from 40% to 75%, with isolated reports up to 90%, and pore diameters ranging from a few microns to 30 μm, have also exhibited cellular infiltration throughout the interior of the scaffold (Venugopal et al., 2007).

These results illustrating cellular migration into the small pores contradict that previously found for microscale scaffolds and consequently have raised questions regarding how cells are able to infiltrate nanoscale scaffolds. The ability of cells to infiltrate a nanoscale scaffold starts with a fundamental difference in how cells respond to nanodimensional surfaces. On nanostructures, cell morphology changes to exhibit pronounced pseudopodia-like processes, which extend along individual fibers (Long et al., 2019; Ozdemir et al., 2019). These extensions on randomly orientated fibers produce an image appearing to be a well-spread cell; however, it is important to consider that most imaging techniques depict a two-dimensional field when there is a third dimension not necessarily seen. This implies that cells are extending down into the field of view as much as they are extending out within the field of view and this theory has been corroborated through the use of confocal fluorescence imaging illustrating cells extending in three dimensions (Silva et al., 2004). These well-spread cells exhibiting pseudopodia-like processes have led researchers to conclude that cells utilize ameboidal migration to reach the interior of the scaffold (Friedl and Brocker, 2000). Presumably, this ameboidal migration is driven by soluble factors and proteins adsorbed to the surface of fibers below the cells providing a gradient and driving infiltration to establish a uniform density of cells throughout the construct. In conclusion, microscale scaffolds rely on pore diameter to allow cell migration, whereas nanoscale scaffolds rely on chemical gradients created by adsorbed factors and ameboidal motion to allow cell migration, which suggests that porosity is the critical property of nanoscale scaffolds.

Dimension in Bone Graft Substitutes

In addition to porosity, the characteristic dimension of a polymer scaffold can have tremendous implications on the

success of the scaffold as a bone graft substitute. Initially, the scaffold was viewed as a cell carrier and mechanical substitute; however, more recent research has demonstrated that the characteristic dimension of a scaffold can directly affect intracellular signaling leading to changes in gene expression, a process termed mechanotransduction. Mechanotransduction is defined simply as the process that converts a mechanical force into a biochemical signal (Eyckmans et al., 2011). Scaffold material stiffness and dimension both directly alter the mechanical state of a cell. Research has demonstrated that scaffolds that stimulate the signaling cascades leading to actomyosin contractility also promote differentiation of mesenchymal stem cells to bone tissue (Engler et al., 2006; Ozdemir et al., 2013). Specifically, both scaffolds mimicking the stiffness of osteoid matrix and nanofiber scaffolds presenting diameters of approximately 500–1000 nm promote RhoA activation, which leads to increased actomyosin contractility and bone differentiation. Furthermore, these nanostructured concepts can be applied to other surfaces such as Ti_6Al_4V implants for orthopedic applications (Fig. 2.6.6.5).

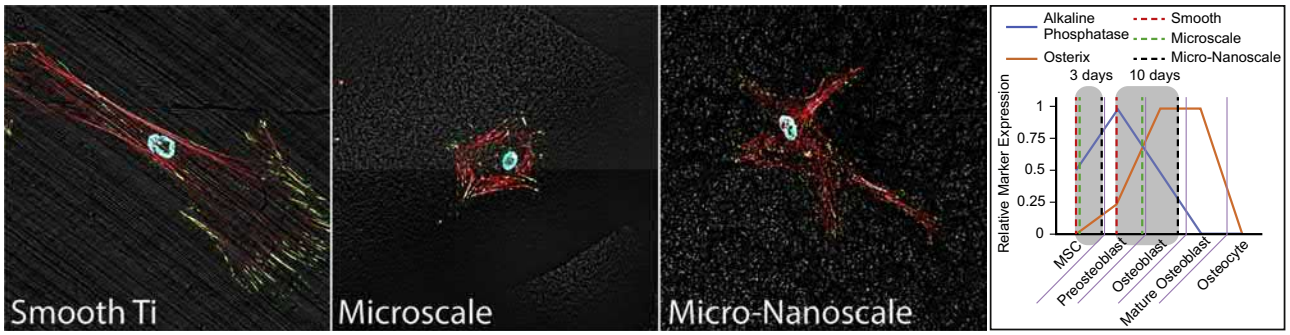
The following are detailed descriptions of two scaffold types with dramatically different characteristic dimensions. The first, sintered microspheres, demonstrates a characteristic dimension an order of magnitude larger than that of a cell; while the second, nanofibers, demonstrates a characteristic dimension two orders of magnitude smaller than that of a cell.

Sintered Microspheres

Sintered biodegradable microsphere scaffolds were first developed by Cato Laurencin's lab in 1996 and were composed of PLGA. These initial scaffolds were fabricated both with and without hydroxyapatite and exhibited mechanical properties and porosity suitable for bone tissue engineering (Devin et al., 1996). Since that time the microsphere scaffold has undergone several compositional iterations. Microsphere scaffolds have been fabricated from other types of biodegradable polyesters such as polylactide and poly(3-hydroxybutyrate-*co*-3-hydroxyvalerate) (Zhu et al., 2007). Sintered microsphere scaffolds have been fabricated from a polymer/ceramic composite microsphere composed of PLGA microspheres fabricated in such a way as to spontaneously induce calcium phosphate precipitation on the surface of the microspheres (Khan et al., 2004). Additionally, microsphere scaffolds can be combined with growth factors, as typical of most polymer scaffolds.

The tremendous interest in the sintered microsphere scaffold is due to it being advantageous over other microscale scaffolds produced by techniques such as gas foaming and porogen leaching. These advantages, which are shared with recent efforts in additive manufacturing technologies, are: reproducibility, scalability, and controllability over pore size, porosity, and mechanical properties. Microsphere scaffolds rely on the chemical properties of a polymer to sinter uniform spheres into scaffolds by elevating the polymer above the glass transition temperature, which causes the adjacent polymer chains to migrate and intertwine forming a cohesive bond when the polymer is cooled. Older techniques, such as gas foaming and porogen leaching, do not have the same level of reproducibility due to variation introduced by having multiple phases, either a heterogeneous mixture of a solid and liquid or a liquid and gas. These heterogeneous mixtures can undergo demixing, which introduces inconsistencies in the mixing of the phases and decreases reproducibility.

Microsphere scaffolds maintain a very high level of interconnectivity among the pores and allow control over the total interconnected porosity as well as the average pore diameter. Gas foaming and particle leaching provide control over the total porosity and pore size as well; however, they often have very poor interconnectivity, only 10%–30% interconnectivity with gas foaming, rendering a percentage of the pores inaccessible (Mooney et al., 1996). Another advantage of microsphere scaffolds compared to gas foaming and porogen leaching is that they can be fabricated to exhibit mechanical properties that mimic that of trabecular bone (Brown et al., 2010). High mechanical properties are



• **Figure 2.6.6.5** Fluorescent microscopy depicting mesenchymal stem cells (MSCs) stained for actin (red), nuclei (blue), and the focal adhesion protein vinculin (green) on Ti_6Al_4V that has been processed to be either smooth (Smooth Ti), demonstrate a characteristic dimension on the order of micrometers (Microscale), or demonstrate hierarchical micrometer- and nanometer-scale characteristic dimensions (Micro-Nanoscale). The representative MSCs shift from a fibroblastic elongated morphology on Smooth Ti to a cuboidal morphology on Microscale and a stellate, or star-shaped, morphology on Micro-Nanoscale. Furthermore, differentiation analysis reveals the introduction of Microscale and MicroNanoscale features increases the rate of differentiation through 10 days as compared to Smooth Ti (Long et al., 2019).

achievable; however, to achieve this the scaffold density must be increased, which causes the internal pore structure to be further compromised. Microsphere scaffolds composed of polylactide and PLGA have been produced previously and have yielded reasonable results in in vitro studies, as well as in in vivo studies examining critical size defect healing (Borden et al., 2004; Botchwey et al., 2001).

Nanofibers

Recent developments in tissue engineering have indicated that nanoscale structures are more advantageous for cellular phenotype expression and morphology when compared to microscale structures. A frequently employed type of nanoscale scaffold is based on polymeric nanofibers. Nanofibers can be fabricated through several different techniques. The initial and most common technique is through electrospinning, which has been in use for over 80 years (Formhals). Electrospun nanofibers are created by applying a voltage gradient between a target and a drop of polymer, either dissolved or melted. Once the voltage gradient overcomes the surface tension of the droplet a polymer stream extends toward the target. As this stream travels, it is thinned out and eventually strikes the target as a nanofiber with the accumulation of these fibers leading to the production of a nonwoven nanofiber mat.

Initially, electrospun nanofibers were made from nondegradable polymers for applications in filtration; however, recent developments have led to the use of electrospun nanofibers made of biodegradable polymers for tissue-engineering applications, such as poly[(amino acid ester) phosphazenes] (Kumbar et al., 2006). Nanofibers created by electrospinning typically have diameters ranging from 300 to 1200 nm depending on the spinning conditions used. Electrospun nanofibers are oriented lengthwise in only two dimensions with the third dimension created from the stacking of the fibers on top of each other. Recent efforts have sought to couple additive manufacturing technologies, such as 3D printing, with electrospinning processes (Fattahi et al., 2017). Nanofibers have also recently been developed using synthetic peptides designed to self-assemble into a 3D nanofiber network. Self-assembled nanofibers often have a characteristic diameter that is within the range of 5–10 nm (Zhang, 2003). The very thin diameter of the fibers in the network and the high porosity created with self-assembly produces a scaffold poor in mechanical properties making them suitable primarily for hydrogel applications.

A final method of nanofiber fabrication is thermally induced phase separation, which relies on the spinodal liquid/liquid phase separation of a polymer solution into a polymer-poor phase and a polymer-rich phase when the solution is rapidly cooled. Spinodal phase differs from binodal phase separation in that the two phases separate and exist continuously throughout the original mixture, whereas bimodal phase separation occurs via nucleation sites that build spherical particles. The selection of an appropriate polymer, one with a high degree of crystallinity, will allow the polymer-rich phase to crystallize into nanofibers, whereas polymers with low degrees of crystallinity form microstructured foams (vandeWitte et al., 1996). Nanofibers created with the thermally induced phase separation technique exhibit a fiber diameter of 50–500 nm, which is similar to collagen, and a 3D fiber structure making them very different from electrospun nanofibers (Hu et al., 2008). These evaluations suggest that nanofibers exhibiting a 3D spatial arrangement promote phenotype progression of osteoblasts and may be osteoinductive. Additionally, complexes of microspheres with nanofibers to create a 3D nanofibrous mechanically viable implant has been demonstrated (Brown et al., 2010).

In Vitro Culture Techniques for Bone Graft Substitutes

A critical limitation of static culture conditions is that waste efflux and nutrient influx are governed by diffusion, which becomes exponentially more problematic with large 3D constructs. As time passes, the accumulation of waste within a construct can lead to an acidic microenvironment that impedes calcification of the developing tissue and compromises the viability of osteoblasts within a construct. To alleviate these issues the use of bioreactors becomes necessary when trying to achieve significant tissue growth in vitro. The bioreactor provides fluid flux that replenishes nutrients and removes waste; additionally, for tissues such as bone, bioreactors can provide mechanical stimulation to encourage the development of a mechanically viable tissue.

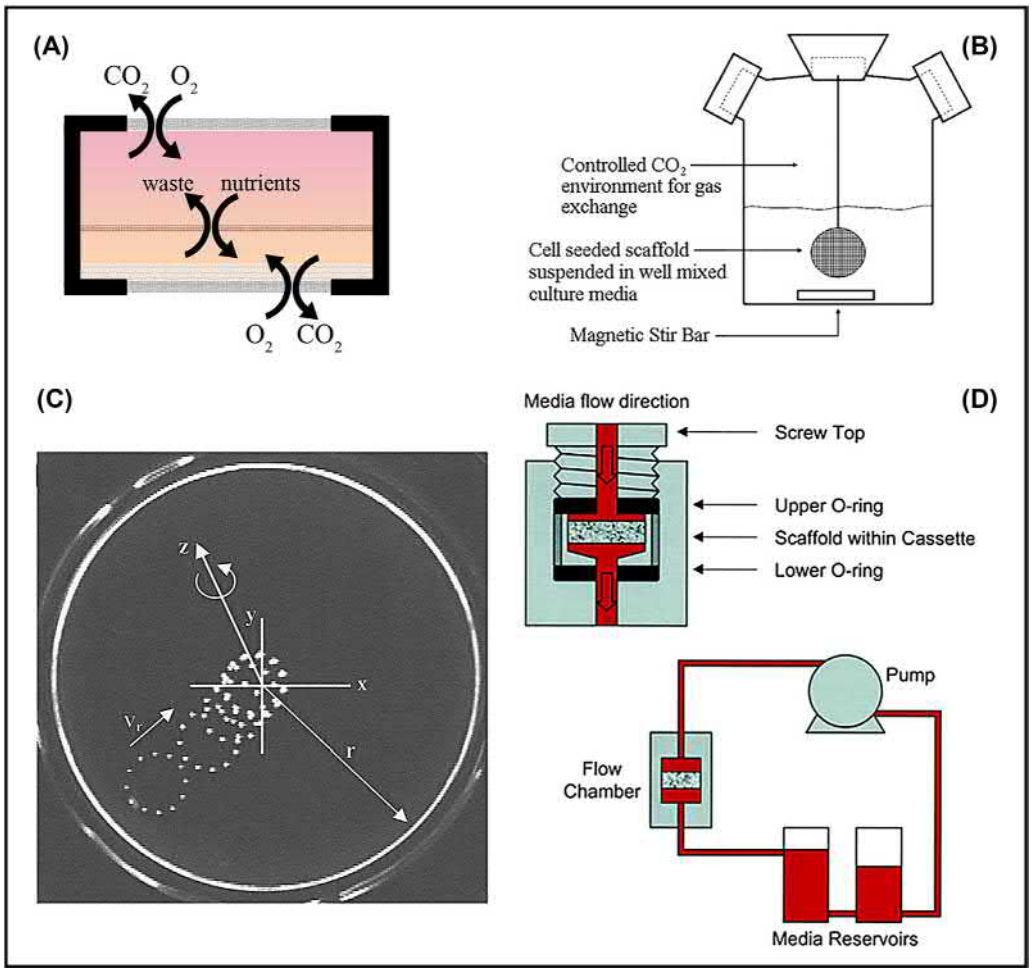
The earliest bioreactor that has been applied to bone tissue engineering involves dialysis membranes that are either gas or small molecule permeable. The bioreactor is divided into two compartments that are separated by a small molecule permeable membrane and each compartment also contains a gas permeable membrane (Vogler, 1989). The gas permeable membrane provides a liquid/air boundary to provide oxygen and CO_2 and the membrane between compartments serves as a liquid/liquid boundary between the culture medium surrounding the cells and a reservoir of fresh medium. This boundary provides fresh nutrients while removing waste, but also allows the soluble factor gradients to remain intact during media changes. Recently, this bioreactor design has supported the development of simple osteoid tissue after culturing osteoprogenitor cells for 10 months. Despite the development of osteoid tissue this bioreactor design still relies on passive diffusion to supply nutrients and therefore limits the ultimate thickness of the construct to only a few cell layers (Mastro and Vogler, 2009).

The next iteration of the bioreactor involved rotation, either of the reactor itself or of the construct within the bioreactor. NASA developed rotating wall bioreactors to simulate microgravity. These bioreactors consist of a cylinder and a gas exchange membrane either on one face of the cylinder or as a separate inner cylinder. In this design the shear force exerted by fluid rotation negates the effect of gravity on the constructs and also provides a well-mixed volume of culture medium. This strategy was employed by tissue engineers to culture constructs seeded with osteoblasts in the hope that

the rotating well-mixed volume of culture medium would overcome diffusion limitations and allow tissue development throughout the thickness of the construct (Botchwey et al., 2004). Research suggests this is certainly the case, with osteoblasts found throughout the thickness of the construct; however, the simulation of microgravity seems to discourage bone tissue development (not surprisingly due to a lack of mechanical stimulation). This is demonstrated by both lower levels of phenotype markers and less mineralization as compared to static cultured constructs (Yu et al., 2004).

The next type of bioreactor involving rotating fluid is the spinner flask. Spinner flask bioreactors suspend the constructs on thin needles that are extended into a stirred flask of media. This configuration not only provides a well-mixed environment to avoid accumulation of waste in the local environment of the construct, but also provides mechanical stimulation through shear forces on the constructs. Since the spinner flask also provides a well-mixed environment, it is not surprising to see that cells migrate throughout the construct suspended in the spinner flask similar to those cultured in rotating wall bioreactors. Additionally, because the spinner flask provides much higher shear forces than the rotating wall bioreactor, there is a marked increase in the calcification of the construct and the differentiation of osteoblasts in the spinner flask (Stiehler et al., 2009).

The final bioreactor for bone tissue engineering is a perfusion bioreactor. The perfusion bioreactor works by forcing culture media through a construct with a pump. This system provides control over the shear experienced by the cells in culture. Similar to the spinner flask, osteoblasts generated more calcium and exhibited increased expression of phenotype markers in the perfusion bioreactor (Gomes et al., 2003). Fig. 2.6.6.6 presents a graphical depiction of these bioreactor types.



• **Figure 2.6.6.6** Graphical depiction of four bioreactors. The simplest bioreactor that supports multilayered growth of cells on the bottom surface and consists of two gas permeable membranes on the top and bottom and a dialysis membrane in the middle (A). A spinner flask bioreactor that utilizes a stir bar to force nutrient flux through the constructs, which remain in a fixed position (B) (Martin and Vermette, 2005). A high aspect ratio rotating vessel bioreactor demonstrating the trajectory of a lighter than water construct within the rotating wall bioreactor; the fluid shear on the scaffold is low. However, the back panel of the bioreactor is a gas permeable membrane and the rotation maintains a large volume of well-mixed media to support nutrient supply (C) (Botchwey et al., 2004). Finally, a schematic illustrating a perfusion bioreactor that utilizes a pump to force media through a construct, which research suggests also promotes bone tissue formation through mechanical stimulation provided by fluid shear forces on the construct (D) (Gomes et al., 2003).

Conclusion

The concepts of tissue engineering have made profound advances in developing clinically relevant solutions for tissues such as skin, bladder, and to some extent bone. However, where the clinical strategies for skin and bladder exist as a straightforward solution based on the requirements of those tissues, bone presents a more complicated situation. Skin and bladder tissue are essentially a uniform 2D sheet, whereas bone often takes many unusual 3D and nonuniform geometries.

The evolution of bone tissue engineering began with osteoblasts cultured on rudimentary polymer foams and has progressed to include an array of bone graft substitutes cultured with mesenchymal stem cells in bioreactors to drive the development of de novo bone tissue. Significant clinical achievements have occurred in using biodegradable scaffolds with or without growth factors or cells as synthetic bone grafts to heal large defects in bone tissue. However, despite the ground that has been covered thus far, there persist unmet goals and challenges ahead. No research has yet demonstrated the capability to grow de novo bone in an in vitro setting; so far only rudimentary calcified cell masses approaching bone tissue have been developed. Moving forward, future researchers should consider the flexibility in design of the macroscale structure to accommodate the unusual architectures and mechanics necessary for bone graft substitutes, the biodegradability of the structure such that natural healthy bone is ultimately all that persists, the osteoconductivity of the bone graft substitute to promote proliferation of progenitor cells and osteoblasts throughout the bone graft substitute, and the osteoinductivity of the bone graft substitute to promote the differentiation of the mesenchymal stem cells to osteoblasts into eventually organized bone tissue.

To date, the one aspect that the earliest bioreactor managed to get right has been lacking in all future designs: the ability to maintain gradients in soluble growth factors secreted by cells. The development of the bioreactor for bone tissue engineering has moved from a series of static chambers separated by dialysis membranes to reactors that provide mechanical stimulation. Future successful bioreactors will depend on the ability to incorporate aspects of existing bioreactors: nutrient influx, waste efflux, mechanical stimulation, and the establishment of soluble factor gradients. Providing all four of these bioreactor elements with a bone graft substitute may lead to the development of hierarchical bone tissue and ultimately the de novo formation of bone in vitro.

Biomaterials for Cardiovascular Tissue Engineering

JENNIFER L. WEST

Duke University, Durham, NC, United States

Cardiovascular tissue engineering offers potential solutions in a variety of clinical conditions such as heart failure, atherosclerosis, myocardial infarction, valve disease, congenital heart defects, and vascular access. While this represents a wide variety of applications, there are significant commonalities across the tissue types in the cardiovascular system that impact approaches to the development of engineered tissues. For example, endothelial cells that line the entire cardiovascular system change function under different shear stress conditions, while vascular smooth muscle cells respond to cyclic strain. This chapter discusses the tissues and cells that comprise the cardiovascular system as well as optimization of biomaterials for these tissue-engineering applications.

Introduction

When selecting or developing biomaterials to use as scaffolds in cardiovascular tissue engineering, all of the design parameters that would broadly apply in tissue engineering need to be considered—biocompatibility, appropriate biodegradation, the ability to homogeneously seed cells throughout the scaffold, and maintenance of requisite cell function. Scaffold materials used in cardiovascular tissue engineering usually need to be compatible with culture in bioreactor systems. In addition, there are some unique aspects of cardiovascular tissues, such as control of thrombosis and mechanical sensitivity of vascular cells, that introduce additional criteria for an optimal scaffold material. In order to understand these design constraints, let's first develop your understanding of the tissues and cells of the cardiovascular system.

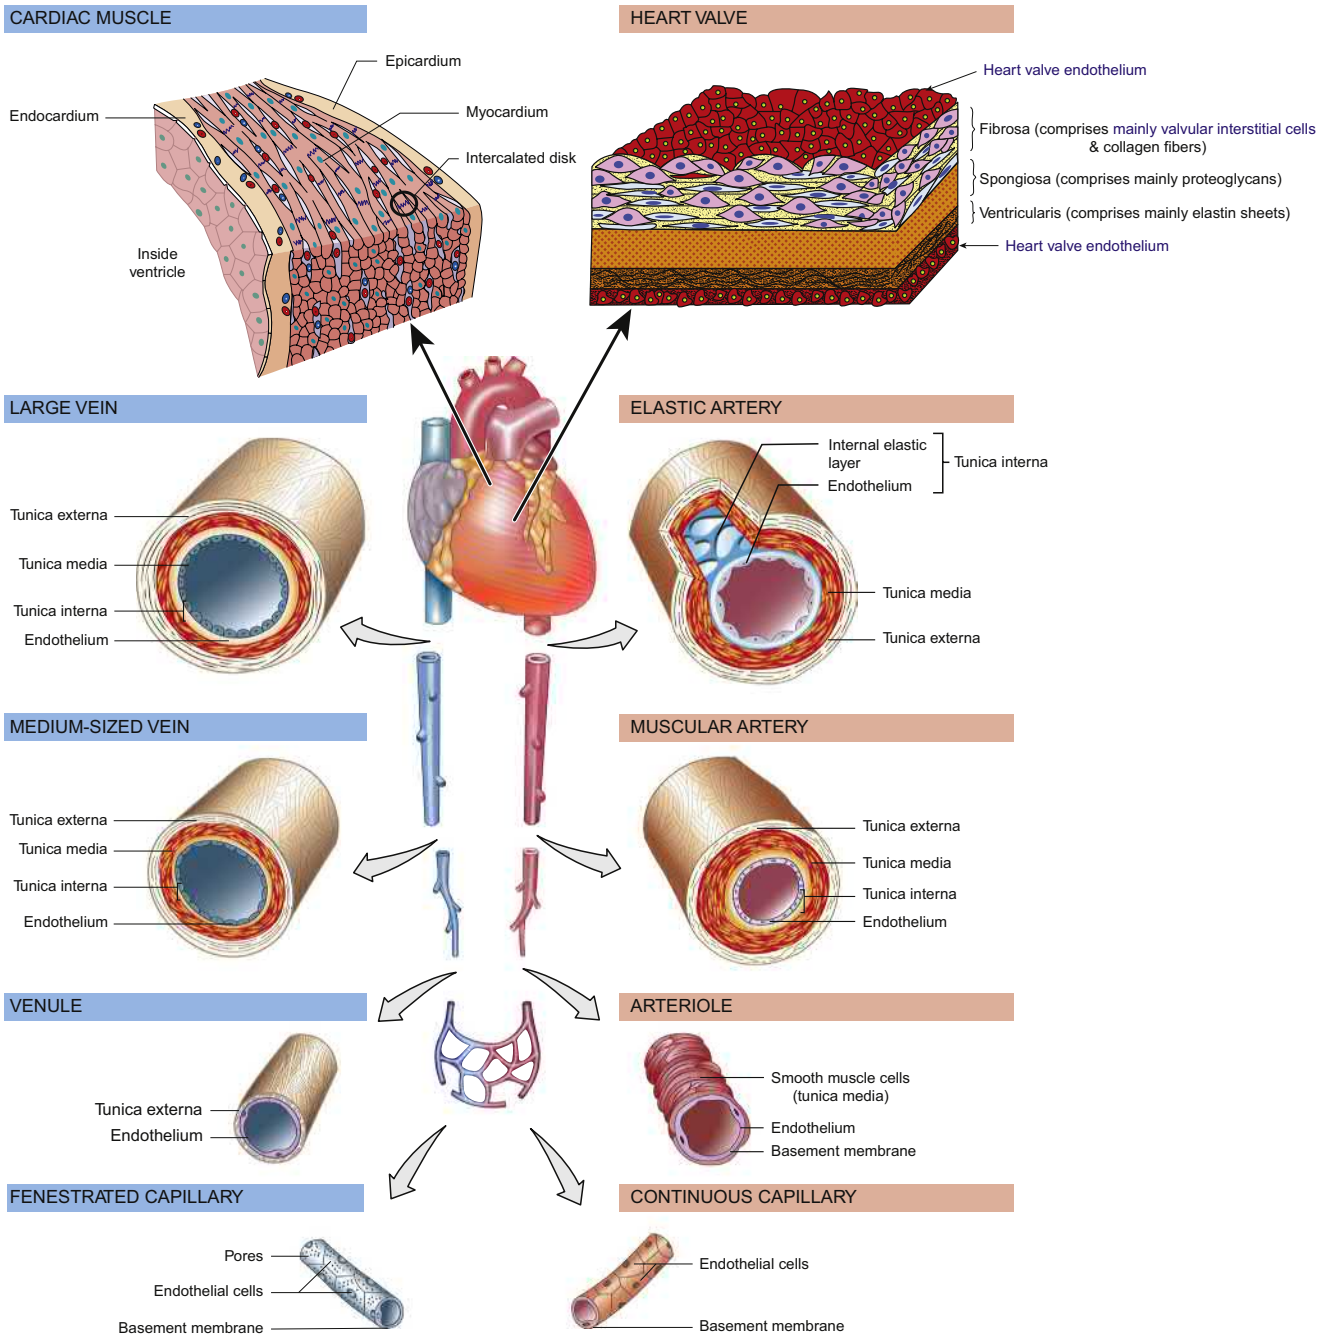
As shown in Fig. 2.6.7.1, the cardiovascular system includes the heart (including both the heart wall and the valves) and blood vessels (including arteries, arterioles, capillaries, venules, and veins). The entire cardiovascular system is lined with a monolayer of endothelial cells. These are critical to prevention of thrombosis and to vascular homeostasis. The entire cardiovascular system also includes muscle or muscle-like cells. These include cardiomyocytes in the heart wall, valve interstitial cells for heart valves, vascular smooth muscle cells in the blood vessels, and pericytes in capillaries.

Endothelial Cells

As stated above, endothelial cells line the blood-contacting surfaces of the entire cardiovascular system and are critical to both prevention of thrombosis and vascular homeostasis. Endothelial cells actively produce antithrombotic factors such as nitric oxide (NO), prostacyclin, plasminogen activators, and thrombomodulin (Cines et al., 1998). Endothelial cell surfaces also display a thromboresistant glycocalyx, a dense layer of polysaccharides attached to the membrane (Sieve et al., 2018). Endothelial-derived NO also has a critical function in maintaining other vascular cells (namely smooth muscle) in a quiescent state (Bian et al., 2008; Lloyd-Jones and Bloch, 1996). Endothelial cells are highly responsive to shear stresses at their surface (normally in the range of 5–20 dyne/cm^2), and are typically aligned in the direction of shear (Nerem, 1993; Nollert et al., 1992). Abnormal shear stress environments can lead to loss of appropriate endothelial cell function, and thus adverse events like thrombosis. A complete and functional endothelial monolayer is likely required for success in any cardiovascular tissue-engineering application.

Cardiac Muscle

Tissue-engineered cardiac muscle (heart wall) is being explored to treat damage from myocardial infarction, heart failure, and a variety of congenital heart defects. The myocardium is composed primarily of multinucleated cardiomyocytes, and the interior surface is a monolayer of endothelial cells. The organization of cardiac muscle is highly anisotropic. Cardiomyocytes are highly elongated

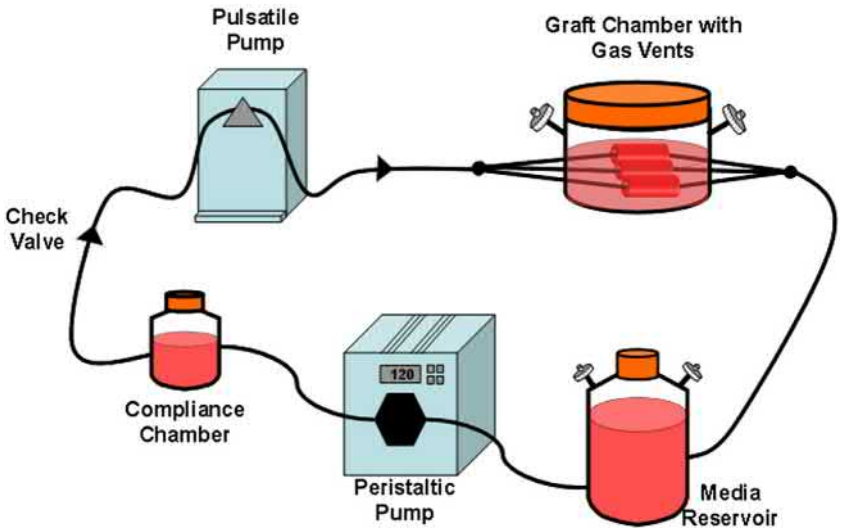


• **Figure 2.6.7.1** The cardiovascular system includes the heart and the network of systemic blood vessels. The entire system is lined with endothelial cells, critical to the prevention of thrombosis and maintenance of vascular homeostasis. Tissues where engineered replacement are needed include cardiac muscle, heart valves, and blood vessels.

and align relative to one another in the heart wall, with structural and electrical connections between cells to enable coordinated and effective contractions of the tissue. Intercalated disks (Fig. 2.6.7.1) formed between cardiac myocytes are critical in enabling electrical signals to be transmitted at appropriate speed and with directional control and also in allowing transmission of forces during contraction (Veeraraghavan et al., 2014). Additionally, because of the metabolic demands associated with its contractile activity, cardiac muscle has dense capillaries. Efforts to engineer cardiac muscle will likely require construction of a functional microvasculature in the engineered tissue or rapid induction of in-growth of host vasculature.

Heart Valves

Tissue-engineered heart valves are being explored as options for repair of congenital defects or for treatment of valve disease. As shown in Fig. 2.6.7.1, the valve leaflet has three layers, with endothelial cells covering the outer surfaces.



• **Figure 2.6.7.2** Example design of a pulsatile flow bioreactor for culture of tissue-engineered blood vessels. The cell-seeded scaffolds are placed into the graft chamber, where they are bathed in cell culture media while additional cell culture media is pumped through the lumen of the vessel. Physiological flow and pressure profiles can be achieved, providing the cells on the scaffold with mechanical conditioning to optimize tissue formation.

The cells within the leaflet are referred to as valve interstitial cells (VICs). VICs actively remodel the extracellular matrix (ECM) that dominates the valve structure, allowing the tissue to remain mechanically functional without experiencing fatigue failure with about 40 million cycles per year (Grande-Allen and Liao, 2011; Ayoub et al., 2016; Cirka et al., 2015). Deposition and organization of new ECM by VICs has been shown to respond to mechanical forces (Ayoub et al., 2016). While the underlying biology of VICs is not well studied, they display some similarities to both vascular smooth muscle cells and to fibroblasts (Grande-Allen and Liao, 2011; Cirka et al., 2015), and when VIC phenotype is not appropriately controlled, calcification and fibrosis may result (Cirka et al., 2015).

Blood Vessels

Tissue-engineered blood vessels are being explored for use as vascular grafts, especially in small-diameter applications where synthetic grafts typically fail, and also as arteriovenous grafts for hemodialysis access. As shown in Fig. 2.6.7.1, vessels on both the arterial and venous sides of the vascular tree have distinctly layered structures, with differences between vessel types based primarily on differences in the thickness of the layers. All of the vessels possess an endothelial cell lining, with the layer referred to as the tunica intima. Below the endothelial lining there is a layer referred to as the tunica media or the medial layer. The tunica media is composed of vascular smooth muscle cells (SMCs) and an elastin-rich ECM, with both the SMCs and elastin aligned circumferentially. SMCs require physiologic cyclic strains for optimal alignment and function (Haga et al., 2007; Chan-Park et al., 2009). Additionally, SMCs can be in either a contractile or synthetic phenotype (Chan-Park et al., 2009). During initial formation of an engineered tissue, a proliferative synthetic phenotype can be advantageous, but for long-term success, a quiescent contractile phenotype is needed. Signaling between endothelial cells and SMCs is important for regulation of the SMC phenotype and tissue homeostasis (Chan-Park et al., 2009). Most approaches to tissue engineering of blood vessels have focused on creating the intimal and medial layers, as these are clearly required to have a functional blood vessel. Some efforts also add the tunica externa (also called the adventitia), a fibroblast-rich connective tissue that further supports the structure.

Scaffold Materials

As discussed above, the cell types employed in cardiovascular tissue engineering are highly responsive to mechanical conditioning, and because of this, most engineered tissues in this field are grown in various types of flow bioreactors that can generate appropriate shear stresses and cyclic strains (Mironov et al., 2006; Freed et al., 2006; Huang and Niklason, 2014). An example of a typical bioreactor used for tissue engineering of blood vessels is shown in Fig. 2.6.7.2, where pulsatile flow of cell culture media through the lumen of the vessel creates shear stress at the intimal surface and cyclic strain across the vessel wall (Hahn et al., 2007). To realize the benefits of mechanical conditioning in bioreactors, it is important to use materials that allow appropriate transmission of forces through the structure, giving preference to soft, elastic materials, ideally with properties approximating those of cardiovascular tissues. Note that bioreactors for cardiac tissue engineering will sometimes also include electrical stimulation (Radisic et al., 2004), so integration of electrodes may also be necessary. In order to achieve these goals, while also having appropriate biocompatibility and biodegradation, efforts have largely focused on protein hydrogels, synthetic biodegradable polymers,

and synthetic biodegradable hydrogels. Decellularized tissues have also been explored as scaffold materials. Additionally, it is important to have materials that support the formation of an endothelial cell monolayer at the blood-contacting surface. Scaffold design strategies to promote endothelialization are also discussed below.

Protein Hydrogels

Protein hydrogels such as collagen gels and fibrin gels have been employed in numerous cardiovascular tissue-engineering studies (Zhang et al., 2015; Reis et al., 2016; Barsotti et al., 2011). These types of materials are very supportive of cell attachment and growth, providing ligands for integrins and other cellular receptors. These scaffold materials are biodegraded by cells using natural proteolytic mechanisms, such as matrix metalloproteinases (MMPs) or plasmin, linking the rate of biodegradation to cellular activity within the scaffold. Fabrication of these gels into appropriate shapes is also straightforward, essentially just pouring liquid precursors into molds, and homogeneous cell seeding can be achieved by mixing cells with the aqueous gel precursor solution. In most cases, these protein hydrogels experience very significant contraction by cells growing within them, reducing dimensions by as much as 90% (Schutte et al., 2010; Tranquillo et al., 1996; Weinberg and Bell, 1986).

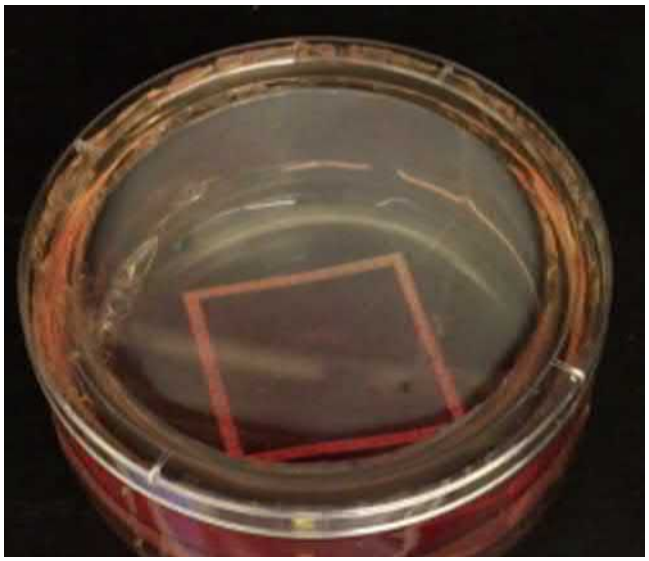
Pioneering work by Weinberg and Bell utilized collagen gel scaffolds to form the first tissue-engineered blood vessels (Weinberg and Bell, 1986). This was accomplished by casting SMCs and collagen in an annular mold, allowing gelation of the collagen to form the medial layer of the tissue-engineered blood vessel. Later, an adventitial layer of fibroblasts was added, and after further culture, endothelial cells were seeded on the inner luminal surface to form the intimal layer. Collagen gels have also been used as scaffolds for tissue-engineered myocardial patches (Costa et al., 2003; McCain et al., 2014; Sun et al., 2017) and tissue-engineered heart valves (Gupta et al., 2007; Neidert and Tranquillo, 2006).

Collagen gels are formed by neutralizing an acidic solution of collagen, initiating fibrillogenesis that will induce gelation at sufficient collagen concentrations (Weinberg and Bell, 1986). The mechanical properties of collagen gels depend on the concentration of collagen in the precursor solution, but can be further enhanced via chemical cross-linking with agents such as formaldehyde or glutaraldehyde, though these can compromise the viability of encapsulated cells (Huang and Niklason, 2014; Charulatha and Rajaram, 2003). Lysyl oxidase (Elbjeirami et al., 2003) and glycation cross-linking (Girton et al., 1999) have been investigated as more cell-compatible methods. Even with covalent cross-linking, the mechanical properties of collagen gels may be too weak to withstand culture conditions in bioreactor systems, so in some cases "support sleeves" have been added to the design to help prevent rupture of engineered vessels (Schutte et al., 2010; Berglund et al., 2003).

Fibrin gels have similarly been utilized as scaffolds to form tissue-engineered blood vessels (Gui et al., 2014; Yao et al., 2008; Syedain et al., 2011), heart muscle (Bian et al., 2014; Jackman et al., 2016; Shadrin et al., 2017), and heart valves (Moreira et al., 2016; Weber et al., 2015; Robinson et al., 2008). Fibrin gels are formed by mixing fibrinogen with thrombin and calcium to induce cleavage of fibrinogen to fibrin and allow ensuing assembly into fibers (Barsotti et al., 2011; Shaikh et al., 2008). At sufficient concentrations of fibrinogen, fibrillogenesis will result in gel formation. This is the same process observed in coagulation to form a fibrin clot, a material that also serves as a natural, provisional matrix in wound healing. The thrombin treatment that induces gelation is highly cell-compatible, so cells can be added to the fibrinogen solution for homogeneous encapsulation in the ultimate gel material (Barsotti et al., 2011; Shaikh et al., 2008). Similar to collagen gels, fibrin gels have very weak mechanical properties and sometimes require reinforcing materials (Moreira et al., 2016). Fig. 2.6.7.3 shows a fibrin gel seeded with human induced pluripotent stem cell-derived cardiomyocytes that will form a cardiac patch following 5 weeks in culture. The resultant patches have been implanted epicardially in nude rats where, after 3 weeks, they exhibited survival and electrical function but lacked electrical integration with the host heart (Shadrin et al., 2017).

Decellularized Tissues

More recently, there has been substantial interest in using decellularized tissues as scaffolds in cardiovascular tissue engineering (Taylor et al., 2018). Compared to the simple protein gels described above, decellularization of tissue leaves the extracellular matrix largely intact, providing a complex composition and architecture. Decellularization can include physical methods, such as freeze–thaw cycling, pressure and supercritical fluids, and/or chemical methods, such as enzymes and detergents



• **Figure 2.6.7.3** Stem cell-derived cardiomyocytes growing within a fibrin gel scaffold to form a 4 × 4 cm cardiac patch. The fibrin gel is surrounded by a Cerex frame for support of auxotonic tissue loading. The resultant cardiac patches can be implanted on the surface of the heart to compensate for damage. (Photo courtesy of Dr. Nenad Bursac.)

(Taylor et al., 2018). Approaches can use relatively simple and widely available extracellular matrices, like decellularized small intestine submucosa (Badylak et al., 1989), or organ-specific decellularized tissues, like decellularized heart (Ott et al., 2008). In a landmark study by Taylor et al., a coronary perfusion process was developed to decellularize cadaveric hearts and then repopulate the structure with neonatal cardiac cells (via intramural injection) and endothelial cells (via perfusion) (Ott et al., 2008). These recellularized heart tissues were cultured in a perfusion bioreactor with electrical stimulation for up to 28 days. By day 8, these constructs demonstrated some electric and contractile responses. Perfused endothelial cells were able to line the coronary vessels and ventricles. While additional developments are needed, this is a promising avenue for whole-heart tissue engineering.

Synthetic Polymers

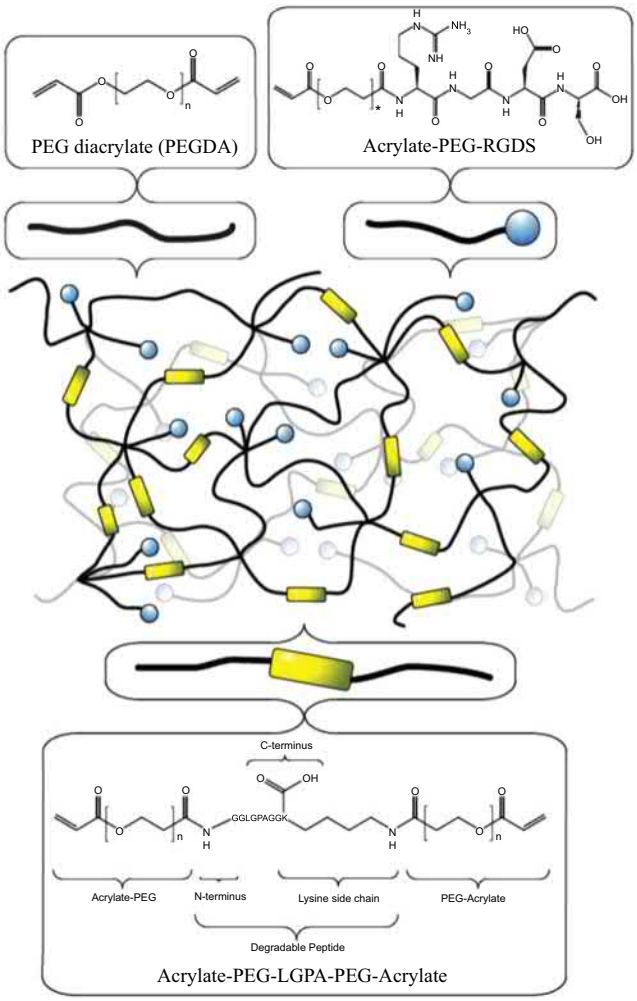
Some of the earliest efforts in cardiovascular tissue engineering utilized porous polyester scaffolds such as poly(caprolactone), poly(glycolic acid) (PGA), poly(lactic acid) (PLA), and copolymers thereof (PLGA). These have been used as scaffolds for tissue-engineered blood vessels (Niklason et al., 1999), heart valves (Shinoka et al., 1995), and cardiac muscle (Bursac et al., 1999). These materials provide tunable hydrolytic degradation rates, production of nontoxic (though acidic) degradation products, and the ability to fabricate interconnected pore networks to allow cell seeding. Pore networks are most commonly formed using porogen processing, such as incorporation of salt crystals in the polymer melt, followed by leaching of the salts from the solidified polymer matrix upon immersion in water (Mikos et al., 1993). Gas foaming (Zhu et al., 2008), electrospinning (Li et al., 2002), and 3D printing (Lee et al., 2008) can also be utilized to generate porous networks. Pore sizes in the range of hundreds of microns are generally required for efficient cell seeding, accomplished by infusing a cell suspension through the porous network.

The first report of in vivo assessment of a tissue-engineered vascular graft utilized a PGA mesh scaffold (Niklason et al., 1999). In this effort, PGA mesh scaffolds were sewn into a tubular form using Dexon sutures. Vascular smooth muscle cells were seeded onto the scaffolds, and the constructs were then grown in a pulsatile flow bioreactor for 8 weeks. Endothelial cells were then introduced to the flow system and allowed to adhere to the inner surface of the graft. The resultant tissue-engineered vascular grafts exhibited burst strength akin to saphenous vein grafts, and after implantation in a Yucatan miniature pig, graft patency (maintenance of blood flow) was observed. A key limitation of these scaffolds was their poor elasticity. As a result of the material mechanical properties, there was very little strain transmitted across the graft wall, limiting the mechanical conditioning experienced by the smooth muscle cells growing in the scaffold, especially during early phases of tissue growth before the biodegradable polymer was replaced by cell-secreted extracellular matrix.

Similar scaffold materials have also been employed in cardiac muscle tissue engineering (Bursac et al., 1999). Because alignment of cardiomyocytes is critical to development of a functional tissue substitute, techniques to produce scaffolds with aligned topographical cues have been of interest. For example, electrospinning can be used to form nanofibrous scaffolds of polymers like PLA, PGA, or PLGA, and it is possible to create alignment of the fibers in the scaffold by spinning fibers onto a rotating mandrel (Zhu et al., 2010; Streeter et al., 2019) or through postprocessing uniaxial stretching (Zong et al., 2005). When neonatal rat cardiomyocytes were seeded onto electrospun scaffolds, comparing scaffolds with random fiber orientations to ones with very high fiber alignment, it was found that while the cells attached, grew, and exhibited sarcomeres and intercalated disks on the random scaffolds, the oriented scaffolds seemed to provide guidance to the cells, resulting in an organized and aligned cell population (Zong et al., 2005). Others found that alignment of electrospun PLA scaffolds also enhanced production of α-actinin and troponin I (Liu et al., 2017).

Polyester scaffolds were also investigated as scaffolds for tissue-engineered heart valves (Shinoka et al., 1995; Breuer et al., 1996; Shinoka et al., 1996). In these studies, tissue-engineered heart valve leaflets prepared with PGA and PLA scaffolds were implanted in lambs for up to 11 weeks. Unfortunately, only single leaflets could be tested, as the stiffness of the scaffold material made it impossible to create a functional trileaflet valve replacement. The stiffness of PLA and PGA would also limit appropriate conditioning in a bioreactor system. The bending motion of the heart valve occurs in response to pressure differentials across the valve and the anisotropic material properties of the valve tissue. In order to achieve appropriate bending behaviors, tissue engineers have investigated several alternative porous synthetic polymer scaffold materials with improved pliability, such as poly(hydroxyalkanoate), a biodegradable elastomer (Sodian et al., 2000). Tissue-engineered trileaflet heart valves formed with PHA scaffolds, sequentially seeded with myofibroblasts and endothelial cells, and cultured in a pulsatile flow bioreactor were implanted in the pulmonary position in lambs for up to 20 weeks. The valves remained mobile and functional without signs of stenosis, thrombosis, or aneurysm. The valves had a confluent endothelial lining on the surface, and the PHA had fully degraded and been replaced with cell-secreted extracellular matrix proteins.

There remains significant need for new biodegradable elastomers for use as scaffolds in cardiovascular tissue engineering to provide biocompatibility, tunable biodegradation rates, and also elasticity and compliance closer to native cardiovascular tissues. Examples of emerging biodegradable elastomers include poly(glycerol sebacate) (Wang et al., 2002), poly(1,3-diamino-2-propanol-copolyol sebacate) (Bettinger et al., 2008), and poly(diol citrate) (Yang et al., 2005), and biodegradable polyurethanes are also being developed (Hung et al., 2014; Guelcher, 2008; Hao et al., 2016). These new materials offer mechanical performance better suited to cardiovascular tissue-engineering applications.



• **Figure 2.6.7.4** When designing a biodegradable and cell-adhesive synthetic hydrogel, a bioinert material such as PEG can be modified to include degradation sites (yellow) in the backbone of the hydrogel network as well as grafted cell adhesion ligands (such as RGDS, blue). Degradation sites could include hydrolytically degradable blocks, such as oligo (lactic acid), or proteolytically degradable peptides (such as LGPA) for cell-mediated degradation. Cross-linkable groups such as acrylates at the termini of the individual polymers allow conversion of aqueous polymer solutions into 3D hydrogels under conditions mild enough for cell encapsulation.

Synthetic Hydrogels

Alternatively, synthetic hydrogel materials have also been investigated for use as flexible and elastic scaffold materials in cardiovascular tissue engineering. Synthetic hydrogels are formed by cross-linking of hydrophilic polymers such as poly(ethylene glycol) (Mann et al., 2001) or poly(vinyl alcohol) (Schmedlen et al., 2002). Often, cross-linking conditions are mild enough to be carried out in the presence of cells, allowing the cell suspension to be mixed with the hydrogel precursors for homogeneous incorporation of cells throughout the hydrogel material (Mann et al., 2001; Schmedlen et al., 2002). Most synthetic hydrogels are very bioinert, so it is usually necessary to modify the materials to enable biodegradation and cell adhesion (Nguyen and West, 2002). As shown in Fig. 2.6.7.4, these goals can be accomplished by including degradation sites, such as proteolytically degradable peptides or hydrolytically degradable polyester blocks, into the backbone of the hydrogel network and grafting cell-adhesive peptides to the hydrogel network. Additionally, when the hydrogel scaffold provides a bioinert background with little or no protein adsorption, cell attachment to the hydrogel is limited to the cell adhesion sequences specifically and intentionally added to the material. This can allow one to select cell-adhesive ligands that interact with a desired cell type, such as endothelial cells, but not undesired cell types such as platelets or fibroblasts. Examples of cell-adhesion peptides that favor adhesion of endothelial cells include REDV (Hubbell et al., 1991), YIGSR (Jun and West, 2005), TPSLEQRTVYAK (Li et al., 2013), CRKRLQVQLSIRT (Puperi et al., 2015), and CRRETAWAC (Bastijanic et al., 2016). Finally, while most synthetic hydrogels have substantially greater mechanical integrity than collagen and fibrin gels, they are mechanically weak.

Hydrogels formed from acrylate-terminated derivatives of PEG have been used as scaffolds for both tissue-engineered blood vessels (Hahn & et al., 2007) and heart valves (Puperi et al., 2015; Durst et al., 2011; Zhang et al., 2015). In these studies, the hydrogel scaffolds were modified to be proteolytically degradable and cell adhesive. When tissue-engineered vascular grafts formed with these hydrogel scaffolds were cultured in pulsatile flow bioreactors with pressure waveforms ranging from a minimum of 80 to maximum of 125 mmHg, cyclic strains across the vessel wall ranged from 3% to 11%, depending on the hydrogel formulation, closely mimicking the transmission of strain across vessel walls in vivo (Hahn et al., 2007). Fig. 2.6.7.5 shows these hydrogel scaffolds formed into tubes and mounted into the graft culture chamber of a pulsatile flow bioreactor.

• **Figure 2.6.7.5** Vascular SMCs were encapsulated in hydrogel scaffolds fabricated into tubes using annular molds during cross-linking. These constructs are mounted in the graft chamber of a pulsatile flow bioreactor. Culture media will be added to the bath surrounding the tissue-engineered blood vessels and also pumped through the center to provide physiologically relevant mechanical conditioning.

In some of the work to develop tissue-engineered heart valves, hydrogels were fabricated with differential display of cell-adhesive peptides in the bulk versus the surface in order to provide different cues and interactions for VICs versus endothelial cells in order to optimize formation of an endothelial monolayer (Puperi et al., 2015). The bulk hydrogel was designed to be proteolytically degraded by cell-secreted MMPs and had immobilized RGDS peptides to mediate cell adhesion. VICs were encapsulated in this material, after which the surface of the hydrogel was covalently modified with the peptide CRKRLQVQLSIRT to enhance subsequent endothelial cell attachment. Endothelial cells were finally seeded onto this surface. This provided both the anatomically appropriate layering of cell types and also optimized endothelial cell attachment and phenotype.

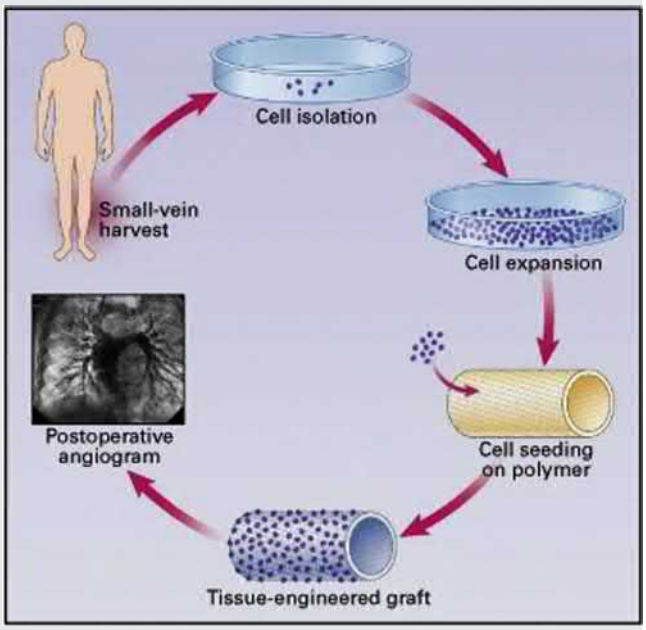
Conclusions

With cardiovascular disease remaining a major cause of mortality, there is a significant need for tissue-engineered products for the heart and vasculature. We are beginning to see clinical impacts of the tremendous advances that have been made in this field (Drews et al., 2017; L'Heureux et al., 2007; Benrashid et al., 2016). Nonetheless, significant progress is still needed in order to develop functional engineered tissues for the cardiovascular system.

CASE STUDY

A girl born with a single right ventricle and pulmonary atresia underwent pulmonary artery angioplasty and the Fontan procedure at the age of 3.25 years (Shin'oka et al., 2001). Seven months after this surgery, she developed total occlusion of the right intermediate pulmonary artery. The decision was made to construct and implant an autologous tissue-engineered pulmonary artery.

To accomplish this, a small segment of peripheral vein was harvested as a cell source. Following expansion in culture, the cells were seeded on a tubular, biodegradable PCL-PLA scaffold reinforced with woven PGA. Ten days after cell seeding, the tissue engineered construct was implanted to bypass the occluded pulmonary artery. Follow-up angiography indicated that the implanted graft remained completely patent.



Chapter Exercises

1. Compare and contrast the following scaffold materials: collagen gel, decellularized small intestine submucosa, poly(glycolic acid), poly(hydroxyalkanoate), and poly(ethylene glycol)-diacrylate.
2. Explain why a confluent endothelial lining on the blood-contacting surfaces of an engineered cardiovascular tissue is critical.
3. What scaffold properties are most important for tissue engineering a heart valve replacement?
4. If a cardiac patch incorporating cardiomyocytes is implanted epicardially, what events would need to occur to provide improvements in cardiac output?
5. Design a process for production of a tissue-engineered vascular graft that you believe will have optimal performance.

Soft Tissue Engineering

NICOLE R. RAIA, MEGHAN MCGILL, TYLER MARCET, SARAH E. VIDAL YUCHA, DAVID L. KAPLAN

Department of Biomedical Engineering, Tufts University, Medford, MA, United States

Introduction

In tissue engineering, "soft tissue" is a broad term that typically refers to all tissues except bone. This includes, but is not limited to, skin, musculoskeletal (cartilage, ligaments/tendons, muscle, connective tissues), adipose, cardiovascular, neural (brain, nerves), gastrointestinal, vasculature (blood and lymph vessels), liver, lung, kidney, and ocular tissues. In this chapter, the basic properties of soft tissues and the types of biomaterials that have been used in soft tissue implants or engineered in vitro models are reviewed. The progress made in the fields of adipose, gastrointestinal, and skin tissue engineering is then explored in greater detail. The design criteria for each of these tissue types is different, depending on the native anatomy, physiology, and the intended application, and the material requirements for each application also differ. Progress in mimicking the native environment for in vitro tissue models or clinically used fillers and grafts has been made in each of these fields. However, limitations associated with current tissue models and biomaterials open the door for biomaterial engineering principles to be applied to develop the next generation of soft tissue scaffolds.

Properties of Soft Tissues

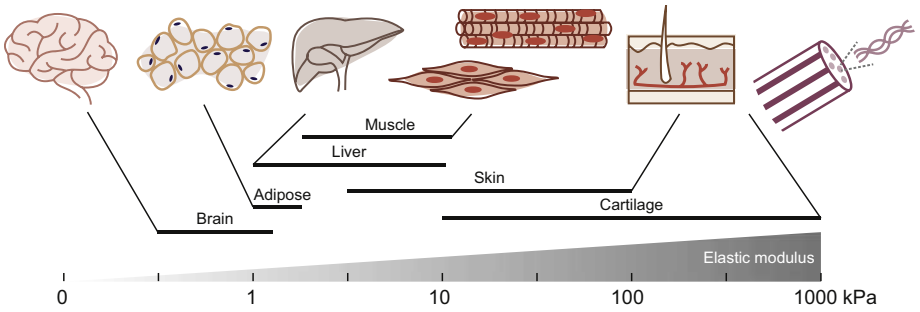
Soft tissues are highly flexible with stiffness values ranging from 0.1 kPa to 1 MPa (Liu et al., 2015; Comley and Fleck, 2009, 2010; Skeldon et al., 2018; Mckee et al., 2011; Kalra et al., 2016; Levental et al., 2007) (Fig. 2.6.7.1), and the mechanical properties are related to the tissue function. For example, load-bearing tissues, such as cartilage and tendon, are much stiffer than nonload-bearing tissues, such as brain. The mechanical properties of tissues are driven by the composition and organization of the extracellular matrix (ECM). The main components of soft tissue ECM are fibrous proteins (i.e., collagen, elastin), glycosaminoglycans (GAGs: i.e., hyaluronic acid, chondroitin sulfate), and proteoglycans (i.e., aggrecan, versican), though the relative concentration of each component and the structural organization depend on tissue type, age, and disease state (Cox and Erler, 2011; Frantz et al., 2010; Shuttleworth, 1998; Kurtz and Oh, 2012). For example, the brain contains high concentrations of GAGs and lower amounts of collagens (Novak and Kaye, 2000), whereas cartilage (specifically articular cartilage) is primarily composed of collagens, and proteoglycans are a secondary component (Palukuru et al., 2014).

Common Biomaterials Used for Soft Tissue Engineering

When designing biomaterials, the goal is to match both the biochemical and mechanical properties of the native tissue to establish a favorable environment for tissue regeneration. Biochemical cues, whether derived from the inclusion of ECM proteins, bioactive peptides, or cytokines, play an integral role in driving cellular responses, host reactions, and tissue integration. Matching the mechanical properties of native tissue provides the appropriate cues to drive cell behavior. Tissue–biomaterial mechanical mismatch can result in mechanical failure if the biomaterial is too weak, induce inflammation and tissue damage if the material is too stiff, and lead to a loss of interfacial connections between the implant and native tissue (Kalaba et al., 2016).

Biomaterials for soft tissue engineering take the form of 2D or 3D scaffolds (films, sponges, meshes, porous mats, tubes, hydrogels) as well as injectable matrices (hydrogels, nanoparticles, microparticles, suspensions, compressible sponges). 3D scaffolds offer greater control over mechanical properties and can provide complex, heterogeneous structures, mimicking the native environment (Xia et al., 2018). Injectable biomaterials are advantageous in that they can fill complex voids and be implanted through minimally invasive techniques, reducing the risk of surgical complications (Xia et al., 2018).

Independent of format, biomaterials for soft tissues can be fabricated from synthetic and/or natural polymers (Table 2.6.7.1). Synthetic polymers have highly controlled, reproducible compositions and can usually be chemically modified.



• **Figure 2.6.7.1** Range of elastic modulus of different types of soft tissues (Comley and Fleck, 2009, 2010; Kalra et al., 2016; Mckee et al., 2011; Skeldon et al., 2018).

TABLE 2.6.7.1 List of Common Synthetic and Natural Materials Used for Soft Tissue Engineering

Type of Material	Examples
Synthetic	Poly-lactic acid, poly-glycolic acid, poly(lactic-*co*-glycolic acid), poly(ethylene glycol), polyethylene glycol diacrylate, polytetrafluoroethylene, polyethylene terephthalate, polypropylene, poly(methyl methacrylate), polyacrylamide, poly(*N*-isopropylacrylamide), poly(ε-caprolactone), polyvinyl alcohol, poly(2-hydoxyethyl methacrylate), poloxamers, poly(propylene fumarate), polyurethane, poly(glycerol sebacate), silicone
Natural	Collagens, hyaluronic acid, decellularized extracellular matrix, silks, fibrin, gelatins, alginates, agarose, dextran, chitosan, chondroitin-sulfate, laminin, cellulose, amylose/amylopectin, polyhydroxyalkanoates, keratin

However, they lack intrinsic bioactivity and exhibit varying degrees of biocompatibility, with some synthesized or crosslinked using toxic reagents (Xia et al., 2018). On the other hand, natural biomaterials are generally biocompatible and chemically and physically similar to native tissue. However, naturally derived materials tend to have weaker mechanical properties, degrade more quickly compared to synthetic materials, can be challenging to modify in terms of biological and physical properties, and often have more variable compositions, depending on the source (Xia et al., 2018). Currently, no single material is optimal for broad-spectrum soft tissue-engineering applications, and therefore ongoing research in the field involves optimizing materials alone or in combinations to overcome existing limitations for specific applications.

Synthetic Polymers

Poly(lactide-*co*-glycolide) (PLGA) is a Food and Drug Administration (FDA)-approved polymer widely used in tissue engineering and drug delivery. It is also one of the few synthetic polymers that is degradable, and has a tunable degradation rate. PLGA can be developed into a variety of different formats, including sponges, foams, fibers, hydrogels, microparticles, and nanoparticles (Sun et al., 2017). PLGA microspheres, which can be injected, have been used as delivery vehicles for growth factors to facilitate regeneration of adipose tissue (Chung et al., 2012) and cartilage (Andreas et al., 2011). However, PLGA degradation products are acidic and can decrease the local pH when present in high concentrations. This local effect can negatively impact cells, the delivery payload (i.e., growth factors, therapeutic stability), and the surrounding tissues (Fu et al., 2000).

Poly(ethylene glycol) (PEG) is another commonly used, FDA-approved synthetic biomaterial. It is nontoxic, bioinert, and can be functionalized to enable crosslinking or incorporation of bioactive components (Zhu, 2010). The mechanical properties of PEG are suitable for soft tissue engineering, as they can be tailored to match the tissue of interest (Parlato et al., 2014). Additionally, the polymer precursors to PEG-based hydrogels are cytocompatible, thus allowing for in situ gelation (Bakaic et al., 2015). Due to these advantages, PEG has been utilized in many soft tissue-engineering applications, such as cartilage (Wang et al., 2017), adipose (Young and Christman, 2012), neural (Mahoney and Anseth, 2006), and cardiac (Grover et al., 2014) tissue.

Another FDA-approved synthetic polymer used in soft tissue applications is poly(ε-caprolactone) (PCL). This biocompatible and thermoresponsive polymer has relatively slow biodegradation and can be formed into films, hydrogels, and electrospun fibers. The elasticity, stability, and ease of processing of PCL make it an attractive material for tissue engineering (Mondal et al., 2016; Stratton et al., 2016). It is often used in combination with other polymers, including collagen, chitosan, and PEG, and has been applied in nerve, cardiovascular, skeletal muscle, ligament, bladder, ocular, skin, and cartilage tissue engineering (Mondal et al., 2016; Malikmammadov et al., 2018).

Natural Polymers

Collagen and hyaluronic acid (HA) are two of the most commonly utilized natural polymers in tissue engineering. Both polymers are present in the ECM and are biodegradable and biocompatible. Collagen can be isolated from

natural sources, and contains epitopes for cell interactions (Parenteau-Bareil et al., 2010). Collagens can be formulated into sponges, microparticles, fibers, and injectable hydrogels, allowing for use in a range of biomedical applications, including ocular, urogenital, skin, cardiovascular, and neural tissue engineering (Parenteau-Bareil et al., 2010). Collagen-based scaffolds are limited by their tendency to contract and rapidly degrade in vivo, necessitating modes to crosslink the protein to improve stability over time (Davidenko et al., 2015; Parenteau-Bareil et al., 2010). HA is a hydrophilic, naturally occurring polysaccharide that has a similar water content to soft tissues when formed into hydrogels (Collins and Birkinshaw, 2013). Although native HA is rapidly degraded in vivo through endogenous enzymes, it can be chemically modified and crosslinked, thus altering the degradation profile, mechanical properties, and cellular interactions (Collins and Birkinshaw, 2013; Burdick and Prestwich, 2011).

Silk fibroin is another natural polymer often used in biomedical applications such as adipose, neural, and intestinal tissue engineering (Stoppel et al., 2017). It is isolated from *Bombyx mori* cocoons and can be formed into sponges, foams, hydrogels, films, and microparticles (Rockwood et al., 2011). Silk has favorable characteristics for tissue-engineering applications, such as slow and tunable degradation rates and mechanical benefits in comparison to other naturally derived polymers (Vepari and Kaplan, 2007). The mechanical properties of silk biomaterials depend on format and processing. Silk hydrogels exhibit stiffness values between 200 and 10,000 Pa, covering a large range of native soft tissues (Partlow et al., 2014). Silk from *B. mori* degrades by proteolysis, but lacks cell-specific epitopes for cell signaling. Thus the incorporation of exogenous bioactive components can be used to direct cellular interactions (Murphy and Kaplan, 2009).

Decellularized Tissues

Decellularized tissues are natural biomaterials that have been utilized in tissue engineering. They can provide the biochemical composition and structural complexity found in native ECM, which has been challenging to recapitulate de novo (Neves and Reis, 2016). If possible to source, ECM derived from the tissue of interest is the most appropriate to use (Badylak et al., 2009), for example, decellularized heart valves for heart valve replacements (Bader et al., 1998; Vedepo et al., 2017), decellularized myocardial tissue for treatment of myocardial infarction (Singelyn et al., 2009), and decellularized adipose tissue to facilitate adipogenesis (Flynn, 2010).

Soft Tissue Engineering Applications: Adipose, Gastrointestinal, and Skin

In this section we explore the design criteria, current biomaterial technologies, and challenges in the fields of (1) adipose, (2) gastrointestinal, and (3) skin tissue engineering.

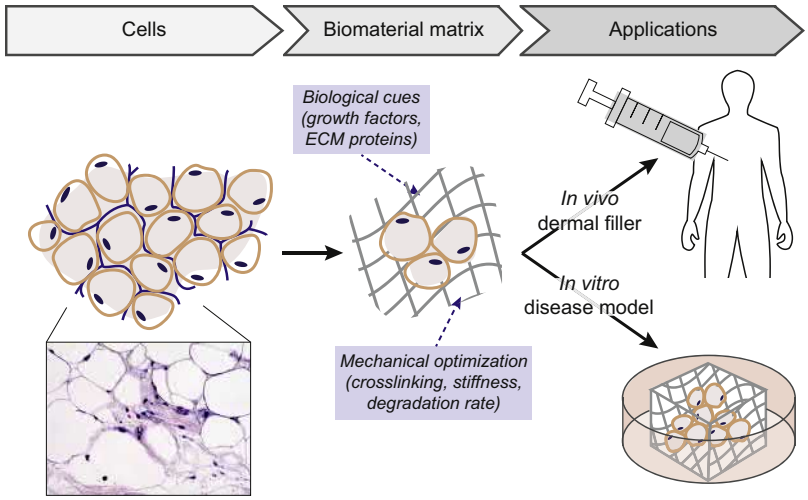
Adipose Tissue Engineering

Adipose tissue, commonly referred to as fat, is found throughout the body. The need for adipose tissue replacement arises when this soft tissue is lost or damaged due to trauma (i.e., burns), congenital defects (i.e., hemifacial lipoatrophy), tumor resections, or for elective cosmetic procedures (Patrick, 2001; Young and Christman, 2012). The most commonly used clinical treatments are soft tissue fillers for small defects (Van Nieuwenhove et al., 2017; Broder and Cohen, 2006; Cheng et al., 2002; Alam et al., 2008), and prosthetics (e.g., silicone implants) or autologous adipose tissue transplants for larger defects (Van Nieuwenhove et al., 2017). In the past few decades(2000–17), the soft tissue filler market has increased over 300% for cosmetic surgical procedures ("American Society of Plastic Surgeons report of the 2017 plastic surgery statistics"). Significant limitations associated with current treatments are poor long-term stability and donor or recipient-site morbidity (Flynn and Woodhouse, 2008; Choi et al., 2010; Van Nieuwenhove et al., 2017). Current material implants only temporarily augment or bulk the tissue (Van Nieuwenhove et al., 2017; Young and Christman, 2012; FDA, 2018). Due to these limitations, tissue-engineering principles are being used to develop new materials for the replacement of adipose tissue, focusing on the regeneration of fully functional tissue to provide a permanent solution.

Anatomy and Physiology

The main role of adipose tissue is providing energy via lipid storage and catabolism. Secondary roles include providing cushioning for structures and organs within the body, contributing to appearance, and secreting paracrine factors that communicate with other systems of the body (Klein et al., 2007). There are two major types of adipose tissue: brown adipose tissue (BAT) and white adipose tissue (WAT) (Colaianni et al., 2015). BAT is most prominent at birth, decreasing in abundance with age (Gesta et al., 2007), and serves to generate heat as triglycerides are broken down in a process referred to as nonshivering thermogenesis (Cannon and Nedergaard, 2004). WAT, which becomes redistributed as we age, acts as an energy storage depot and endocrine organ (Choi et al., 2010).

Adipocytes are the dominant cells in adipose tissues (Young and Christman, 2012). These cells store fatty acids within lipid droplets and release them when there is a demand for energy. Other cell types present in adipose are endothelial, immune, and progenitor (historically referred to as preadipocytes) (Choi et al., 2010; Tsiloulis and Watt, 2015). Preadipocytes are of unique interest in tissue engineering as their multipotency allows them to differentiate into adipogenic, chondrogenic, osteogenic, and myogenic (Zuk et al., 2001). Due to this plasticity, preadipocytes are commonly referred to as adipose-derived adult stem cells (ASCs) (Bunnell et al., 2008). ASCs that differentiate during lipogenesis are responsible for synthesizing and



• **Figure 2.6.7.2** Principles of adipose tissue engineering. *ECM*, Extracellular matrix.

reorganizing the ECM (Nakajima et al., 1998), which is primarily composed of collagen, laminin, and proteoglycans (Mariman and Wang, 2010; Song et al., 2018).

Design Criteria for Adipose Tissue Engineering

The goal for adipose tissue engineering is to provide **volumetric persistence** while stimulating the **regeneration of functional adipose tissue**. To achieve this goal, a biomaterial system must be: (1) biocompatible, (2) provide appropriate mechanical properties and degradation profiles, (3) facilitate and promote adipogenesis, and (4) promote vascularization.

Inducing adipogenesis and promoting vascularization are key to regenerating functional adipose tissue, especially in the case of large tissue defects (Chiu et al., 2011). Research has focused on combining biomaterials with cells and bioactive molecules, such as native ECM and/or growth factors. ASCs are often studied due to their patient specificity, ease of isolation, and ability to differentiate into adipocytes and endothelial cells (Nakajima et al., 1998; Gimble et al., 2007; Zuk et al., 2002; Fischer et al., 2009; Deng et al., 2015). In addition to ASCs, endothelial cells have been introduced into scaffolds to enable neovascularization (Chen et al., 2009; Kaihara et al., 2000; Tsuda et al., 2007). Some common growth factors used for adipose tissue engineering include fibroblast growth factor-1 (FGF-1), basic fibroblast growth factor (bFGF), insulin-like growth factor-1 (IGF-1), and vascular endothelial growth factor (VEGF) (Mahoney et al., 2018). FGF-1 increases peroxisome proliferator activated-receptor γ (PPARγ) expression, which helps prime preadipocytes for proliferation and differentiation. bFGF stimulates angiogenesis and adipogenesis, IGF-1 facilitates differentiation of preadipocytes and regulates triglyceride synthesis, and VEGF regulates vasculogenesis and angiogenesis (Mahoney et al., 2018). Native tissue, such as that from lipoaspirate or tissue explants, can also provide a complex source of growth factors and proteins that establish a favorable environment for regeneration (Gealekman et al., 2011; Young and Christman, 2012).

In choosing a biomaterial, it is critical to assess toxicity, cytocompatibility, and inflammation, either from the bulk material or its degradation products, which can induce a foreign body response, cause tissue damage, and prevent functional regeneration (Choi et al., 2010; Levenberg and Langer, 2004). Mechanical integrity and an appropriate degradation rate are also important parameters to consider (Lavik and Langer, 2004; Choi et al., 2010). Adipose tissue is not subjected to mechanical loads unlike tissues, such as cartilage and bone; however, it can experience compressive forces from the surrounding tissues and can also be exposed to significant deformation during normal daily functions like sitting (Young and Christman, 2012; Linder-Ganz et al., 2007). In addition, matching the native mechanics of adipose tissue can facilitate human adipose-derived stem cell (hASC) differentiation into mature adipocytes (Young et al., 2013; Shoham and Gefen, 2012). As with most applications, degradation is a key factor in the success of the biomaterial; in adipose tissue engineering, the material must maintain volume while facilitating tissue regeneration (Van Nieuwenhove et al., 2017) (Fig. 2.6.7.2).

Both in vitro and in vivo assessments can be performed to determine whether a particular biomaterial is suited as scaffolding for adipose tissue. For in vivo assays, biomaterials are commonly implanted or injected subcutaneously in small animal models (mice and rats) (Patrick et al., 2008). For in vitro and in vivo assays, a variety of analytical tools have been used to assess tissue regeneration, including mechanics, biocompatibility/toxicity, and material degradation (Table 2.6.7.2).

Commercially Available and Clinically Tested Biomaterials

The most common biomaterials used clinically include: (1) dermal fillers for small facial defects or (2) autologous tissue transfers or synthetic prosthetics for reconstruction after trauma or tumor resection (Van Nieuwenhove et al., 2017).

TABLE 2.6.7.3 Food and Drug Administration-Approved Soft Tissue Fillers (FDA, 2018; Van Nieuwenhove et al., 2017)

Biomaterial	Products
Collagen	*Bovine*: Zyderm collagen implant (Allergan), Zyplast (Collagen Corp.) *Human*: Cosmoderm 1 human-based C (Inamed Corporation) *Porcine*: Evolence collagen filler (Colbar Lifescience I), Fibrel (Serono Laboratories)
Hyaluronic acid	Juvederm (Allergen), Restylane (Q-med), Captique (Genzyme Biosurgery), Belotero Balance (Merz Pharmaceuticals), Prevelle Silk (Genzyme Biosurgery), Elevess (Anika Therapeutics), Hylaform (Hylan) (Genzyme Biosurgery)
Hydroxyapatite	Radiesse (Bioform Medical, Inc.)
Poly-L-lactic Acid	Sculptra (Sanolfi Aventis)
Polymethyl-methacrylate beads + collagen	Artefill (Suneva Medical Inc.)

Current FDA-approved materials in the United States for dermal fillers are outlined in Table 2.6.7.3 (FDA, 2018).

Collagen was one of the first dermal fillers approved by the FDA in the 1980s, and has been extensively researched for adipose tissue regeneration due to its bioactive nature and similarity to native ECM. FDA-approved collagen products are from bovine, porcine, or human sources and can be injected as uncrosslinked or crosslinked formulations (FDA, 2018). However, collagen scaffolds degrade quickly and exhibit rapid resorption rates (approximately 3–4 months for products currently on the market), providing only a temporary solution (FDA, 2018). HA is the most common polymer used in soft tissue fillers. HA-based medical products generally last longer in vivo than collagen-based products, degrading in 6–12 months (FDA, 2018). The only nondegradable FDA-approved soft tissue filler is poly(methyl methacrylate) microspheres suspended in collagen (FDA, 2018). This composition has shown promise in extending volumetric persistence; however, limitations include the presence of nodules and lumps, the lack of degradability, rendering it irreversible, and restriction to small facial defects (Lemperle et al., 2010).

Clinical procedures for the reconstruction of large defects involve either autologous tissue transplants (free flap tissue or free fat grafts) or synthetic prosthetics (silicone- or saline-filled implants). Autologous fat grafts are considered the gold standard in soft tissue augmentation and adipose tissue replacement (Mahoney et al., 2018; Van Nieuwenhove et al., 2017). In this technique, autologous lipoaspirate is collected through liposuction and reinjected into areas of need. The use of lipoaspirate has limitations, including rapid resorption and the potential for necrosis, especially when large volumes are injected due to the lack of vascularization (Mahoney et al., 2018). Improvements to autologous fat grafting focus on increasing persistence and reducing necrosis by modifying the harvesting, processing, and readministration techniques (Landau et al., 2018; Strong et al., 2015). Advantages of this approach remain, such as reduced immune response and the promotion of new adipose tissue formation, which is in part due to the presence of native ASCs, ECM, and growth factors in the lipoaspirate.

Novel Materials and Technologies

Adipose tissue engineering is a growing field due to limitations with current clinically used dermal fillers and reconstruction procedures. There is also interest in developing more relevant in vitro tissue models to study tissue development, disease progression, and therapeutic effects. 3D scaffolds (e.g., sponges) and injectable formats (e.g., hydrogels, microparticles) have been studied for adipose tissue regeneration (Van Nieuwenhove et al., 2017). Scaffolds with a predetermined, customizable 3D shape may be useful for larger defects (Flynn and Woodhouse, 2008). However, these designs typically require surgical implantation, which can result in scarring and increase the risk of complications (Young and Christman, 2012). Injectable biomaterials can reduce such complications and adapt to fill defects of variable shapes and sizes (Van Nieuwenhove et al., 2017).

PATIENT-SPECIFIC 3D ADIPOSE TISSUE MODELS

As the prevalence of obesity and obesity-related disorders (e.g., type 2 diabetes) increases, there remains a need to generate physiologically relevant in vitro tissue models to gain insights into disease progression and new treatment options. 3D systems that used porous silk protein scaffolding to culture patient-derived adipose tissue (from lipoaspirate), which included numerous cell types, including adipocytes, preadipocytes, endothelial cells, and smooth muscle cells, has been reported (Abbott et al., 2016). This system supported long-term culture up to 3 months and showed a proof-of-concept patient-specific system by utilizing low volumes of lipoaspirate and differences in response after tumor necrosis factor-alpha stimulation. Ultimately, in vitro tissue models provide utility in the study of patient-specific disease mechanisms and drug responses toward more effective, customizable therapeutic options.

Collagen-based scaffolds can support adipose tissue formation both in vitro and in vivo, particularly when combined with adipose-derived cells (Gentleman et al., 2006; Von Heimburg et al., 2001). Porous scaffolds fabricated from poly(L-glutamic acid) (PGA) supported ASC spheroid formation, leading to significant adipogenesis and angiogenesis in vivo (Zhang et al., 2017). Lipoaspirate can be included in tissue models to introduce ASCs, ECM, and growth factors into scaffolds (Bellas et al., 2013; Chung et al., 2012). In one example, silk sponges combined with lipoaspirate supported the generation of adipose tissue with functional vasculature while maintaining volume for over 18 months in a rat model (Bellas et al., 2013). The development and use of decellularized adipose tissue has increased within the last decade (Van Nieuwenhove et al., 2017). For instance, decellularized adipose tissue loaded with bFGF showed significant tissue formation and neovascularization with volume stability for up to 12 weeks in a mouse model (Zhang et al., 2016). Decellularized adipose tissue is currently in clinical testing for soft tissue injuries.

CASE STUDY: ACELLULAR ADIPOSE TISSUE FOR SOFT TISSUE INJURIES

Decellularized or acellular adipose tissue (AAT) has favorable properties conducive for adipose tissue engineering. AAT can be formed by processing subcutaneous adipose tissue using mechanical and chemical methods. The removal of antigenic compounds provides an "off-the-shelf" product that can be implanted in patients without rejection. This option is of particular interest for patients that do not have excess adipose volume to contribute to autologous fat grafts, which can be due to underlying diseases such as human immunodeficiency virus/acquired immunodeficiency syndrome or from chemotherapy treatments. Mechanical processing followed by treatment with peracetic acid to remove cells, surfactant to remove lipids, and enzymes to remove residual DNA has been utilized (Wu et al., 2012). The resulting material can then be crosslinked using 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide (EDC) and *N*-hydroxysuccinimide or hexamethylene diisocyanate to reduce enzymatic degradation rates in vivo to improve persistence. Upon preclinical in vivo evaluation using rat models, the EDC crosslinked AAT was encased in a fibrotic capsule, whereas the uncrosslinked and hexamethylene diisocyanate crosslinked AAT materials facilitated cell infiltration and promoted adipose tissue formation. This technology is licensed to AEGERIA Soft Tissue LLC, a startup biotech spinoff from Johns Hopkins University (Rosson et al., 2016). Recently, the safety of AAT implants has completed Phase I clinical trials in healthy human volunteers and the results showed that the AAT biomaterial was safe for use in humans and easy for physicians to administer to patients (Payne et al., 2017). In addition, preliminary results from these trials showed that the material was associated with proregenerative immune responses. These results show the promise of AAT for adipose regeneration; however, further studies and Phase II trials will be necessary to assess the potential as a therapeutic strategy for soft tissue injuries.

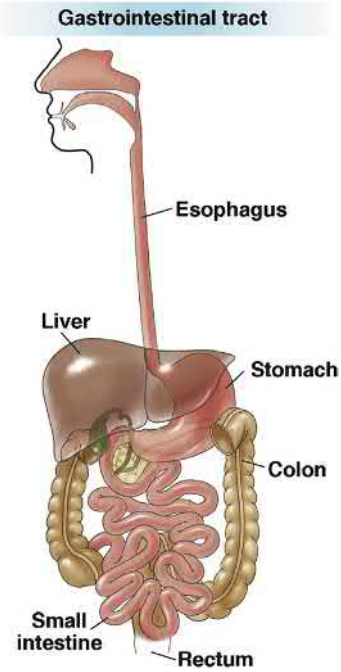
Challenges

Although there have been advances in adipose tissue engineering, challenges remain due to obstacles in predicating the performance of patient-sourced materials, assessing long-term persistence, scalability for large tissue defects, as well as hurdles associated with the manipulation of patient-derived materials.

The success of lipoaspirate and decellularized adipose tissue was reviewed earlier; however, preclinical research and clinical outcomes using such materials have resulted in variable results. This variability is due to the heterogeneous source material, with compositions differing between patients or within the same patient in different anatomical locations (Strong et al., 2015). Along similar lines, current methods to isolate and expand hASCs have not been standardized and thus there is heterogeneity in ASC cultures (Strong et al., 2015; Palumbo et al., 2018; Agostini et al., 2018). Other challenges include the need to assess biomaterials for long-term treatment, as well as assessments in defects of different sizes and shapes (Mahoney et al., 2018). The majority of preclinical studies last up to 1 year and usually involve small volume implants/injections tested in rodent models (Patrick et al., 2008). To fully assess these technologies, it is necessary to understand the long-term stability in relevant sized defects (Choi et al., 2010; Mahoney et al., 2018). To remedy these limitations, some studies have been conducted in large animals such as sheep or pigs (Patrick et al., 2008), or scalability assessed using computer-assisted model simulations (Chhaya et al., 2015).

Gastrointestinal Tissue Engineering

The gastrointestinal (GI) tract is a series of connected hollow organs, beginning at the mouth and ending at the anus (Fig. 2.6.7.3). Swallowed food travels through the esophagus to the stomach, where it is exposed to digestive enzymes and gastric acid. The resulting chyme—or partially digested food—passes through the pyloric sphincter to the duodenum, the upper portion of the small intestine. Digestion continues and nutrients are absorbed as the chyme is propelled through the small intestine to the colon, where water is reabsorbed



• **Figure 2.6.7.3** The organs of the gastrointestinal tract (Hussey et al., 2018).

and indigestible material is excreted as feces. Proper GI tract function relies upon complex coordination between multiple systems and an array of cell types. In this section, we: (1) provide an overview of relevant GI anatomy and functions; (2) explain the need for GI regenerative medicine; (3) summarize design criteria relevant to GI soft tissue engineering; (4) present a selection of strategies currently in clinical, preclinical, and developmental stages; and (5) describe current challenges and future goals with these systems.

Anatomy and Physiology

In healthy individuals, the only direct contact between ingested food and the body is at the epithelium, which consists of different cell types of specialized function depending upon location within the GI tract. The esophageal epithelium consists of stratified squamous cells and mucus-secreting glands to protect against abrasive damage (Kuo and Urma, 2006), while columnar gastric epithelial cells secrete digestive acids, enzymes, and autodigestion-preventing mucus. The gastric epithelium also contains hormone-secreting enteroendocrine cells that help to regulate GI function, representing a major interconnection between the GI and endocrine systems, which continues into the small intestine. The primary function of the small intestine is carried out by abundant enterocytes, specialized absorptive cells that deliver nutrients from the intestinal lumen to the bloodstream. Also present are Goblet and Paneth cells, which produce mucus and antimicrobial agents, respectively, contributing to the immunological importance of the small intestine. Excluding Paneth cells, the colonic epithelium contains similar cell types as the small intestine, though relative abundances are shifted to favor mucus production and waste excretion (Gregorieff and Clevers, 2005). The complexities of the GI tract are compounded by ubiquitous and crucial integration with the lymphatic, vascular, and enteric nervous systems. The importance of this integration is most apparent when considering a bodily function that is largely unique to the GI tract: peristalsis. In this involuntary process, synchronized contractions of both longitudinal and circular smooth muscle generate motion responsible for carrying food along the length of the gut. These repeating patterns of contraction and release are modulated by the enteric nervous system (ENS) and the interstitial cells of Cajal (ICC) (Huizinga, 1999). Given that disruption of any of the functions just described, or numerous others not covered here, can impact homeostasis of the entire system, it is not surprising that GI disorders are major causes of hospitalization, morbidity, and mortality worldwide.

THE INTERSTITIAL CELLS OF CAJAL: PACEMAKERS OF THE GUT

Without peristalsis, the GI tract cannot function. The ICC play a critical role in ENS to regulate smooth muscle contractions to keep food moving in the right direction. Embedded within the gut musculature, these "pacemaker cells" serve as intermediaries between the ENS and the smooth muscle, modulating excitatory and inhibitory neurotransmission. The ICC generate and propagate electrical slow waves, leading to synchronous contraction of the smooth muscle and driving the peristaltic motion that keeps the contents of the GI tract moving. While there is still much to learn about ICC and the role in GI motility, without the ICC the system does not function (Klein et al., 2013).

Gastrointestinal Disorders and the Need for Tissue Engineering

In 2009, it was estimated that nearly 50 million outpatient visits in the United States resulted in a diagnosis of a GI disorder, with evidence suggesting that the incidence of some disorders may be increasing. Many of these problems were associated with damage to the GI tract and lasting impairment, either as direct pathological outcomes or as the result of surgical interventions (Peery et al., 2012). As soft tissue-engineering techniques continue to develop, it may become possible to heal or replace GI tissues that have been removed, damaged, or have otherwise lost normal functions, thus improving patient quality of life.

Cancers of the esophagus, stomach, and colon are of particular interest, as they share a universally poor prognosis unless the affected tissue is surgically removed. In addition to leaks, infections, and other complications associated with excision and repair of GI tissues, secondary disorders may arise, such as malnutrition due to reduced bowel length or incontinence due to loss of sphincter control (Bitar and Zakhem, 2016). Similar complications can result from surgeries used to treat inflammatory bowel diseases like Crohn's disease and ulcerative colitis. In these cases, replacement of removed tissues or even entire organs could help to restore structure and function.

Potential benefits of tissue engineering are not necessarily limited to surgical insertion of engineered tissues. Although surgical options exist for motility disorders of the GI tract, tissue engineering may allow clinicians to design targeted, less invasive treatments that aim to restore function to dysfunctional components rather than to remove the tissues altogether. In patients with achalasia, for example, neurodegeneration in the esophageal smooth muscle causes the lower esophageal sphincter to remain in a contracted state, preventing food from reaching the stomach (Krill et al., 2016). Similar disorders can occur throughout the GI tract, such as in the stomach (e.g., gastroparesis) (Scott and Koch, 2015), intestine (e.g., colonic inertia) (Bharucha and Camilleri, 2015), and anus (e.g., fecal incontinence) (Costilla and Foxx-Orenstein, 2015). Pathologies can vary widely, but neurodegeneration in the smooth muscle is common to many motility disorders, even when musculature, vasculature, and the epithelial surface may remain intact and viable. In such cases, it may be possible to restore lost function if the otherwise healthy tissues can be successfully reinnervated.

Design Criteria for Engineered Gastrointestinal Tissues

As discussed in previous sections, all engineered tissues must be biocompatible, biodegradable, mechanically and architecturally suited to the intended application, and readily scalable (O'brien, 2011). However, because the GI tract consists of a series of organs with substantial structural and functional heterogeneities, assembling a single comprehensive list of design criteria for the entire system would be inappropriate. Instead, each criterion must be catered to the specific organ, pathology, and extent of tissue regeneration required (e.g., mucosal restoration vs. organ replacement). Generally, any successful strategy would result in GI tissue satisfying the following minimum requirements: (1) regeneration of the epithelium and organ-specific epithelial function; (2) regeneration of the longitudinal and circular smooth muscle in proper alignment; (3) innervation of the smooth muscle and restoration of peristalsis; and (4) reintegration with the vascular and lymphatic systems with concurrent interactions with the immune system. In the next section, an overview of GI soft tissue engineering strategies demonstrates the progress toward reaching these goals, while also highlighting continuing challenges.

Gastrointestinal Soft Tissue-Engineering Strategies

Efforts to engineer the soft tissues of the gut have been slower to translate to clinical use than other tissues (e.g., lung, airway, liver). However, results from animal studies and a small number of human studies promote optimism that regenerative medicine could play a significant role in the future of GI disease treatment.

The most successful preclinical GI tissue-engineering strategies to date have relied upon use of ECM-based scaffolds, often decellularized porcine small intestinal submucosa (Hussey et al., 2017); in such cases, the scaffold is typically sutured to the wall of the GI tract, providing the necessary porous structure to facilitate tissue regeneration. In vivo degradation of these biologically derived scaffolds also gradually releases growth factors, structural molecules, and other components important to the proliferation, differentiation, and phenotype of the varied and complex GI tissues (Hussey et al., 2018). Positive preclinical outcomes have also been demonstrated using synthetic biomaterials (e.g., lactic acid/caprolactone copolymer) for stomach regeneration (Miyazawa et al., 2015) and naturally derived scaffolds (e.g., chitosan) (Denost et al., 2015) for colorectal tissue engineering. Examples of GI regenerative medicine strategies that have reached preclinical or clinical stages are presented in Table 2.6.7.4. Note that the examples provided were selected to convey a variety of available strategies, and thus should not be considered comprehensive or indicative of relative clinical significance.

In some cases, the use of healthy tissues from similar locations within the GI tract to generate ECM scaffolds has resulted in improved tissue-specific regeneration (Keane et al., 2015). Seeding scaffolds with cells isolated from nearby locations prior to implantation can similarly improve outcomes. For example, collagen sponges seeded with autologous gastric smooth muscle cells enhanced the regeneration of the small intestinal epithelium and underlying musculature in canines relative to unseeded controls (Nakase et al., 2006). While these results are promising, translation of clinically significant treatment options is hindered by the availability of sufficient autologous tissue, particularly in cases where significant tissue regeneration is required, such as following colectomy. These limitations contribute to the growing interest in the use of stem cells to regenerate GI tissues in vitro and in vivo. Stem cells have been used in vivo to successfully regenerate enteric neurons (Hotta et al., 2013), smooth muscle (Walthers et al., 2014), and functional small intestine complete with differentiated epithelium and neuromusculature (Levin et al., 2013).

The use of organoids or miniature tissue models that represent the cellular diversity and function of native organs demonstrates a comparatively new, yet useful approach to engineer the soft tissues of the GI tract. Organoids have been isolated from tissues all along the human GI tract and can be grown in vitro (Dedhia et al., 2016), representing a major, expandable source of stem cells capable of differentiating into various cell types found in the complex GI tissues. By implanting esophageal organoids into collagen-coated PGA/PLA acid scaffolds in mice, the formation of esophageal epithelium and neuromusculature was demonstrated (Spurrier et al., 2014). In other in vitro and in vivo studies, organoid seeding and differentiation was demonstrated in scaffold materials, including Matrigel (Sato et al., 2009), collagen (Yui et al., 2012), PGA (Choi, 1997), porcine intestinal ECM (Finkbeiner et al., 2015), and silk (Chen et al., 2017). Even in the absence of a scaffold material, in vitro culture of colon organoids and subsequent transplantation into damaged mouse colon restored the structure, function, and continuously self-renewing properties of the epithelium (Yui et al., 2012).

TABLE 2.6.7.4 Examples of Gastrointestinal Soft Tissue-Engineering Strategies That Have Reached Preclinical or Clinical Stages

Organ	Model	Procedure	Scaffold	Outcome	References
Esophagus	Human	Circumferential endoscopic resection affecting mucosa and submucosa in patients with Barrett's esophagus	Porcine small intestinal ECM	Restoration of squamous epithelium in 5/5 patients	Badylak et al. (2011)
Esophagus	Human	Full-thickness patch esophagoplasty in patients requiring esophageal reconstruction	Porcine urinary bladder ECM	Restoration of squamous epithelium in 4/4 patients	Nieponice et al. (2014)
Stomach	Rat	Patch of full-thickness, circularly excised tissue	Porcine small intestinal ECM	Regeneration of smooth muscle, neuronal, and epithelial cells	Nishimura et al. (2010)
Stomach	Pig	Patch of resected tissue	50% lactic acid, 50% caprolactone copolymer with polyglycolic acid fibers	Structural regeneration of mucosa, musculature, and connective tissue	Miyazawa et al. (2015)
Small intestine	Dog	Patch of full-thickness, longitudinally excised tissue	Porcine small intestinal ECM	Restoration of epithelium; smooth muscle and neuronal reorganization; contraction of reorganized tissue under in vitro stimulation	Nakao et al. (2015)
Small intestine	Dog	Patch of surgically applied defect	Collagen sponge seeded with gastric smooth muscle cells under silicone sheet	Regeneration of epithelium and smooth muscle	Nakase et al. (2006)
Colon	Rabbit	Induction of ulcerative colitis and administration via enema	Porcine small intestinal ECM hydrogel	Restoration of epithelial barrier function and reduction in number of inflammatory macrophages	Keane et al. (2017)

ECM, Extracellular matrix.

Challenges and Future Goals

Despite the substantial progress made toward regenerating the soft tissues of the GI tract, key milestones remain to be met before clinical translation is feasible. Of the GI-specific design criteria described in previous sections, the most significant progress has been made toward regenerating epithelial structure and function. Restoration of peristalsis has been more difficult. Even in cases where smooth muscle development has been demonstrated, the cells often do not maintain the alignment and contractile properties necessary for peristalsis. This failure to reproduce and maintain smooth muscle phenotype represents one of the most immediate barriers to clinical translation. Because of the interactions between smooth muscle, vasculature, and the enteric nervous system, including the critically important ICC, future progress toward restoration of peristaltic function will likely require a system capable of restoring these various components simultaneously. Once the structure and function of the neuromusculature can be reproduced, the focus should shift to scaling up these engineered tissues. Similar to the adipose tissue-engineering field, most studies in GI tissue engineering have used in vitro or small animal models requiring only small amounts of scaffold materials and cells. As the field translates from preclinical to clinical studies, sourcing of these finite resources (e.g., homologous tissues) may pose logistical limitations. Although the rapid growth of stem cell and organoid engineering offers promise in this regard, it is difficult to predict what impact these

budding technologies will ultimately have on the regenerative medicine field for GI tissues.

Tissue-Engineered Skin: Future Goals of Skin Substitutes

The skin is the largest organ in the body and was one of the first organs to be tissue engineered (Bell et al., 1979). Skin equivalents are used across many industries, from clinical applications (i.e., wound coverings) to in vitro research models, and as a result the engineering constraints for each industry are different. In general, skin substitutes are composed of a biomaterial matrix (typically collagen) with either fibroblasts (dermal component) and/or keratinocytes (epidermal component). Skin equivalents have been used in the clinical field for therapeutic purposes for decades with a great deal of success; however, there are limitations such as a lack of innervation and vasculature (Biedermann et al., 2013; Blais et al., 2013). No commercial or clinical skin tissue model currently addresses the full complexity of cell type composition of the human skin.

Anatomy and Physiology

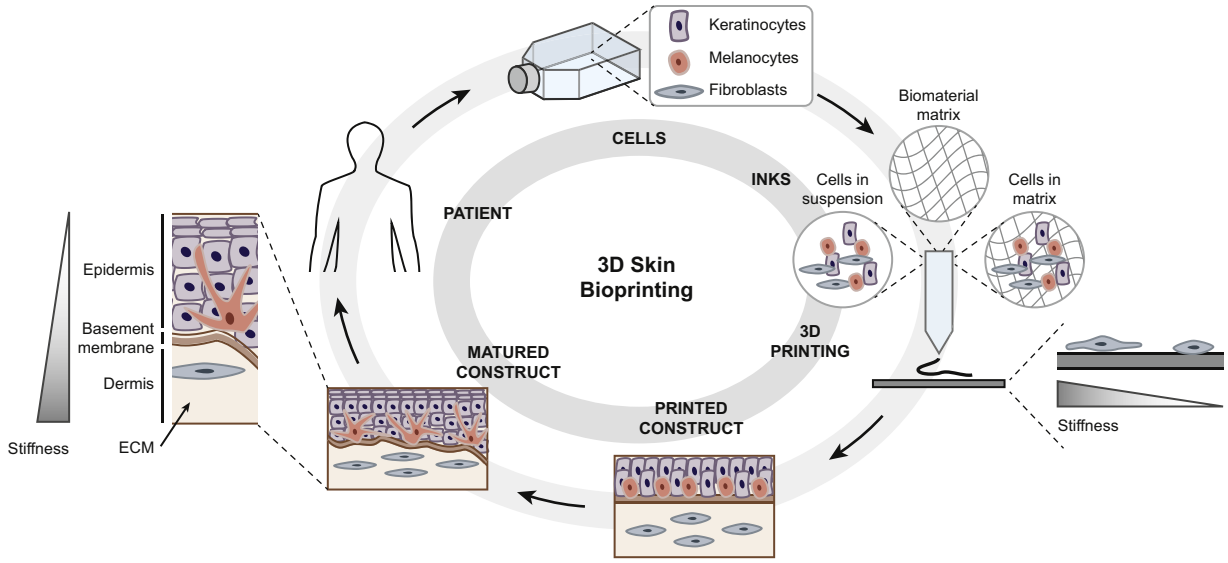
The skin is a complex organ with multiple layers and functional components (Biedermann et al., 2013). The outermost layer of the skin, called the epidermis, is mainly composed of differentiated, striated keratinocytes and melanocytes that organize into the following layers: cornified layer (outermost), granular layer, spinous layer, and basal cell layer, followed by the basement membrane (Mathes et al., 2014). Beneath the epidermis is the dermis, which contains numerous cell types, including dermal fibroblasts, endothelial cells, neurons, and immune cells (including Merkel cells, Langerhans cells, macrophages, monocytes, and B cells, among others) (Kim, 2015; Steinhoff et al., 2003; Valladeau and Saeland, 2005). The dermis ECM consists of collagens and other components such as GAGs and elastin, which contribute significantly to tensile strength and the mechanical integrity of the skin (Metcalfe and Ferguson, 2007; Nyame et al., 2014). The subcutaneous adipose layer underneath the skin ("subcutis" or "hypodermis") is composed of adipose tissue that contains a plurality of cell types, including adipocytes, preadipocytes, endothelial cells, smooth muscle cells, and immune cells. Typically, the subcutis had been thought of as a "load-bearing" protective layer, but it also has important roles pertaining to the skin as a whole, involving metabolism, endocrine, and immune functions (Coelho et al., 2013; Mathes et al., 2014). The skin is also composed of other functional components such as hair follicles, sweat glands, cutaneous nerve (a component of the peripheral nervous system), and blood vessels (Paus et al., 2006).

Design Criteria

The main goal of developing skin substitutes, either for skin replacements or for the development of in vitro tissue models, is to create a system that is physiologically similar to that of native skin. Beyond mimicking the biochemical and structural components of skin, there are other parameters that are necessary to consider to develop successful skin equivalents. These factors include developing technology that is cost effective, has a long shelf-life and low storage requirements, and involves standardized processing (including sterility) and scaleup. Additional criteria are necessary depending on the use of the equivalents. For instance, skin replacements in the clinic need to adhere to the wound bed and protect this damaged tissue site from infection, be biocompatible and noninflammatory, match the physical and mechanical properties of skin, provide controlled degradation, allow for water vapor transmission, and facilitate proper wound healing and angiogenesis (Vig et al., 2017). However, in addition to these technical/engineering concerns in the clinical field, there remains a need for accurate recapitulation of the human skin in terms of complexity (cell types, accurate barrier layers), especially in the development of in vitro tissue models to study mechanisms of skin disease damage and regeneration and for testing therapeutics. As mentioned previously, the skin itself is highly complex with multiple cell types, layers, and functional components, all of which are necessary to maintain homeostasis (Mathes et al., 2014; Zhang and Michniak-Kohn, 2012; Yamate, 2018; Paus et al., 2006; Abraira and Ginty, 2013; Klicks et al., 2017). Therefore research on skin equivalents has focused on the development of complex tissue models by inclusion of many different cell types, including nerve (Roggenkamp et al., 2012, 2013; Lebonvallet et al., 2012), adipocytes or adipocyte-derived stem cells (Keck et al., 2011; Bellas et al., 2012), endothelial cells (Black et al., 1998; Quan et al., 2013), immune cells (Ramadan and Ting, 2016; Ouwehand et al., 2011), or combination systems (Vidal et al., 2018). The ultimate goal of many of these systems is to develop a skin system relevant to human biology and one that maintains or promotes aspects of physiological function of the skin in either in vivo (clinical) or in vitro (research) applications. In recent years, 3D printing approaches have also been utilized for preparation of human skin equivalents as a novel means of adding complexity, cell types, and spatial resolution to engineered soft tissues (Ng et al., 2016).

Skin Substitute Technology

Commercially available products: There are many skin substitutes on the market today. These materials can be biologic or synthetic or a combination of both. Biological skin substitutes can either be from autologous, allogenic, or xenogenic sources and have been developed from human skin or from biomaterial-based strategies, including ECM components such as collagen or chondroitin sulfate, for example. In addition, some skin substitutes consist of cultured cell sheets or cell suspensions. Synthetic materials used as substrates for these systems include silicone, nylon, PLGA, PEG, and PCL. These scaffolds are often combined with either keratinocytes and/or fibroblasts to facilitate proper wound healing. Commercially available products have been reviewed recently (Vig et al., 2017). Although



• **Figure 2.6.7.4** Schematic of patient-derived bioprinting of human skin and generalized approaches with design considerations—matrix stiffness is important to control both bioink and tissue structure (inspired by Ng et al., 2016). *ECM*, Extracellular matrix.

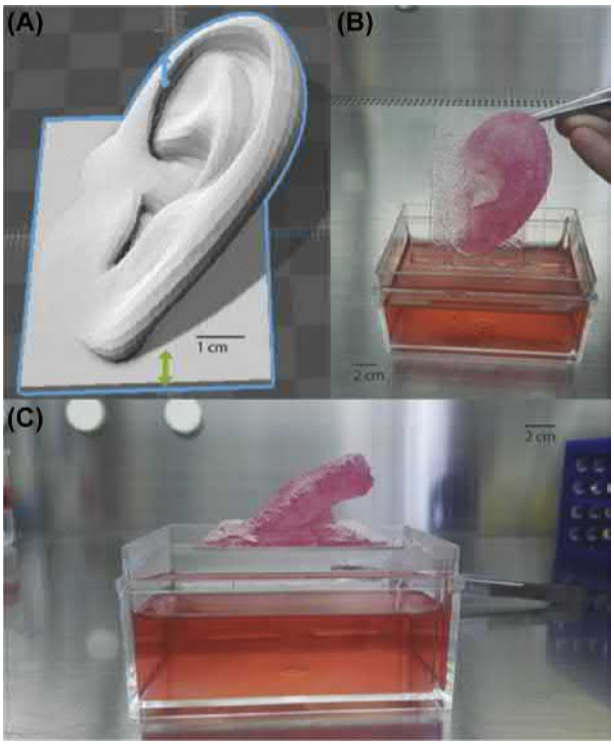
these equivalents have shown great success in the clinic, they still lack the physiological complexity of native skin.

Novel technologies—3D printed skin equivalent constructs: 3D printing of skin can provide high control over size and thickness of layers, spatial resolution in seeding cell types, selection of cell types, the ability to seed cell-specific layers, and utility in patient-derived replacement applications. One advantage of 3D printed systems versus standard engineered tissues involves improved reproducibility when compared to more traditional scaffold fabrication approaches (Klicks et al., 2017). 3D printing allows for additional control in seeding cell types in specific layers as well as in enhancing cell densities to improve overall skin cell morphology and cell–cell interactions (Ng et al., 2016). This methodology allows for a high degree of spatial control for this organ where the tissue layers and cell morphology are critical.

The main approaches for 3D printing skin include inkjet, laser, and bioextrusion processes (Ng et al., 2016; Pourchet et al., 2017), or combination processes (Kim et al., 2017). The main considerations for 3D printed skin tissue constructs include the biomaterial or ink composition, cell type(s), cell sourcing, printing parameters, and the general requirement of including an air/liquid interface to encourage differentiation and barrier function of the resultant skin tissue (Fig. 2.6.7.4) (Yan et al., 2018).

"SCAFFOLD-FREE" 3D PRINTING

One interesting approach to skin bioprinting is a "scaffold-free" approach, which leverages the abilities of 3D printing to form 3D morphologies with an application in skin, often only investigated on flat surfaces (Fig. 2.6.7.5) (Pourchet et al., 2017). The ability to construct different geometries by 3D printing allows for application in sophisticated tissue-engineering needs, such as in full-thickness wounds or in complex regenerative areas for surgical reconstruction.



• **Figure 2.6.7.5** "Scaffold-free" bioprinting of human skin in complex 3D architectures allows for proof-of-concept printing of a human ear (Pourchet et al., 2017).

Challenges

The field of skin engineering still presents multiple limitations to overcome, such as the high cost of production, potential immune rejection, lack of vascularization, and lack of complexity (Vig et al., 2017). Currently, clinically used materials consist of a few relatively simple layers, involving fibroblasts and keratinocytes, whereas normal skin consists of many different, complex structures, cells, and functions.

Current research focuses on incorporating such complexity to facilitate physiologically relevant skin systems with significant room for technology growth.

Conclusions

Soft tissue engineering is an exciting and growing field. It encompasses many subsets of tissue types, and in this chapter we focused on three: adipose, gastrointestinal, and skin. Other soft tissue fields such as neural, skeletal muscle, cartilage, and reproductive organs have also experienced significant progress in the development of tissue-engineered constructs due to advances in stem cell biology, biomaterial engineering, cell signaling, and related fields. Although each field has different requirements, the collective goals involve developing tissue systems that facilitate functional tissue regeneration and provide physiologically relevant tissue models. Ongoing challenges include sourcing components (e.g., cells, biomaterials, growth factors), standardizing procedures for the processing of these components, and defining storage and handling requirements that match regulatory and clinical requirements.

Chapter Exercises

1. What are the advantages and disadvantages of using natural and synthetic polymers for soft tissue-engineering applications? Choose one type of polymer and provide ways to overcome the disadvantages listed.
Answer:

	Advantages	Disadvantages	Ways to Overcome
Synthetic	–Easily tunable properties (mechanics, degradation, modifications) –Highly reproducible	–Lacks bioactivity –May use cytotoxic reagents or degradation by-products	–Combines with bioactive peptides, extracellular matrix components, or natural polymers to increase bioactivity
Natural	–Bioactive –Generally biocompatible	–Degrades rapidly –Lowers mechanical strength –Variability due to source and processing	–Crosslinks the materials or combines with synthetic polymers to increase mechanical strength

2. Strategies to engineer the soft tissues of the GI tract have been slow to translate to clinical significance. What are some possible reasons for this slow translation?
   a. The GI tract consists of multiple organs with dramatically different properties. While the system is continuous, efforts to regenerate individual organs are largely discrete. Strategies that show promise in the esophagus may not be feasible in the colon. An analogy can be drawn to cancer: it is frequently referred to as if it were a single—albeit major—problem to be solved, yet it is unlikely that any single approach will be able to cure the many different cancer types.
   b. The soft tissues of the GI tract are complex and highly interrelated. The success to date has been in the regeneration of the epithelial layer, presumably because the epithelium does not contain the abundant vasculature of the underlying tissues. For this reason, its regeneration is easier. This is not the case for other tissues, such as the smooth muscle. Although regeneration of smooth muscle has been demonstrated, maintenance of phenotype over the long term is required. This will rely upon simultaneous regeneration not only of the smooth muscle, but also the enteric nervous system, vasculature, and lymphatics.
   c. There are still key gaps in our understanding of how the GI tract functions. We know, for example, that the ICC are vital to GI motility, but the precise mechanisms by which the ICC help to drive peristalsis are still active research areas. Without a clear picture of the processes that govern GI function, it may be difficult to engineer soft tissues capable of recapitulating those functions.
3. There are multiple biomaterial technologies on the market for soft tissue fillers; however, there is still much research in finding optimal materials. Explain the limitations of current soft tissue fillers.

   The main limitation is that current fillers serve only to provide augmentation without inducing functional tissue regeneration. Also, most fillers on the market are degradable and without tissue formation, therefore it is necessary to have repeat injections to maintain tissue volume.
4. Design a biomaterial to stimulate adipogenesis. Explain the reasons behind the biomaterial you choose and any other components you include.

   This is an open-ended question; however, the main factor to include will be to provide biochemical cues either through the biomaterial itself or by adding in bioactive components. Other properties include appropriate mechanical properties similar to native adipose tissue, sufficient degradation as tissue is formed, and to include cells.
5. Using your biomaterial developed in the previous question, design an experiment to determine if it can stimulate adipogenesis.

   Experiments can be either in vitro or in vivo. For in vitro tests, the type of cells used should be specified if the proposed material does not already include cells. For in vivo tests, the animal model and location of implantation/injection should be specified. For either setup, adipose tissue-related assays such as immunohistochemistry of adipocytes (Oil Red O) or new ECM productions (collagen type IV, laminin, fibronectin), gene expression of adipogenic and lipogenic factors (RT-PCR of PPARγ, GLUT4, FABP4, ACS, GPDH), lipid quantification (AdipoRed, triglyceride), or measuring metabolic/enzymatic activity (lipolysis, glucose update, GPDH enzyme activity) can be performed.
6. Discuss challenges to the development of skin equivalents.

   There are numerous ways that students could answer this question based on logical challenges to current

tissue-engineering approaches, which include: recapitulation of human biology, biomaterials choice (mechanics, degradation, biocompatibility), or other issues pertaining to manufacturing, including production cost, manufacturing process, stability, etc.

7. For maintenance of systems, what are the main considerations or parameters?

Answers should include concepts such as nutrient transfer, cell culture composition, shelf life, and ability of cells to expand appropriately before transplantation.

8. For clinical substitutes, name three aspects that are important to consider in product development.

Can include: cell sourcing, scaleup, sterility, shelf life, storage.

9. Propose an experimental design to investigate a disease process in the skin. What components should be included to evaluate the process? Provide a process flow diagram of your design.

Answers should develop a skin equivalent that is capable of probing some aspect of the disease in a logical way—for example, if the student chose melanoma, it would follow that they should design a skin model that includes keratinocytes and melanocytes, and their experimental protocol should include some method to investigate that process such as inducing an ultraviolet event externally, or attempting to physically recapitulate a cancer-like environment. The cells could also be isolated from a patient with the disease to provide comparisons.

3.1.1

Introduction: Biomaterials in Medical Devices

FREDERICK J. SCHOEN[1], GUIGEN ZHANG[2]

[1]Department of Pathology, Brigham and Women's Hospital and Harvard Medical School, Boston, MA, United States

[2]F Joseph Halcomb III, M.D. Department of Biomedical Engineering, University of Kentucky, Lexington, KY, United States

This section highlights some of the key considerations, many nontechnical, in the development and implementation of medical devices that depend so importantly on biomaterials. Several principles underlie the approach presented in this section. The major driving force to technological innovation in biomaterials, implants, and medical devices is to improve the quality of life and survival of patients. The early phase of the process includes these steps: (1) identification of a clinical problem that needs solving ("clinical pull"); (2) determination that a viable market exists for the resultant innovation; and (3) the judicious and sophisticated application of existing, or development of, novel technology to solve this problem. In this sense, hospitals and clinics provide a "problem-rich" environment, and a laboratory for testing and translating the latest technologies and materials into clinical successes. An invention, by itself, is of little value; the value of the idea represented by an invention is through innovation, i.e., the validation and implementation of that idea or embodiment thereof to affect individuals and populations through its utilization and acceptance by others. In addition, it is important to recognize that the future of a new biomaterial associated with a device and/or implant-based treatment utilizing a biomaterial usually depends on the successful commercialization and clinical implementation of a medical product. For any product, such as an implant or medical device, the needs of commercialization (involving development, design optimization, a viable fabrication process, financing, regulatory considerations, reimbursement, manufacturing and scale-up, a suitable and profitable business model, marketing, etc.) are vital, and the scientific development, fabrication, clinical trials, and subsequent regulatory approval must occur in the context of, and concurrent with, sound business, ethical, and legal considerations (Fig. 3.1.1.1).

Indeed, medical device innovation is complex; the generic process and the requisite skills in technological innovation in medicine, including identification, invention, and implementation phases, have been summarized systematically and in detail.[1] Moreover, although demonstration of clinical effectiveness and safety are vital to clinical translation of any new medical product, today's economic pressures demand serious consideration of cost–benefit and cost effectiveness, i.e., the relative gain in health from a measure (e.g., years of life, freedom from pain) and the relative costs of different ways to achieve an equivalent gain in health, respectively. Finally, as embodied by the total collection of chapters in *Biomaterials Science: An Introduction to Materials in Medicine (Fourth Edition)*, progress in biomaterials and their implementation in clinically useful medical devices requires multidisciplinary collaboration, thinking, and communication, where engineers, physical scientists, biologists, and clinicians are on an equal footing, and share a common language and objectives.

Part 3 of this text provides a "toolkit" for medical device innovation addressing all the integral parts of the medical device development processes highlighted in Fig. 3.1.1.1. It begins with a discussion on total product life cycle for biomaterials-based medical devices in Chapter 3.1.2 by Duncan. The need for the management of total product life cycle of a biomaterial-based device reflects the fact that the process of medical device development and utilization is dynamic from conception to obsolescence. This, in turn, suggests that management of risks and performance controls may vary and indeed be iterative during the lifetime of the product. With the concept of product life cycle introduced,

[1]Yock, P.G., Zenios, S., Makower, J., Brinton, T.J., Kumar, U.M., Watkins, F.T.J. (Eds.), 2015. Biodesign: The Process of Innovating Medical Technologies, Second ed. Cambridge University Press, Cambridge, UK, pp. 839.

• **Figure 3.1.1.1** Technical path and business processes integral to medical device development must proceed simultaneously.

in Chapter 3.1.3 Duncan further discusses safety and risk considerations in medical device development. Medical devices that rely on biomaterials for function in medium- to high-risk applications are subject to technical evaluations based upon understandings of risk to the patient. A new device with new performance claims must undergo stringent safety and efficacy testing. A premarket approval application is required when the truly new device may only have an indirect basis for comparison to prior or alternative therapy, or when there is no or little evidence that the new device performs as intended. Even a device designed to be "like" another product already on the market must demonstrate that it is indeed "equivalent" to an existing device. The so-called "me-too" device has as its threshold for premarket notification [510(k)] evidence of equivalence to a prior accepted device: performing in essentially the same way to do essentially the same function without introducing new risks. Since cleaning, disinfection, sterilization, and assurance of maintained sterility are crucial to the safety and success of these medical devices, the importance and various methods of sterilization and disinfection of biomaterials for medical devices are highlighted by Harrington and Guda in Chapter 3.1.4.

Following the discussions on product life cycles, safety and risk management, and sterilization and disinfection considerations, considerations concerning the transitioning of a medical device from idea to a commercial setting, or from bench-to-bedside translation, including the verification and validation of medical device design, design control, and types of tests are all discussed in Chapter 3.1.5 by Simon. Moreover, in Chapter 3.1.6 Goldenberg highlights some strategic business considerations for device development and commercialization, market opportunity, reimbursement concerns, issues of intellectual property and funding, as well as sales and marketing.

In Chapter 3.1.7, Duncan dives deep on issues concerning regulatory pathways and constraints for medical products using biomaterials. Aside from the numerous pathways established by the US Food and Drug Administration, it also introduces other global premarket assessment methods, requirements, clearance and approvals, and other related issues. The role of standards for testing and performance requirements of biomaterials, and various types of standard documents as well as how they are developed, are addressed by Simon and Kuhn in Chapter 3.1.8.

Although medical devices serve their recipients well by performing as intended for extended duration, failures with significant consequences to recipients do occur, sometimes because of individual patient characteristics, and sometimes systematically in a patient group (i.e., cohort failure). Various aspects of medical device failure—and the means to document and understand failure modes and mechanisms through implant retrieval, evaluation, and analysis—are presented in Chapter 3.1.9 by Harman. Particularly, the discussion is focused on the characterization of the human biological response and associated performance of implant designs after they have functioned in patients during general clinical use. Several case studies demonstrating the role of implant retrieval, evaluation, and failure analysis are also provided.

Though a less talked-about subject by many biomaterials engineers, some legal concerns over the use of biomaterials in medical devices are also highlighted in Chapter 3.1.10 by Grody and Badylak. Throughout the course of a career, biomedical engineers will routinely encounter a range of issues that require legal consideration or can have legal ramifications. The discussions in this chapter could

be important for such professionals to develop a general awareness and familiarity with the types of situations in which legal issues will arise. For example, issues concerning employment agreements, confidentiality and materials use agreements, intellectual properties, contract negotiation and compliance, sponsored research agreements, license agreements, and litigation are all discussed. Finally, a brief review on ethical issues in the development of medical products by Brown et al. in Chapter 3.1.11 helps conclude Part 3. Often overlooked or minimized, ethical considerations in biomaterials and medical device development and use are crucial. The discussion of ethical principles covers several different types of medical products, including drugs, medical devices, and other types of therapy, highlighting mainly issues related to the safety, regulatory compliance, animal and human testing, as well as emerging issues such as the use and inclusion of stem cells in medical products and gene editing, among others.

3.1.2

Total Product Lifecycle for Biomaterial-Based Medical Devices

ELAINE DUNCAN[1,2]

[1]Paladin Medical, Inc., Stillwater, MN, United States

[2]Joseph Halcomb III, MD. Department of Biomedical Engineering, College of Engineering, University of Kentucky, Lexington, KY, United States

Total product lifecycle management refers to the philosophy that a medical device has a natural cycle of concept through obsolescence and therefore the management of the safety and performance of that product depends upon the current phase of the product.

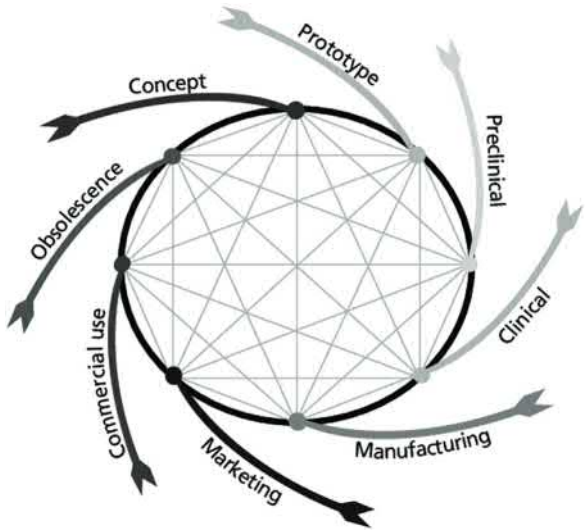
Total product lifecycle is a catchy phrase but what does it mean to the biomaterial student, the aspiring development engineer, and the physician or patient user? For a biomaterial-based medical device it means that management of risks and performance controls will vary during the lifetime of the product. And since implanted biomaterial-based medical devices must interface with the lifecycle processes of the patient, medical device lifecycles can be critically important. What if that lifecycle interfaces with one's own life or that of a loved one? Understanding the total product lifecycle of a medical product can quickly turn personal and thus product lifecycle concerns are not an abstraction (Fig. 3.1.2.1).

The product lifecycle is conventionally described as the period of time over which the product moves through various phases of development, commercialization, and eventual removal from the market. For a biomaterial-based implantable medical device the lifecycle necessarily includes the in vivo lifecycle of the device from implantation, integration with the host environment, to disintegration. Quality systems for medical devices take into account postmarket surveillance of product performance, such as monitoring complaints and reporting adverse events to regulatory authorities. But in most circumstances a product's approval process (or "clearance" as the case may be) does not require that design criteria consider the end stage of the implant. In other words, few if any medical devices are specifically designed to incorporate a "fail-safe" mode at end of life. And in most respects, patients cannot be fully informed or prepared for the consequences of having to remove the device in the event of failure.

Ironically, it is a tribute to the success of medical device technology and the biomaterials of construction that we can now be concerned for the "total lifecycle" of the device. We can shift the focus of concern from "will it work?" to "how long will it work?" Implicit design-life expectations for many implanted medical devices have shifted from 10 years to the remaining life of the patient, which can be a long time! Indeed, the patient's expectations for the functionality of an implanted medical device are often more than the performance of their natural organ or structure that is being replaced by the prosthesis! A patient may be sanguine when their natural hip wears out, but they expect their prosthetic device to last forever.

But can a biomaterial-based medical device be designed to perform indefinitely within the body and, if not, can the mode of failure be designed so that further damage to natural structures are limited, thus allowing the subsequent replacement to perform to the same requirements? The field of implantable medical devices is too vast to explore this question for every device, but this section will attempt to address some of the issues and the subsequent mitigations that are employed today, and raise topics for the student's continued consideration.

Conventional bench testing can often predict one or more modes of failure and even extrapolate an expected lifetime using standardized test data (e.g., fatigue cycles and load stresses). But these methods are designed for the conventional biomaterials that replace the existing structures and few, if any, can analyze the mechanical performance of a biomaterial that is intended to integrate and/or be absorbed into the body. Clinical device trials attempt to provide the best indicator of device success under controlled circumstances. Very commonly now, regulators are insisting upon longer and longer trial follow-ups and device registries to try to help monitor long-term consequences. All such attempts to predict and mitigate device failures have serious limitations as predictors of total product lifecycle performance. Clinical studies evaluate the idealized



• **Figure 3.1.2.1** According to the US Food and Drug Administration, medical device development is an iterative process that rapidly incorporates preclinical, clinical, and manufacturing experience into next-generation concept and design.[1]

device in the idealized patient, whereas market-released devices are placed in patients who need the product, in spite of their preexisting conditions and confounding health factors, such as diabetes. Even a 2- or 5-year follow-up of clinical trial patients has practical limitations as a predictor of success. Setting aside the costs of such trials, patient compliance with regimens for long-term follow-up cannot be enforced. Diagnostics for implants without symptoms are limited in value, particularly for biomaterials that are designed to integrate into the surrounding structures. Since most implantable devices are expected to perform indefinitely it is problematic to manage the total product lifecycle through a controlled clinical trial protocol. Quite literally a clinical trial patient would have to become indentured to the manufacturer for perpetual follow-up to serve as a sentinel for potential lifecycle issues. Rolling a clinical trial patient into a postoperative database (registry) has limited value because such data are usually "self-reported."

Quality programs for design control and review begin with understanding the "user need," which for biomaterial-based medical devices include the physician and the patient. Defining the user needs in the context of how current devices do or do not adequately fulfill those needs can certainly lead to better product designs and materials selection, but in a design program that considers total product lifecycle the designers should have explanted devices and failed devices for analysis to better appreciate how the current technologies and materials are fulfilling the requirements for late-term performance. In other words, is it adequate to design a device to have enough strength or flexibility at implantation, if over time the material weakens or stiffens within the body and thus fails to function? If such changes in properties cannot be avoided, should the recipient be warned of a finite life of the device?

Designing for shifting customer requirements is seldom part of the design input requirements for a new product. One aspect of total product lifecycle management that is frequently overlooked in medical product development is the inevitable shifting of the skills of the dominant user. Consider that during the development and initial product evaluation phase the "inputs" typically come from the highly specialized physicians who are comfortable in the vanguard of the new technology. These physicians guide the medical product development company to understand the needs for the new product and may participate in clinical studies, physician training, and other aspects of the new product development assessments. In the early months and years of product introduction the medical device manufacturers naturally sell to these "early adopters" of the new technology. The product can show immediate success in the marketplace. The more successful these new materials and devices become the more patients will demand these innovative products and more physicians may seek training in their use. Can the curse of success change the user profile and thus instead of the well-trained user and dedicated specialist, subsequent users may be too busy for training and may have a wider patient base with varying needs, possibly unlike those in the focused clinical trial. How can the design team anticipate these changing user needs?

Medical devices can never be totally risk free. When a device is offered to the market, regulators expect to see evidence that the benefits outweigh these risks.[2] Continued market surveillance and corrective and preventive action programs constantly attempt to maintain the balance between benefits and risks as the medical device moves through the introduction phase to market maturity. Another factor in total product lifecycle management is understanding the potential effects as a product moves into differing global markets. Surgery techniques, long-range distribution, and postimplant aftercare can impact product performance.

The expectation, particularly in the European regulatory scheme, is that the manufacturer will conduct periodic clinical evaluation assessments comparing the performance of their own device(s) to the prevailing trends in the marketplace, with the focus on the device continuing to offer benefits that outweigh the risks, in the context of alternative therapies.[3] This presents a kaleidoscope of changing expectations and assessment methods. Various countries and organizations may collect data on patient outcomes in "registries." The rules for collecting information vary for nearly each registry and the methods of retrieval from these registries can vary widely. ("Private" databases often require that the soliciting company pay to obtain data.) Attempting to gather and analyze the data in a manner that can accurately and reliably indicate when a medical device is not keeping up with the

[3] EU Medical Device Regulation 2017/745 (MDR) and MEDDEV 2.7/1 Rev 4.

state of the art has the tendency to homogenize the information to the lowest common denominator. Although established for noble purposes, can registries provide balanced and qualified data for medical device manufacturers in the quest to determine if their products remain "state of the art?"[4]

Until recently, medical device manufacturers and regulatory agencies could put trust in professionally managed adverse event reporting and evaluation systems such as with the US Medical Device Reports (also known as MAUDE database). Medical device manufacturers and users, such as physicians and hospitals, relied on a system of organized reporting of malfunctions, injuries, and/or deaths to help to signal any change in device risks in the general marketplace. The database can become useless if plaintiff attorneys make reports in "batches" without clinically relevant information. Reports by hospitals and physicians may withhold critical information due to concerns for patient privacy to the extent that investigating an event is nearly impossible. Devices are often sequestered, instead of being returned to the manufacturer for examination, thus no failure mode analysis can occur. Corporate complaint systems established under QSR.820 thus have limited benefit because direct reporting of adverse events to a company through the complaint system is dependent entirely on the attitudes of the institutions with the information. Corporations may attempt to monitor published literature and even the internet for any signals of dissatisfaction about the product, but without a direct, per se allegation against the performance of the product and the willingness of the reporter to provide meaningful information, there is little valuable input to the primary method for postmarket product surveillance. Therefore these idealized early warning systems, incorporated into the regulations of the industry, may no longer provide the surveillance of the medical device performance needed to help manage the expectations for the total product lifecycle and thus fail to provide reliable data for the determination of risk versus benefit.

Despite the many practical challenges and barriers to gaining real-life information, medical device manufacturers seek to understand how the device may function over time. Certain standardized methods for chemical characterization (such as ISO 10993-18: Chemical Characterization of Materials) seek to identify the chemistries extracted under aggressive conditions as a model for how the material may break down over time in the body. Various in vitro simulator methods seek to predict failure modes, but until there is real-life human data, the relationship of simulator data to human device performance can only be estimated. Most such in vitro failure mode simulators can only evaluate the device under limited stresses (such as wear) and simulated biologic environments, such as in saline or simulated blood. (An example method is ASTM F1875-98 (2014) Standard Practice for Fretting Corrosion Testing of Modular Implant Interfaces: Hip Femoral Head-Bore and Cone Taper Interface.)

[4] Registries for Medical Device Evaluation, Benjamin C. Eloff, Ph.D., Senior Scientific Program Manager, Division of Epidemiology Center for Devices and Radiological Health, FDA. https://www.fda.gov/media/89553/download.

Trying to estimate the effect of enzymes and cellular attachment can only approximate a finite time window. As a result, there are few simulators that can reliably predicate the mechanisms of late biomaterial decline. Even attempting such studies in live animals is problematic because the animal model may not be an accurate anatomical substitute for the human and maintaining an animal through its natural lifespan in hopes of simulating the natural processes of biomaterial decline is prohibitively expensive and introduces other variables not found in humans. With the conventional biomaterial a necropsy may yield information about the device–tissue interface through histopathological analysis or even postimplant biomechanical studies. But what of the materials designed to integrate and absorb in such a way as to leave behind a regenerated organ or structure? Certainly, acute examination of the biological interface may be warranted, but what of the assessment of the regenerated tissues over time? Will there be adequate methods to discern how these regenerated "zones" have fared in the aging patient? Is it a device failure if the newly incorporated tissues suddenly fail to thrive or give way to the onslaught of progressive disease?

The consequences to a manufacturer that decides to remove a product from the market due to its obsolescence can be staggering. Not only can this mean a sudden disruption of product supply to physicians and patients, it can cause major expenses for hospitals and distributors and serious anxiety to patients with a device determined to be obsolescent. Some regulatory jurisdictions have no category for "recovery" or "removal," only for *recall*. In the United States the term "recall" typically refers to a device that fails to meet the product specification, such as for packaging tears or sterilization batch failures. There are no obvious reasons why a product should simply stop being marketed beyond the lack of customer demand. And who will make the determination that a product no longer offers a benefit above risk when there is no standardized, objective measure for "risk?"

It is not just as simple as not making or selling a device anymore, because device manufacturers and healthcare providers often enter into long-term purchase agreements and "consignments." Including the international shipping pipeline and intermediaries in the distribution stream, a medical device can be legitimately on the shelf for 5 years after manufacture. "Recovering" such devices, if a device manufacturer decides the device should no longer be used, represents a massive undertaking with financial and logistical consequences.

Conventional wisdom depends upon the integration of quality system design controls, control of raw materials, control of equipment, verification and validation of performance and usability, facilities and worker training, risk analysis and risk mitigation, postmarket surveillance, and adverse event reporting for management of total product lifecycle. All these systems for managing the total product lifecycle are applicable to the biomaterial-based medical device, but inchoate for the foreseeable years of biomaterial-based implanted medical devices. There are ample opportunities for future innovations in implanted biomaterial lifecycle management strategies that will hopefully keep pace with biomaterial innovation.

Chapter Questions for the Student

1. When a product, for any reason, no longer meets customer expectations or is no longer a benefit compared to risks due to outmoded technology, should the manufacturer be encouraged to remove the device from the market?
2. If the methods for retiring a device at the end of its natural product lifecycle due to obsolescence were easier, might patients benefit from an orderly market retraction?
3. What might device retraction from the market mean for a patient who may still have the implanted device?
4. Does this suggest a need in medical device regulatory authority to provide for an orderly retraction of a device from the market without the risk that a manufacturer will face major liability because the device is no longer state of the art?

3.1.3

Safety and Risk Considerations in Medical Device Development

ELAINE DUNCAN[1,2]

[1]Paladin Medical, Inc., Stillwater, MN, United States

[2]Joseph Halcomb III, MD. Department of Biomedical Engineering, College of Engineering, University of Kentucky, Lexington, KY, United States

Introduction

Medical device development requires systematic assessment to assure the device will meet its intended use. Even a device designed to be "like" another product already on the market must demonstrate that it is indeed "equivalent" on two levels: (1) does this device meet the same performance requirements of the predicate device, and (2) is this device as safe as the predicate device? The so-called "me-too" device has as its threshold for premarket notification [510(k)] evidence of equivalence to a prior accepted device: performing in essentially the same way to do essentially the same function without introducing new risks.

A new device with new performance claims and unproven safety (such as due to a new technology) must undergo not only safety testing but must also prove its use is efficacious. A premarket approval (PMA) application is required when the truly new device may only have an indirect basis for comparison to prior or alternative therapy, or when there is no or little evidence that the new device performs as intended. A device requiring a PMA must also be able to demonstrate that the intent to treat is medically justifiable with a reasonable benefit over risk.

A new medical device will typically seek to provide a new solution to an existing problem within the confines of a target medical area. If a new device has multiple potential applications a company engaged in medical device development must select a target "intended use" to focus the development program on a realistic goal, or maintain separate development tracks for each different intended use. The development team must establish the "voice of the customer," meaning a set of performance expectations that fulfill a specific function. This process can be iterative and may require that certain medical applications are excluded from the target use of the device. Recognizing differences between "indication for use" and "intended use" are extremely important. For example, the requirements of a wound dressing could be very different if the dressing is intended to be used to cover a surgical wound, compared with a bandage applied by the lay user on a skin scrape after a bicycle spill. Although each may have the same indication for use (wound protection) the intended user and intended environment for use are very different, and thus the "voice of the customer" is different.

Known as design control and review (aka stage-gating) the proper design and development of a medical device must recognize these "inputs" from the voice of the customer and convert these to technical specifications. Typically, the translation of inputs will consider the prevailing expectations and standards within the industry to aid in setting boundaries on the requirements. Even when a device is totally novel, there may be standardized methods for evaluation that help to define the input development. For example, if the device must execute data storage or transmission, the development engineer must be aware of any standards that might impose constraints for the use of energy transmission to store or transmit the data. The development engineer may have to refine the basic input to transmit energy to call out percutaneous couplings or determine if data and power can be transmitted transcutaneously. Regardless of the indication for use or intended use, the device under development may face input constraints based upon local best practices, industry standards, or even the features of the predicate device.

Once these input requirements are sufficiently described, the development process moves to determining the potential risks associated with the potential failure of the device to meet its stated requirement. Ideally, this analysis is done on a detailed level, requirement by requirement, assessing each potential failure mode for its probability to occur and its associated risk if it does occur. An appreciation of "detectability" of the potential failure mode can heighten the development team's ability to predict the probability of occurrence and determine the most effective mitigation strategy. By parsing

these potential risks (hazard severity times probability) the team can assess where mitigations should be focused. The analysis of potential risk mitigation may require many layers of evaluation. Examples of testing and evaluation could include appreciation of the intended usability of the device and the potential for failure inherent in the design and materials. Historical design, publications, and testing of comparable devices may be resources for determining potential risks associated with the desired device design.

Absence of Toxicity Is Not Evidence of Safety

For several decades the medical device industry has attempted to qualify the biocompatibility of medical materials by a series of increasingly complex testing methods striated to reflect the relative risk categories associated with the type of tissue contact and longevity of exposure. Although individual protocols may have been validated through the years for their specific purpose, the testing schemes (table of testing) represented in the ISO 10993 series have not been proven to assure biomaterial safety. Rather this scheme of testing is a means to rule out the likelihood of a risk of the test material *not* being suitable (toxic to cells at some level). Putting it bluntly, if a material's use could have longer exposure and involve vital tissues, and thus represent a greater potential risk to the patient, more testing is expected, even though it has not been proven that *more* test results offer better risk mitigation.

One attempt to rectify the checkbox-testing mentality and to provide for better devices is to encourage a systematic assessment of biological risks associated with the device and its materials, which attempt to consider more universal factors such as prior clinical use of the material in the same intended use. Adopting this more comprehensive safety assessment has met resistance. Development planners like to seek an authority who will just tell them what to do so they can get it done. Test laboratories have no incentive to minimize the scope, length, or cost of repetitive testing. Regulators understandably prefer to have a checklist and to rely less on subjective arguments within a risk analysis.

Efforts to create a "database" of materials used in certain applications were rejected years ago due to the logical basis that materials and processing methods used in a given device were usually proprietary to a company, so an inventory of the uses of a particular material by the supplier within various devices did not provide "evidence" of safety. Material suppliers certainly can promote their materials for various uses and supply baseline biocompatibility test results, but the final manufacturing methods (machining, cleaning, sterilization, and so on) must be considered in biomaterial safety assessments.

The pressure to *prove* safety (remove risk) has propagated expensive and at best obliquely relevant laboratory tests "of the finished device." So, despite the ideal to conduct a logical risk analysis, the assessment for safety invariably comes back to a table of standardized tests. It should be understood that these tests cannot and do not prove the safety of the biomaterial in the intended use of the device. Rather the role of the standardized tests is to provide comparative data derived within the confines of the protocol. These data, typically compared to a standardized control material also evaluated within the same protocol, may indicate a *relative level of hazard* of the material within the selected model.

For devices to be presented to the US Food and Drug Administration (FDA) for premarket review, developers must be mindful of the *Guidance for Industry and Food and Drug Administration Staff Document* issued June 16, 2016: Use of International Standard ISO 10993-1, "Biological evaluation of medical devices—Part 1: Evaluation and testing within a risk management process."[1]

The general principles of biological evaluation of medical devices (Section 4 of ISO 10993-1) instruct the reader that the evaluation plan must be made "within a risk management process in accordance with ISO 14971." This same section also provides an "informative" annex to help guide the reader in how to go about biological risk management. The standard attempts to pull the risk management process toward validated in vitro models and away from repetitive live animal testing. The standard urges the reader to give preference to identifying chemical constituent testing, where such methods *may* yield equally relevant information. The chemicals in their estimated concentration are then compared to toxicity tables that estimate a safety threshold. But again, the student of biomaterials must remain mindful that while chemical toxicity assessment may help to identify the risk of a biological reaction in certain persons over time periods relative to the device use, such tests are "*not* evidence of biocompatibility," which is defined as:

> *the ability of a material to perform with an appropriate host response in a specific application.*[2]

The table of "endpoints" in Annex A of ISO 10993 might seem to reflect assessments for the "specific application" because it considers the type of tissue contact and the duration of use, but biocompatibility evaluation needs to consider a far more detailed risk analysis than provided for in this table, which is why the FDA guidance and Annex B stress the need to characterize the materials and processes in the context of the intended use of the device. The student of biomaterials must understand that biological evaluation of the use of the device is only one aspect of a risk management practice. Risk assessment must also consider potential hazards associated with the *failed use* of the biomaterial device within the patient. Rational biological risk assessment compels the responsible medical device developer to consider the failure modes of the biomaterials in the subject device and consider the potential severity of the risk to

[1] https://www.fda.gov/downloads/medicaldevices/deviceregulationandguidance/guidancedocuments/ucm348890.pdf.

[2] Williams, D.F., 1987. Definitions in biomaterials. In: Progress in Biomedical Engineering, vol. 4. Elsevier, Amsterdam, p. 72.

the recipient patient. Although not yet universally adopted, the task of analyzing and understanding the biological risk assessment inherent with the acute and chronic failure of the medical product not only serves the process of initial design but also identifies risk factors for biocompatibility assessment through the total lifecycle of the product.

Characterization of the materials and processes in a medical device, including processing agents, is the first step of any biological risk assessment. Not only should the source of each material be carefully qualified, but the actual material received should be scientifically verified (not just the identification of what is sold). A critical material performing a critical function within the device should be identifiable using a standardized test method and engineering should set in place the criteria for routine evaluation of incoming raw materials. Ideally, critical materials should have verifiable specifications that will permit the future qualification of alternative sources for the critical material. Although manufacturers may choose to rely on a material certification from a vendor, this practice represents a calculated risk to the safety of the device. Best practices establish a baseline of quality materials from the source before accepting a certificate of compliance.

All manufacturing processes should be "mapped" such as with a flow chart, to demonstrate the junction points when energy and other chemicals (including water) may be brought to the processing of the starting materials. Screening cytotoxicity testing along the interim manufacturing steps during the development phase of the product could help to identify if a manufacturing process alters the otherwise known safety of the starting materials. The quality of water and other cleaning agents is essential. Controlled, validated processing, particularly for polymerized materials, is necessary to assure safe and uniform biomaterials batch to batch.

Assessing the Continuum of Biological Risk in Performance

ISO 10993, Annex B.3.1.2 includes a list of "physical and chemical material properties" but this is not really an accurate name for the list. Rather, this list represents some of the energy or force vectors that might act on a biomaterial when used in the medical device, and reminds the student to consider the contribution that the physical form the material may play in the body's response, such as porosity and roughness. Thus the long and expensive standardized tests may show no apparent risk, but the biomaterial could be altered by the biologic processes over time (such as static compression, wear fatigue, or crumpling due to scar contraction). These converted forms of the biomaterial in the functioning device, over time, could drastically change the biocompatibility of the material. As a corollary, the definition for bioincompatibility considers:

> *the material loses its ability to perform as a result of the host response in the specific application.*

Modeling device performance using an in vitro simulator, such as a fatigue tester, could provide insight into the failure modes of the materials within the device. Such test systems would ideally standardize and control for temperature, fluid composition, and forces on the device and run cycles far longer than an animal or human might be expected to stress the device. Test fixtures of this type can be expensive and due to design constraints may only evaluate an isolated element of a given device. But such fixtures can be remarkably versatile for testing the potential for wear debris and the nature of the debris, if properly designed and built. Wear debris can then be characterized for size, morphology, and potential toxicity. Fracture failures in simulators may give insight into internal material weakness and provide the "canary in the mine" early warning of potential delamination, fatigue striations, and unanticipated concentrations of stress.

Thus when divining for potential biological risk, "toxicity" tests are only one of a large and detailed number of "mitigations" to reduce the potential of biological risk. Tests alone cannot prevent toxicity and can only provide an oblique assessment of the potential for toxicity risk according to the limits of the protocol. The test methods may even introduce a "false positive" if the study director is not mindful of how results of a test may be skewed by errors in sample preparation. For example, one of the most common false failures for cytotoxicity testing occurs when the cells are subject to an extraction solution with the wrong pH, which can simply lyse the cell walls. Because standardized test labs may overlook these details, it is necessary for the sponsor of the tests to be involved and understand both the rationale for the selection of the tests and what the tests are intended to show. Following Good Laboratory Practices regulation (21 CFR 58) for definitive laboratory testing helps to ensure the laboratory performs the studies to protocol with proper quality oversight. Regardless, it is critical to remember that these tests do not *prove* biocompatibility or incompatibility. These tests can only indicate the relative risk of material toxicity when the material is in sufficient concentration or material form to be detectable with the specific test system.

For certain applications and certain functional claims, the common wisdom may be that only an in vivo assay can be trusted to characterize the biocompatibility of a material. One common example of expected biomaterial evaluation to support the claim that a biomaterial can enhance bone formation where there has been a deficiency or injury is to test the material in an artificially induced bone void. Conducting all of the toxicity-based assays (including genotoxicity or carcinogenicity) will not demonstrate that such materials can perform as intended, that is, to grow bone. Only a postmortem evaluation for the presence of new bone in association with the biomaterial produces sufficient evidence for osteointegration at the cellular level.

Studies for biomaterial performance in a functional medical device require careful study protocol design and can be as complicated and as expensive as a human clinical study. In fact, the animal cannot speak for itself so systematic monitoring of vital conditions and/or daily animal welfare checks may be necessary. Proper animal performance studies need

to begin with an understanding of comparative anatomy and physiology to assure that the animal is even the correct model for the condition to be tested. Size and configuration of human devices simply may not fit in an animal and thus may introduce artifacts in the study and unnecessary hardship for the animal. But such "in-life" performance studies may be the only way to fully understand the complex interactions of the device within its intended use. While monitoring the device in the living animal is important, postmortem assessment can be most revealing, particularly when it is possible to design a study with serial sacrifice of numerous animals over sequential time periods. Assessing the device as it behaves in the animal at different times may provide insight into the progression of tissue integration, device wear, and any potential for material migration. Histology, microcomputed tomography, pre- and postmortem X-rays, and organ necropsy should be anticipated for explant analysis. The methods of preservation and sample fixation must be planned well in advance with consideration for embedding, stains, forms of microscopic examination, and other analytic methods. Transporting tissues is regulated and even preserved specimens may require adherence to international treaties.

Assessing the Contribution of Secondary Processes to Biological Risk

Once the fundamental design hazard analysis and risk assessment has begun, including the detailed biological risk assessment for intended use, a comprehensive analysis of the potential risks contributed by processes is essential. Elements of proper design control and review (detailed elsewhere) include verification and validation. To simply state, verification is intended to show conformity to specific requirements and validation attempts to confirm the overall performance for intended use. Thus inherent in a thorough biological risk assessment program is the understanding of how processes and secondary processes can contribute to the performance of a biomaterial in a medical device. Producing a process flow chart early in the biological risk analysis should help to pinpoint processes that could impact the biomaterial. In fact, it is prudent to assume that every process could impact biomaterial properties until evidence confirms performance is not altered.

A few real-life examples of how poor manufacturing controls altered biomaterial performance illustrate the point. One manufacturer had invested a great deal of time, money, and scientific sweat to perfect an anticoagulation coating on a hemodialysis catheter. The superior performance of the catheter with the coating statistically demonstrated benefit to the patient. When moving the prototype manufacturing process into the factory setting the engineers were unaware of the use of a silicone spray release agent on an adjacent manufacturing line. The "overspray" from that process deposited silicone release agent on the dialysis catheters laid out on a separate assembly line in readiness for dip coating. As a result of this contamination by an otherwise "safe" material, the anticoagulation coating would not adhere to the catheter surface, despite the pretreatment step that was designed into the manufacturing process. The unintended release agent might have caused the coating to sluff off in the patient's blood vessel. Fortunately, based on planning due to good risk analysis, the manufacturer had anticipated the need for a postdipping quality control check. An observant inspector detected a lack of uniformity to the coating and an "oily sheen" appearing after some catheters had been dipped. Surface analysis techniques detected the presence of silicone on the catheters. The line supervisor was convinced the tests were wrong because no silicone spray was allowed in the factory. A walk through the assembly area by an outside observer showed a can of silicone spray located on the shelf below the adjacent production line. Not authorized for use in the facility at all, the contraband silicone mold release had come into use by an operator to make an assembly connector push on easier.

Another manufacturer who did not apply proper biological risk analysis caused serious harm in many patients. In an effort to bring a contracted manufacturing step in house, and thus save money, a device company began to conduct the process of making a surface porous without understanding the need for serial cleaning steps. As a result, oils from manufacturing steps were embedded deep within the pores of the surface treatment. The single, superficial cleaning step applied at the end of the device manufacturing phase was not adequate to remove the embedded manufacturing contaminants, which migrated to the device surface after implantation and thus came in contact with surrounding tissue. This contaminant interfered with bone growth and implant stabilization. Because the manufacturer had not understood the hazards of the machining process, the validation plan for the cleaning process did not consider that surface cleaning would not be sufficient to remove toxins embedded in the tortuous porous surface. Weeks to months after implantation the prosthetic joint failed to osteointegrate and remedial joint replacement surgery was required, with all of its inherent additional risks. Patients were directly harmed by the failure of the product team to mitigate the risks associated with the manufacturing process, which when properly handled by the original contractor had been safe and effective.[3]

Sterilization methods introduce biological risks, not only with the potential that the cycle may not adequately sterilize the product, but also from the sterilization process residuals or changes to polymers. Some biological risks are well known and can be characterized. Standards for evaluation of residuals and by-products from ethylene oxide gas are routinely employed.[4] Manufacturers understand that a biomaterial can be altered in the presence of gamma sterilization energy and thus attempt to protect the materials from this

[3] https://www.fearnotlaw.com/wsnkb/articles/cueva-v-sulzer-orthopedics-11280.html.

[4] ISO 10993-7:2008; Biological Evaluation of Medical Devices—Part 7: Ethylene Oxide Sterilization Residuals.

effect or avoid the sterilization method entirely. Steam and dry heat sterilization can also alter a biomaterial.[5] As new sterilization methods have been introduced, manufacturers have had to become analytical detectives to determine the potential hazards associated with the chemicals and processes with their biomaterials. Some alternative sterilization processes have been shown to interact with a polymer during the sterilization process, thus altering the biomaterial chemistry. During standardized toxicology testing these chemicals can register as surface toxins.

Even a sterilized device can introduce a biological risk called pyrogenicity. A pyrogen can invoke a febrile reaction. Material-mediated pyrogens are chemicals that might leach from a medical device material to create a febrile response. Material-mediated pyrogens may take many forms, but a commonly overlooked source may be a mined mineral, such as a calcium carbonate deposit. Bacterial endotoxins are typically associated with the condition brought on when a sterile device harbors the remains of the outer membrane of a Gram-negative bacterial cell wall. Reducing the risk of pyrogenicity is especially critical for intravascular devices and implants. Strides have been made to reduce the risk of pyrogens on or within sterile medical devices by strictly controlling the use of water as a cleaning agent and ensuring that water is not allowed to stand on the surface of a device, even in a clean-room. Once again, understanding and controlling the risks associated with the processing of a biomaterial is critical to assuring a device is safe.[6]Transportation, storage, and shelf-life aging for most conventional medical device biomaterials can be characterized by standardized testing. Packaging systems, including sterile barriers, are generally reliable and can be tailored to the shape and stability needs of the medical device. Evaluation of the in-package, shelf-life aging of the device materials is standard practice to assure that the device just prior to the expiration date on the package performs as well as it would the day the device is released for sale.[7] Combination products (drug/device and biologic/device) and tissue-derived or custom-grown biomaterials have unique requirements for "shelf-life" qualification and delivery. It is expected that materials that are designed for "tissue engineering" could require almost immediate use, placing the manufacturing location immediate to the patient in the hospital. These questions already exercise the talents and imagination of the biomaterials scientist.

Assessing Biological Risk of Aging Biomaterials in the Aging Patient

Medical device development necessarily focuses on the requirements of the device at the time the device is delivered to the point of the intended use. In the case of implanted medical devices, the device performance requirements do not stop upon receipt. Although clinical trials attempt to evaluate the performance of the device within the scope of the intended use, in the ideal patient included for evaluation, excluding those whose conditions are not ideal, all clinical trials have an endpoint. For practical reasons, clinical trials beyond 2 years are problematic because of the mobility of patients. Patients who "feel good" are reluctant to return to a physician and financial incentives for follow-up visits are deemed unethical. A 5-year controlled, prospective, randomized clinical study without significant follow-up loss is rare. Although institutions may attempt to publish long-term performance results from their own practice, the results often reflect drift in their practice, which can introduce bias. There can even be impacts of weather disasters (hard to have a patient back for follow-up when the hospital is leveled by a hurricane). The mobility of patient populations and the impact of patient lifestyle on healthcare decisions can impede direct follow-up by the original clinic. Even with electronic feedback systems and "satellite" clinics, obtaining the qualified data of a complex implanted device trial is problematic.[8] Unfortunately, it is the longer follow-up data that might show a trend in biomaterial performance, but such data can become less reliable with time. To truly understand the long-term performance of a biomaterial in an implanted device can require tens of thousands of patients in numerous geographic areas before the true performance of a biomaterial-based medical device can begin to emerge period.

Some postmarket performance programs[9] attempt to follow the same patients after the formal end of the clinical trial, such as in registries or postmarket surveillance studies. Some postmarket studies evaluate the outcome of treatment without stricture on trial enrollment, again more in the style of a registry of the patient. (Typically, a registry does not receive new data until there is an adverse event or death of the patient, so information can only be assessed compared to the total number of patients known to be "at risk" for device failure.)

Some medical devices have a "tracking" limitation imposed at the time of approval, which attempts to know where the device may be in the event of a recall, but otherwise collects no data. None of these monitoring methods can effectively evaluate the biological risk of a biomaterial as the device ages, within an aging patient, even when the patient/device are available. Occasionally, a physician can evaluate how well the patient is performing with the device. Actual device-specific observations might include a blood test, computed tomography scan, X-ray, or magnetic resonance imaging to "see" the implant in situ, but other than an observable fracture or migration there are few assays to show with certainty that the biomaterial is performing safely.[10]

[8] https://www.ncbi.nlm.nih.gov/pmc/articles/PMC3684189/.

[9] https://www.fda.gov/medical-devices/premarket-approval-pma/pma-postapproval-requirements.

[10] The performance of certain devices, such as pacemakers and defibrillators, can be interrogated after implantation, but it remains difficult to assure that a biomaterial is performing as intended until performance failure is otherwise detectable.

If a manufacturer receives a complaint or adverse event report with sufficient information to conduct an investigation, the records in the device history file can be reviewed. It may be possible to determine if there were manufacturing or material errors in a particular lot, but other than trending such reports to track to a cluster of related failures, it is exceedingly difficult to isolate root cause failure of a single device in a specific patient. If such quality trends emerge, notifications to practitioners can be issued, but beyond watchful waiting, few such trends result in immediate device removal in the absence of drastic outcomes.

The only method that could provide long-term data for biomaterial performance is systematic implant retrieval from patients with normal and abnormal medical device performance. Presently, there are research groups who collect "failed" implants, but this can skew understanding of what makes a biomaterial device successful. Being prepared for retrieving biomaterials from an explanted medical device is critical in an attempt to assure the materials are returned in a manner suitable for forensic analysis. In some instances, research centers have been established to collect the implants on-site,[11] but when an explanted device must be transported, a hazardous material retrieval kit with preservation instructions must be immediately available. Retrieved dental implants and orthopedic joint implants have been available for analysis for many years around the world, but data from the retrieval of soft tissue implants such as breast implants and materials for tissue reinforcement may be more difficult to interpret due to the variability of the implant techniques, lack of traceability of the device to the original manufacturer, and the differences in soft tissue excision around the implant. Implant retrieval discussion is beyond the scope of this section other than to point out that retrieving only "failed" implants fails to teach what did not go wrong. Nevertheless, interpreting the findings from retrieved biomaterials should be incorporated into any new product biological risk assessment when possible.

ISO 10993-1 advises that where well-characterized and functional data support the safety of a biomaterial in the device, repetitious testing not focused on a specific potential risk should not be necessary. Variations from the proven performance parameters can be analyzed more precisely by understanding the differences in the context of known outcomes. The challenge for the biomaterial student is that the chain of custody and factual process information is seldom known for retrieved biomaterials, thus risk analysis involves considerable inference about the vectors affecting outcome. Enhanced value for future biomaterial applications will come when the natural history of the patient's disease condition and lifestyle can be coupled with the implant performance evidence.

Summary and Study Guide

Medical devices that rely on biomaterials for function in medium- to high-risk applications are subject to technical evaluations based upon understandings of risk to the patient. Standardized biological test schemes may help reduce the potential for risk associated with the use of a material, but do not prove the safety of the biomaterial. Well-designed risk-based technical assessments that consider the lifecycle of the use of the device, including risks associated with manufacturing processes and patient age and disease, are necessary to assure the safest medical devices come to market. Armed with satisfactory risk mitigations, biomaterials in medical devices are deemed successful when the benefits are commiserated with the risks over the lifecycle of the product.

Chapter Study Guide

1. Can a medical device manufacturer leverage prior use of a biomaterial in a previous device that has a different intended use and avoid having to do biological testing?
2. If a biomaterial-based medical device manufacturer changes the sterilization method for a slightly different device, using the same material and manufacturing process, can the manufacturer avoid additional biocompatibility testing?
3. When a manufacturer can show that a prior device used the same biomaterial, can the manufacturer avoid additional testing, and, if so, what would the manufacturer have to demonstrate in their own application?
4. After conducting testing in ISO 10993-1, can a manufacturer claim that the materials in the new medical device are biocompatible?
5. If a manufacturer's new device fails cytotoxicity testing, does that mean that the materials in the device are toxic and not appropriate for use in the medical device?

3.1.4

Sterilization and Disinfection of Biomaterials for Medical Devices

Introduction

Biomaterials are intended for applications either in medical devices, which are designed for use in sterile, clinical settings, or as implants, which come into direct contact with human tissue. Thus cleaning, disinfection, sterilization, and assurance of maintained sterility are critical considerations to ensure the safety and success of implants and devices. To this end, biomaterials scientists and engineers must consider not only the requirements of the material, but must choose the appropriate sterilization process so that the functionality of the material and the device are delivered at the clinic. This chapter focuses on the various sterilization techniques available, and the process controls to ensure patient safety.

The term "sterile" refers to the presence or absence of microorganisms and is essentially a binary state; a material is either sterile or it has microorganisms. From a regulatory perspective, the term "sterile" is used to indicate the probability of an implant or device having a bioburden. The current expectation for patient safety is that less that one out of a million devices or implants can be nonsterile. This expectation is known as the "sterility assurance level" (SAL) and the one out of a million is defined as having an SAL of 10^{-6}.

A vast majority of the sterilization practices in use today are terminal processes where the products are sterilized after the entire process of manufacture has been completed. This chapter focuses mostly on these industrial terminal sterilization processes, their appropriateness for different types of materials and devices, and how the processes scale from benchtop development to mass manufacturing. Just as it is the responsibility of the manufacturer of the device or implant to clean any remnants of the manufacturing process and then sterilize, package, and deliver a product that can be validated to be sterile at the point of use, it is also the responsibility of hospitals or medical care facilities reusing devices to clean and resterilize products and equipment. This procedure is known as "disinfection," and depending on the product, its previous application, and the level of anticipated "soil," high- or low-level disinfection might be necessary. Disinfection and reuse of implantable devices is not permitted from a patient safety and regulatory standpoint. Assurance of sterility is a critical aspect of good manufacturing practices and in consideration of patient safety, most processes are designed for overkill sterilization (higher SAL than 10^{-6}, such as 10^{-9}) to ensure that an SAL of 10^{-6} can be met with certainty.

Terminal sterilization is often not possible in some cases, especially when biologics or liquids are added to the device or when a combination product is repackaged for use. In such cases, aseptic processing of the product is preferred to ensure that the SAL can be maintained. When such approaches are not possible, additional chemical sterilization steps might have to be incorporated before the device can be used. Biomaterials scientists need to find a terminal sterilization solution for a product, if possible, and thereby avoid aseptic processing to minimize the complexity of use. The optimization of pairing the appropriate sterilization process with a material is to determine a cost-effective sterilization process resulting in a clean device and a time-effective validation process to assess sterility, while ensuring that the process does not have significant

deleterious effects on the material used. This optimization is relatively easy for standard materials used for most medical devices, but is increasingly complex for biologics and combination devices, both of which are rapidly growing in popularity.

Multiple factors affect the outcome and effectiveness of the sterilization process; some of these include:

1. Cleanliness of the material being sterilized;
2. Nature and extent of initial bioburden;
3. Design, manufacture, and assembly of the device/implant;
4. Chemistry/reactivity of underlying biomaterials; and
5. Features such as convoluted channels or internal porosity.

To navigate these challenges, it is useful for the biomaterials scientist to have a concrete understanding of common terminal sterilization technologies (see the sections "Radiation-Based Techniques," "Chemical Techniques," and "Thermal Techniques"). This section provides a detailed understanding of sterilization technologies from the perspective of their impact on the microbial loads as well as the materials that are being sterilized. Two modalities, radiation sterilization and ethylene oxide (EO) sterilization, dominate the industrial terminal sterilization market, while thermal sterilization is used mostly in hospital settings. These terminal sterilization technologies are paired with established validation processes, which are designed to far exceed regulatory SAL requirements. Neither radiation nor EO causes significant material degradation in traditional devices under well-controlled and validated use. In addition, both are capable of scaleup to high volumes in a cost-effective manner.

Material compatibility constraints often drive the choice of sterilization modality and this is discussed in the Section "Materials Development Considerations for Sterility." Sterility validation necessary to assure patient safety is essential in a timely manner and often plays a crucial role in decision making for clinical adoption (see the Section "Safety Testing and Validation After Sterilization"). The chapter closes with a view toward new developments and challenges on the horizon for sterilization technology. Developments in biologics, especially in combination products, offers a unique challenge for terminal sterilization processes. Prions and endotoxins are the most recent biological contaminants, which need sterilization and cleaning process adaptation to ensure patient safety, and the environmental concerns with increasing use of EO sets the stage for the development of equally effective but environmentally less toxic chemicals. Awareness of these challenges will allow the biomaterials scientist to be prepared with solutions to address them (see the Section "Summary and Future Challenges").

Radiation-Based Techniques

Safety Considerations

Sterilization by radiation carries two main safety concerns: possible lethal exposure to radiation and ozone. The lethal dosage of radiation to humans is about 0.01 kGy with an exposure time of less than a second in some cases. Radiation sterilization occurs at dosages ranging from 8 to 35 kGy. Thus to prevent lethal exposure to workers, safety measures such as considerable amounts of shielding and robust interlocks are implemented in radiation processing. In addition to exposure to radiation, the production of ozone is another cause for concern. Ozone is a toxic gas that is formed when radiation comes into contact with oxygen, causing first the formation of free oxygen radicals and successively ozone. Appropriate safeguards to ozone inhalation include ozone monitors and adequate ventilation. Most industrial-scale radiation sterilization occurs in closed rooms with safety precautions, and prepackaged products are usually loaded on conveyor systems that keep product containers in the path of the radiation for sterilization.

Principles of Action and Efficacy

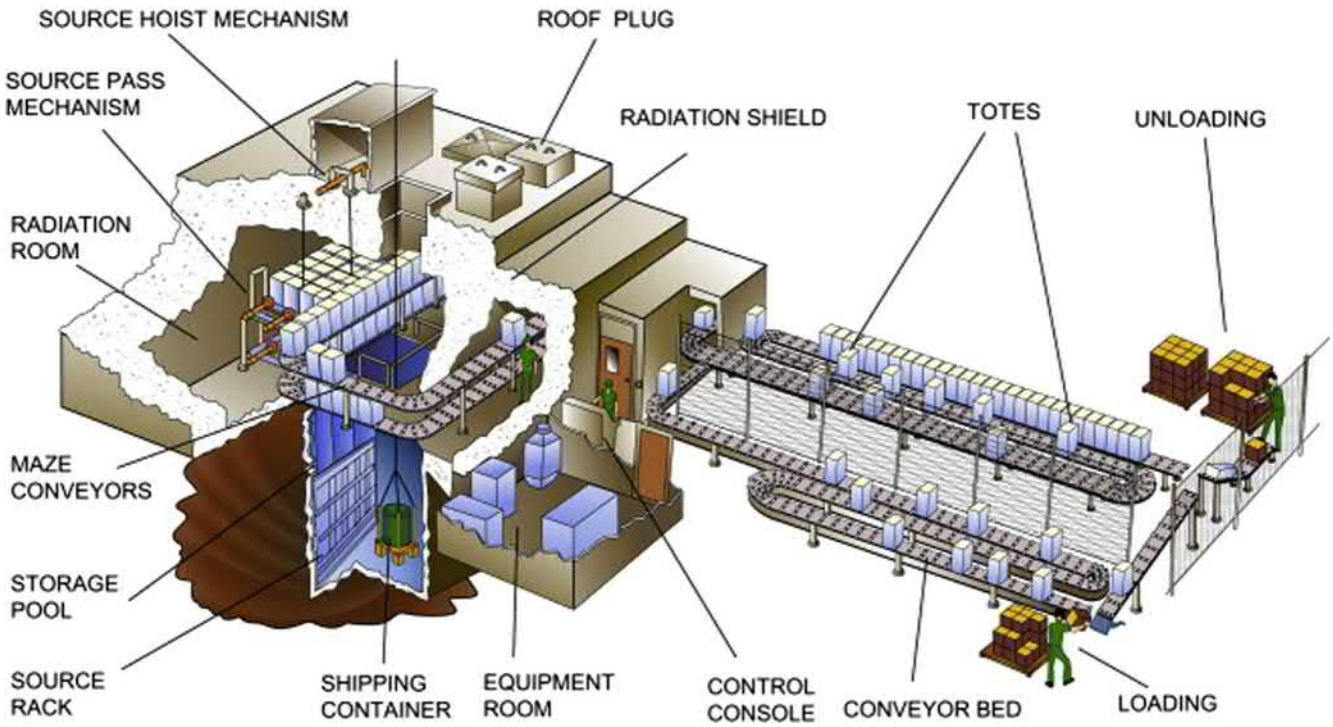
Sterilization by means of radiation is commonly used for mass-produced medical devices because of its simplicity and convenience in terms of large-scale processing. Terminal sterilization is achieved by exposing prepackaged devices to the appropriate dosage of radiation. The radiation will emit electrons or photons that penetrate the packaging and destroy cells, bacteria, and viruses on devices. Radiation causes DNA damage in bacteria and viruses preventing pathogens from reproducing and thus inactivating them. The dosage used to eliminate pathogens depends on its nature, for example, generally, the radiation dosage required for bacteria and spores is lower than that for viruses (Parsons, 2012). Although most pathogens are eliminated, some viruses (HIV-1 is at the highest range of virus radiation doses required for 10-fold reduction; Smith et al., 2001) and bacteria (such as *Streptococcus faecium* and *Micrococcus radiodurans*) are more resistant to irradiation. Thus understanding the bioburden on the materials prior to radiation sterilization is critical for determining dose and validating sterilization.

Radiation sterilization occurs most commonly through three methods: gamma, electron beam, and X-ray. The two most common methods used in industrial sterilization are gamma and electron beam.

Gamma Sterilization

Gamma radiation takes its form in short electromagnetic wavelengths and therefore is more energetic. The gamma rays sterilize a product by providing adequate energy to break down DNA and prevent reproduction. The most common source of radiation is from radioactive cobalt-60, accounting for ~80% of commercial radiation sterilization. The gamma rays produced from ^{60}Co have energies ranging from 1.173 to 1.332 MeV with a half-life of 5.27 years (Parsons, 2012). While the radiation from ^{60}Co sterilizes devices, there is not enough energy to cause the device to become radioactive.

To process devices for gamma sterilization, devices are placed in containers, generally made from aluminum, termed totes. Devices are placed in the totes and moved to the processing room to be sterilized (Fig. 3.1.4.1). Regardless of the amount in the tote, the product will be sterilized due to the lack of charge on ^{60}Co particles, which allows the gamma particles to penetrate evenly and across long



• **Figure 3.1.4.1** Industrial-scale gamma sterilization chamber showing movement of totes on a conveyor system. (Courtesy of MDS Nordion, Canada. Lambert, B., Martin, J., Sterilization of implants and devices. Biomater. Sci. Elsevier, 2013, 1339–1353.)

distances, thus making gamma sterilization an attractive option since the amount does not limit sterilization conditions. After sterilization, packages are evaluated by a dosimeter to verify whether the appropriate dosage was applied.

Sterilization by gamma radiation occurs by the release of high-energy photons that interact with substances. The common dosage used for medical plastics is 15–25 kGy, with 25 kGy being the standard dose applied. The energy of the photon is absorbed onto the material by Compton scattering, which generates high-energy electrons. The high-energy electrons (0.5 MeV) are able to ionize matter by depositing energy onto the material. These primary electrons deposit energy in 60–100 eV bundles that in turn produce secondary electrons. The secondary electrons create free radicals that cause DNA fission among other effects, which is the means by which pathogens are killed. In conjunction with its effect on DNA, the radicals also have the ability to crosslink polymers, which can alter the device's properties, therefore placing a limitation on the use of gamma radiation as a means of sterilization. This is often detected by crazing or discoloration of plastics and a reduction in the tensile strength of the materials.

Electron Beam Sterilization

Electron beam sterilization refers to the application of electrons that are accelerated to form a beam of electrons with an energy of 5–10 MeV, which are then scanned across the devices to be sterilized. These electrons are produced from electron accelerators, the two most common being DC accelerators and radio-frequency power-based accelerators. These accelerators take 200 V electrons and are accelerated to the required voltage. The electron beam is generally magnetically focused to form a beam that is 1–5 cm in diameter, which is then scanned across the product to be sterilized. At these energy levels, neither the processing plant nor product becomes radioactive since the accelerators can be turned off easily.

For gamma sterilization, the distances between devices and radiation source are not a cause for concern since the gamma particles penetrate evenly and across long distances. For electron beam sterilization, this is a limitation since the beam has limited penetration distance. The general rule is that the maximum penetration (cm) from a two-sided electron beam is 0.8 × beam energy (MeV) divided by the density of the device (g/cm^3). Generally, the maximum penetration is less than a meter and penetration distances increase with higher beam energies. Due to this limitation, extra care and planning are required to determine load placements that take penetration depth into consideration, with less dense objects being placed ahead of objects with greater density.

The process by which electron beam sterilization works is very similar to that of gamma radiation, where high-energy electrons are absorbed onto the material and produce secondary electrons. Similarly, the secondary electrons are those that eliminate the pathogens and can alter material characteristics. The process of electron beam sterilization is faster (seconds to minutes) than gamma sterilization (minutes to hours) because of a very high delivery rate of dosage. The short exposure time of the electron beam is also beneficial in that it decreases any material degradation that may occur to the product. Conversely, the penetration depth of

gamma radiation is deeper than electron beam sterilization. From an application perspective, unlike gamma irradiators, electron beam sources have had relatively low commercial availability, resulting in electron beam sterilization becoming a contract commercial sterilization option only.

X-Ray Sterilization

A small part of the radiation sterilization market is composed of X-ray sterilization. X-ray sterilization works by producing high-energy electrons, generally 5 MeV, from accelerators that are bombarded onto a tungsten target to produce X-rays. The photons from the X-rays are similar to those from gamma radiation with regard to the amount of energy deposited and the depth of penetration. Additionally, just as in electron beam processing plants, X-ray processing plants do not become radioactive, as long as the electrons produced do not exceed energies of 5 MeV. Thus X-ray sterilization is a combination of gamma ray and electron beam sterilization.

Application Considerations

To effectively use radiation as a means of sterilization, there are many factors for consideration to determine the accurate dose for a product and the effect of sterilization on the product after it has completed the entire process. Maximum dosage for a product is determined based on the initial bioburden and its nature on the products, the sterilization dose, the minimum dose necessary for a product, the homogeneity of the dose during sterilization, and the number of cycles the device can undergo.

To determine the appropriate dosage, a dose uniformity ratio (DUR) is developed. A DUR is a ratio of the maximum dosage over the minimum dosage, based on the load arrangement and density of a product batch. DURs are always greater than 1 since a product is never subjected to one dose for sterilization but multiple doses. Many factors influence the DUR, such as:

- Radiation source; gamma is much more uniform than electron beam;
- Product density;
- Shipping box/pallet size;
- Configuration of sterilizer; and
- Energy of electrons for electron beam sterilization.

R&D, Pilot, and Low-Volume Technologies

Although radiation sterilization is well suited for industrial operations, it is still an appealing method for biomaterial scientists to sterilize products. Small-scale radiation sources are appropriate for scientists conducting material qualification procedures or affording convenience during product development. Small-scale units are ideal for such cases because of the narrow dose range that will allow for faster sterilization cycles.

Scaled-down radiation sources, such as an R&D gamma cell, provide a very narrow and small dose that results in a DUR extremely close to 1. Furthermore, there are small self-shielded low-energy electron beam accelerators that are able to sterilize single packages rather than multiple doses at a time. Accelerators such as these have low beam energy, 0.5–2.0 MeV, which can only sterilize a product or a portion of a product, often coatings or thin films, which may be sufficient for development and testing.

Material Considerations for Radiation Sterilization

As previously discussed, the process of sterilizing by radiation yields secondary electrons that disrupt the DNA and reproducibility of pathogens. This is done by free radicals that cause scission to DNA but may also disrupt material properties of polymers, resulting in chain scission or crosslinking, or even reacting with oxygen to damage synthetic or biological materials of the sample. Because of these considerations, the interactions of radiation with polymers have been well studied and examined (e.g., Forsythe and Hill, 2000; Clough, 2001; AAMI, 2008). In most instances, the material of the product remains inert to the low doses that occur during the sterilization process. Additionally, some materials may experience crosslinking due to radiation, such as polyethylene, with no adverse effects, but rather potentially helpful outcomes on the function of the material.

However, there are materials that are adversely affected from exposure to radiation. Consequences of exposure include scission and considerable mechanical degradation for polymers such as polytetrafluoroethylene, fluorinated ethylene propylene, polyacetals, and natural polypropylene. Not only does radiation adversely affect material properties, air may also help speed up the scission process through radiation-induced oxidation. This is typically observed in the form of discoloration of the product, and testing has revealed a reduction in tensile properties of the material.

While the consequences of radiation chemistry may be dire, they are not as black and white as they appear, meaning that after alteration by radiation exposure, the device may still be adequate for use. This depends on the material itself, its intended nature of use and the evaluation process of the product after sterilization to guarantee that clinical standards are met. For example, bioabsorbable polymers such as polylactide and poly(lactic-*co*-glycolic acid) experience a decrease in molecular weight (MW) after sterilization. Changes in MW may alter degradation in vivo and drug release kinetics. However, this reduction in MW may be accounted for and considered by making the initial MW higher, so after sterilization the desired MW is reached. If the reduction cannot be accounted for by increasing the initial weight, other avenues may be utilized such as conducting radiation sterilization while the product is refrigerated. By lowering the temperature of the product as it is irradiated, the structural integrity of the polymer may be kept intact because the temperature is lower than the glass transition temperature. Additionally, the small changes in mechanical properties may not critically affect single use or disposable medical plastic products. Care should be taken, however, that sterilization-induced changes in properties are accounted for in shelf life and stability considerations of implants and devices.

In addition to the direct effects of radiation on materials, there may be further effects resulting from sterilization. During the irradiation process, the temperature of the product increases. If the product is being sterilized by electron beam, the temperature increases to about 50°C for materials composed of polymers for a time range of a few seconds. If the product is sterilized by gamma radiation, the temperature will increase to 30–40°C on a time scale of a few hours. This matters primarily for materials that are bioabsorbable and have a low glass transition temperature. However, if this is the case, these secondary effects can be mitigated by sterilizing the product at a lower temperature. In addition to temperature considerations, the presence of oxygen and humidity also plays a role in damaging products. To prevent such occurrences, products can be packaged in an inert environment.

Biologics and Human-Based Tissue: Compatibility With Radiation Sterilization

To better improve the use of radiation sterilization on tissue products, different methods have been explored. Low-dose radiation sterilization methods have been examined and provide confidence in increasing the use of radiation as a means to sterilize tissues and biologics, especially bone and amnion allografts. Other methods have succeeded in terminally sterilizing biologics (sterile liposomal vaccines and human insulin) by first processing the product followed by radiation. Processing methods have included lyophilization, cryoprotection, and adding free radical scavengers/radioprotectors (e.g., the antioxidant ascorbic acid) (Mohammed et al., 2006; Terryn et al., 2007). Radical scavengers have also been used in conjunction with other methods to improve the compatibility of tissue-based products for sterilization. Such innovations potentially pave the way for the increased use of radiation sterilization for drug–material combinatorial products such as tissue-engineering scaffolds.

Chemical Techniques

Safety Considerations

For sterilization purposes, EO gas must be administered and stored at highly concentrated quantities. Under these conditions, EO is toxic, carcinogenic, and very explosive. Tools and equipment must be carefully chosen to prevent the possibility of accidental sparks in the vicinity of EO chambers. Even after an EO process is complete, personnel must take appropriate measures to avoid exposure to the toxic gas. These precautions include the use of personal protective equipment as well as respirators when working with products that have not been fully aerated to dissipate the gas and its residual by-products. Finally, any manufacturer of EO-sterilized products is responsible for abiding by the international standards that allow for adequate aeration to minimize EO residual levels below permissible limits for distribution, which is governed by ISO 10993-7 (Table 3.1.4.1). In addition, contract sterilization facilities are responsible for release of the gas and community safety concerns arising from high environmental levels of EO, which pose significant public health concerns. Environmental protection actions leading to the closure of industrial-scale EO facilities and successively the regulatory push to look for alternative, safer sterilization techniques (FDA, 2019a) underscores the safety concerns associated with the rapid scaleup to meet the increasing demand for medical devices.

Oxidizing methods of sterilization using either hydrogen peroxide or ozone provide less of a threat with respect to human exposure; however, several precautions must still be taken when utilizing them. While hydrogen peroxide provides the advantage of degrading into the nontoxic products of water and oxygen, the sterilizing process begins with a source that is highly concentrated and extremely hazardous. Ozone, on the other hand, must be produced in situ since it is metastable and cannot be stored. After use, ozone rapidly degrades back into oxygen making the process safe and environmentally acceptable. When harnessing the sterile properties of either compound, equipment and devices must be chosen on the basis of resistance to oxidation as often deep vacuums are required and could be compromised if not suitable for the process.

Principles of Action and Efficacy

Sterilization by chemical means is more involved and specific to the product and chemical used than methods such as irradiation. The most popular chemical method, EO, functions on the basis of its strong alkylating property, which causes disruption of cellular processes, including clotting of proteins, inactivation of enzymes, and disruption of DNA, resulting in preventing the replication of microorganisms. The alkylation reaction occurs on the amine side chains of the proteins, enzymes, and nucleic acids. Since this reaction is facilitated by moisture, it is essential that EO sterilization be carried out in a humid environment. The other popular chemical agents, hydrogen peroxide and ozone, primarily leverage oxidation of the cell walls and proteins resulting in destruction of cell walls and even endospores with prolonged contact.

Ethylene Oxide Sterilization

Compatibility with most materials and excellent solid matrix diffusion properties have resulted in EO being used as the preferred sterilization method for almost half the medical device manufacturing market. In addition to being a low-temperature process, EO can sterilize moisture- and radiation-sensitive materials without compromising product integrity. In addition, complex product architectures and designs can be sterilized by adjusting EO concentration and duration of exposure. As multiproduct packaging of groupings by procedure type rather than individual product types is preferred, EO is gaining traction because of its broad applicability.

The basic EO sterilization cycle involves five stages: preconditioning and humidification, gas introduction, exposure, evacuation, and aeration. The packaging used to prepare products for EO sterilization must prevent microbial sterility, but allow diffusion of EO and water vapor. Critical care must be taken after EO sterilization to ensure efficient degassing and aeration to ensure that EO residues on the surface are brought to allowable limits. Typically, aeration methods are utilized because the alternative requires the use of a very deep vacuum. Total cycle times range from 6 h to several days. While EO is effective for porous dressings and woven materials, impermeable tubing or internal channels, such as in catheters, might require special processes or longer exposures for effective sterilization.

The international EO sterilization standard (Table 3.1.4.1, ISO 11135-1) refers to the use of both EO and its mixtures with a diluent. Diluents such as nitrogen blanketing along with other cycle design features are used to reduce the relative proportion of oxygen in the chamber environment and keep flammability low, without affecting the efficacy of the EO cycle. On an industrial level (Fig. 3.1.4.2A), EO sterilization exposure times can range from 6 to 24 h at processing parameters set to 40–65°C and a relative humidity of 30%–90%. This begins with exposure over a prolonged period of time to high relative humidity before the environment is flushed with nitrogen containing high EO. Once complete, EO flushing begins with a series of nitrogen injections followed by dynamic vacuum/steam pulsing and air rinsing. Sterile air is used sometimes alongside consecutive vacuum treatments to eliminate EO from the chamber. The last injection of sterile air brings the chamber back to atmospheric pressure. To meet regulatory standards, the concentration of EO is measured in the chamber after degas and on the product surface with further aeration and active air flow used to ensure removal of surface EO residues. Aeration protocols are designed based on environmental conditions and material properties such as density, size, surface area, etc.

Sterilization by Oxidation: Hydrogen Peroxide or Ozone

Sterilization by oxidative means involves the use of highly reactive, oxidizing agents. Hydrogen peroxide and ozone both have excellent microbicidal properties and their chemistries are well known, so they are often utilized for this sterilization technique. While their effectiveness may seem similar on the basis of mechanism of kill (oxidation), they in fact can produce different outcomes and are therefore used for certain applications.

While hydrogen peroxide has poor penetration properties, ozone sterilization as an alternative is somewhat better in this regard. Hydrogen peroxide is particularly limited in the depth it can reach within a product and is often classified as a surface sterilant. Additionally, hydrogen peroxide has a very high vapor and boiling point requiring the use of deep vacuum pressures in conjunction with it. This can negatively affect materials and their packaging, so most sterilization processes are conducted in small vessels rather than large chambers, limiting scalability. Additionally, hydrogen peroxide and ozone are compatible with fewer materials than EO in terms of chemical reactivity, but are still preferred because exposure times are extremely short in comparison and there is no risk of poststerilization toxic residues since the by-products are oxygen and water vapor.

Some hydrogen peroxide sterilization methods involve the use of plasma to facilitate the degradation of the oxidizing reagent. This also decreases negative effects on polymers that may be susceptible to damage (e.g., acrylics, natural rubbers, polyesters, and polyglycolides) because the plasma destroys more peroxide residues than if simple aeration were to be used. Other adaptations can also be made to minimize the effects on polymers such as reducing the concentration and processing temperature; however, this will require longer exposure times. Caution regarding material degradation and the formation of undesirable salts on the surface of devices must be exercised especially with combinatorial chemical sterilization and oxidizing plasma (see Case Study I).

CASE STUDY I

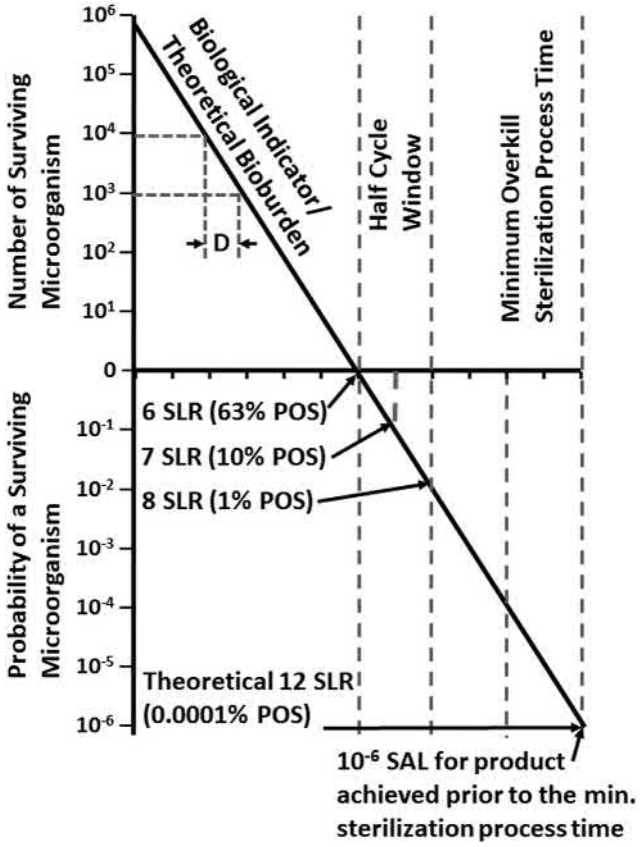
On April 13, 1998, the FDA issued a safety alert regarding the use of the AbTox Plazlyte sterilization system. The Plazlyte sterilizers utilized a proprietary, low-temperature gas plasma, along with vaporized peracetic acid. Although the system provided sufficient lethality, the FDA had not cleared the safety, performance, or instructions for use of this sterilizer. The sterilizers were sold directly to hospitals seeking alternatives for EO sterilizers. The warning was initiated due to serious eye injuries to corneal endothelial cells, which resulted in corneal transplantation in some patients. The problem occurred when surgical instruments were sterilized, and copper and zinc salts formed on the surfaces of the sterile instruments. The copper compound residues were toxic to corneal endothelia and resulted in blindness (FDA, 1998). During the time period of January 8–14, 1998, six of eight patients undergoing intraocular surgery incurred corneal edema and opacification of the cornea (CDC, 1998).

The sterilization process is generally applied to relatively smaller loads as the production of ozone has scalability constraints. Ozone sterilization involves relatively low temperatures making it suitable for heat-sensitive materials, and similar to hydrogen peroxide results in a high degree of humidity. Lowering the chamber temperature even further allows a decrease in the concentration of ozone with similar sterilization outcomes but reduced degradative effects on polymers being sterilized, resulting in longer exposure time requirements.

Physicochemical Methods: Gas Plasma

The word "plasma" refers to a partially ionized gas in which a fraction of the particles is charged while the rest remain neutral. The resulting properties of such a gas include high conductivity, which responds well to electromagnetic fields. Generation of plasma is conceptually simple. In short, a sufficient amount of energy must be supplied to a neutral gas to force a partially charged species to emerge consisting of electrons and ions. The two main types of microbicidal plasmas that will be discussed are low-pressure plasmas and atmospheric-pressure plasmas.

Low-pressure (subatmospheric) plasmas can attribute their microbicidal properties to several different mechanisms. First, the ultraviolet (UV)/vacuum UV photons emitted upon discharge facilitate the production of chemical bonds between thymine residues in DNA strands. This prevents DNA repair mechanisms from working properly and permits damage accumulation in the DNA. Another mechanism involves erosion of the spore walls of the microbe by chemically active species generated from the various gases used for plasma. These mechanisms work synergistically with the heat produced in plasma generation to break down the microorganisms and their DNA protection



• **Figure 3.1.4.3** Measuring the bioburden level on the sample and its logarithmic reduction with exposure time to determine overall gas plasma sterilization time required to achieve an SAL of 10^{-6}. *POS*, Probability of survival; *SAL*, sterility assurance level; *SLR*, Spore log reduction. (Shintani H., 2015. Simultaneous achievement of Sterility Assurance Level (SAL) of 10-6 and material and functional compatibility in gas plasma sterilization running title: simultaneous SAL and compatibility. Pharm Regul Aff. 4, 131.)

proteins. With respect to atmospheric-pressure plasmas, they include the previously mentioned mechanisms of kill—UV photons, heat, and spore wall erosion. In addition to this, they cause the buildup of electrostatic forces on the surface of spore membranes as well as the interaction of reactive oxygen species and reactive nitrogen species with the microbes themselves. Thus atmospheric pressure plasmas cause both chemical as well as thermal degradation of the cell walls, their DNA, and their ability to reproduce.

Practical limitations with the use of plasma include high cost as well as small container limitations because of the sheer amount of energy required to produce the plasma, and the prolonged duration of plasma treatment needed to achieve relevant SALs (Fig. 3.1.4.3). Also, because plasma has trouble penetrating common packaging used for sterilization, large-scale application of the technique and maintaining posttreatment sterility are fairly limited.

Material Considerations for Chemical Sterilization

EO sterilization processing parameters that are of practical importance to the biomaterials scientist are those that not only affect the final product and package, but also affect optimization throughout. Deep vacuum levels and the rate of their cycling along with chamber temperature and concentration, exposure times, and any diluents utilized can all potentially affect packaging and/or device material components, especially when considering pharmaceuticals and biologics. Other parameters such as the size of the chamber, length of the cycle, and any preconditioning, and/or aeration steps can affect cycle times and therefore product throughput.

While ozone and hydrogen peroxide both attribute their microbicidal properties to their high reactivity and oxidative chemistries, their effects can be very different. For example, hydrogen peroxide sterilizes urethanes and natural rubbers better than ozone but ozone is preferred for silicones and cellulose-based plastics rather than hydrogen peroxide. Liquids, oils, powders, cotton, linen, and paper, not just used in surgical supplies but also in packaging, absorb hydrogen peroxide and thus cannot be sterilized by that process. Ozone also has slightly better penetration than hydrogen peroxide. With that being said, understanding the material properties of the load as well as the chemistry of oxidative reaction will be the deciding factor when choosing between the two techniques.

R&D, Pilot, and Low-Volume Technologies

Small EO sterilizers are very powerful tools for biomaterials development. As well as providing a vehicle for well-controlled microbial kill challenge testing, they can be used to explore compatibility solutions and products even with the most limiting parameters. Special low-temperature and/or low-humidity EO cycles can be developed and validated to avoid material compatibility concerns. Small EO chambers are also used extensively within the hospital as well as research laboratory settings due to their convenience and effectiveness. A well-controlled R&D EO chamber is shown in Fig. 3.1.4.2B.

Alkylation chemistry, the microbial kill mechanism for EO, may produce other material effects, but in general the effects are small. Other EO process parameters, i.e., temperature, humidity, and evacuation cycles, can substantially affect device materials and are usually the greater concern. Materials must be able to withstand the most challenging range of conditions used in a given EO cycle, including humidity preconditioning and aeration cycles afterward for several days at 40°C; EO cycles for 6–24 h at processing temperatures of 40–65°C; relative humidity in the range of 30%–90%; and evacuation levels down to 2 torr in some cycles with very fast evacuation rates.

Bioabsorbable polymers may be difficult to process under these conditions because structural integrity is often compromised with them. Both temperature and humidity can degrade bioabsorbable material properties. Packaging materials must also be considered because they need to be able to withstand the evacuation rates and pressures. Materials with known deleterious responses to typical single EO sterilization cycles include polyacrylates, e.g., polymethylmethacrylate and some styrene resins, e.g., polystyrene and

styrene acrylonitrile. These materials may be acceptable in certain applications, but must be evaluated carefully after exposure to worse case cycles ("most challenging parameters") to ensure clinically acceptable performance over the shelf life of the device. It is not expected that EO sterilization will affect device performance over time.

Pharmaceuticals and Biologics: Compatibility With EO Sterilization

In the pharmaceuticals industry, EO is predominantly used for sterilizing packaging components that enter the aseptic processes. These include bottles, plugs, caps, etc. When it comes to the actual sterility of the drugs, EO is often a last resort because it can alkylate or hydrolyze molecules within carriers and because long exposures to high heat could thermally degrade the drug. Additionally, the vacuum processes involved in aeration of the product could lead to evaporation of components of formulation that have low boiling points. Liquids and powders are also not compatible with EO sterilization because the gas has a hard time penetrating them unless they are spread out in a thin layer.

In the same fashion, few biologics are incompatible with EO sterilization. Limitations due to extreme temperatures, the presence of EO residues, as well as unwanted alkylation of the product make this method of sterilization too harsh for this application. Ironically, the alkylating properties that make this gas so effective in sterilizing product also hinder it from being used in the biologics industry, since so many amines and proteins (not belonging to microbes) are actually desired and since EO and thermal processing may often result in the creation of denatured proteins that are equally undesired.

In applications where either human or animal tissues are not compatible with terminal sterilization options, liquid chemical sterilization is often used. A common example of the type of product sterilized by this method is blood dialyzers because they cannot undergo a high level of sterilization for reuse. An appealing characteristic of this technique is its simplicity and time efficiency. The basic process involves the immersion of the device into liquid solutions of either an aldehyde or an oxidizing agent (e.g., glutaraldehyde, hydrogen peroxide, or peracetic acid). These solutions may also contain buffers, detergents, and anticorrosive agents depending on the material being sterilized. One consideration, however, is that this method does not provide the same process control or sterility assurance levels as terminal sterilization processes (Chamberlain et al., 1999). Despite this drawback, automation of the process has led to significant success in providing a safe final tissue product.

Thermal Techniques

Thermal sterilization is the oldest class of sterilization technique. This method can be used with moist or dry heat, which both have many characteristics in common. The high temperature in both techniques is the main principle of microbial inactivation. A combination of high temperature with moisture has advantages over dry heat such as reduced sterilization time. However, to determine which technique is the best choice, we need to consider the following variable factors.

Safety Considerations

The hazards associated with the thermal sterilization technique include heat, steam, and pressure. While this technique is the simplest sterilization technique, following the protocols, regular maintenance, using a proper validation indicator, and controlling the exhaust would reduce the hazards. In addition to the regular safety considerations, choosing a suitable thermal technique plays an important role in the efficiency of the sterilization. The dry heat technique is the most convenient method for heat stable materials such as nonaqueous materials, oil-based injectable pharmaceuticals, powders, glassware, and metallic surgical instruments.

Principles of Action and Efficacy

Thermal processes kill microorganisms by coagulation of proteins, including structural components of the cells, as well as by rupturing cell walls. The nature of the process is strongly impacted by the presence of water or humidity, in terms of the penetration of the heat, the exposure time of the surface of the material, as well as bioburden sensitivity to dry or moist heat. For example, *Bacillus subtilis* var *niger* is less sensitive to dry heat, while *Geobacillus stearothermophilus* is less sensitive to moist heat or steam; thus each bacterium is used as the biological indicator to test the efficacy of the corresponding sterilization treatment. Action and efficacy are also impacted by the ability of the materials being sterilized to high temperatures and to steam at high pressures.

Dry Heat Sterilization

The dry heat technique, one of the simplest sterilization techniques, relies on only two parameters: temperature and exposure time. The simplicity of this technique has made it favorable for clinical and industrial applications for materials that can survive temperatures above 170°C with no deleterious effects. Convection, conduction, and thermal radiation are the major principles of dry heat sterilization. Generally, the dry heat technique includes thermal exposure at high temperature (160–330°C) for up to 3 h; however, lower temperatures (e.g., 105°C) may be effective on some microorganisms if applied for a longer period of time. Dry heat is the most logistically convenient method for devices/components that are not temperature sensitive. The simplest dry heat technique is the use of an oven. Commercial ovens are equipped with horizontal or vertical air supply to force the air inside the oven, which improves heat distribution and ensures a dry environment. The air is generally filtered by high-efficiency particulate air filters to maintain sterility. At larger scales, radiant heat tunnels and unidirectional airflow are preferred.

((A) Courtesy of STERIS Life Science Inc. (B) Courtesy of Tuttnaur Sterilization and Infection Control).

Steam Sterilization and Disinfection

Moist heat requires significantly reduced heat exposure time compared to dry heat and is nontoxic, rapid, penetrating, and energy efficient. However, this technique is not effective at destroying endotoxin (depyrogenation). Moreover, high temperature, humidity, and high pressure may lead to the softening, degradation, and hydrolysis of polymer-based materials. This technique is widely used in industrial sectors and hospitals for sterilization of pharmaceuticals in glass ampules, plasticware, and metallic surgical instruments intended for reuse by applying saturated, pressurized steam. The regulatory preference is that steam sterilization be used for terminal sterilization where possible. Steam sterilization is generally carried out at 120°C for only 20 min and under a pressure of 121 kPa. Autoclaves are widely used for this technique (Fig. 3.1.4.4), which are similar to a pressure cooker with computer control for cycle monitoring. There are generally two main types of autoclaves: gravity displacement autoclave and high-speed prevacuum sterilizer. A gravity displacement autoclave as a prolonged method has the most basic sterilization cycle, which is a suitable technique for laboratory media and pharmaceutical components. A high-speed prevacuum sterilizer is relatively faster since the air is removed from the load chamber mechanically. This technique is favorable to the articles with porous structures since the steam penetrates to the pores, which is not feasible in a gravity displacement autoclave.

Application Considerations

Thermal techniques rely primarily on temperature, time, pressure, and relative humidity. This technique is common in hospitals and industry due to simplicity, low costs of maintenance, no chemical or radiation hazards, and low general costs. Due to the nature of the process, organic solvents, nonstainless steel, polymers with low melting temperature, and degradable polymers are autoclave incompatible materials that might be degraded, melt, or hydrolyzed during sterilization. Especially with dry heat, surface features or morphology may melt or be distorted and the nature of the passivating oxide layer may change on unalloyed bare metal titanium surfaces. Polysulfones and silicones used in medical devices can be sterilized by heat; steam sterilization is preferred for polypropylene and polyvinylpyrrolidone, while dry heat is preferred for polycaprolactones.

Materials Development Considerations for Sterility

Knowledge of a sterilization modality's processing parameters and how they interact with materials (see the Sections "Radiation-Based Techniques," "Chemical Techniques," and "Thermal Techniques") is a key element in assessing material compatibility with a given terminal sterilization process. A summary of material effects with different sterilization modalities is given in AAMI TIR17 (Table 3.1.4.1).

Starting with the best candidate materials is the surest way to optimize material compatibility with terminal sterilization. Guidance on selecting material compatible with six terminal sterilization modalities is available (AAMI, 2008). The most challenging material selection scenario is the combination of a difficult-to-sterilize primary material, which is central to the clinical use of the device, with secondary materials that are also sensitive to sterilization, e.g., an active agent (pharmaceutical or biologic), a bioabsorbable material, and/or active electronics. The best approach is to select a sterilization modality that is compatible with the primary material, and then try to select secondary materials that are compatible with the selected sterilization modality.

Materials and devices are carefully designed, optimized, and delivered to meet performance benchmarks. Careful testing is essential after sterilization to ensure that these benchmarks are met and that the risk of material or device

failure is not increased, especially from the perspective of clinical performance. To characterize drug release kinetics and other combination device properties, micro- and nanocharacterization of drug–polymer matrices may be required (Ding et al., 2009). This is essential not only to ensure that the matrix properties have not changed in terms of controlled release but also that the pharmaceutical activity remains the same. Material biocompatibility can change as a function of sterilization modality and process. Device endotoxin levels are typically not sensitive to the sterilization modality, and testing may often be performed before or after sterilization. The effect of sterilization on the surface of biomaterials should also be considered. Radiation typically has a minimal effect on biomaterial surfaces, while EO, oxidative gases, and liquid chemical sterilants can have either a positive or negative surface effect depending on the application of the biomaterial (Chamberlain et al., 1999).

Ensuring adequate device performance throughout its intended shelf life is the final material compatibility challenge for the biomedical scientist. In the case of dental filling materials, for example, the microstructural properties of glass ionomers were found to be affected by EO sterilization. It was observed that UV exposure affected the hardness of the materials, and that steam sterilization caused both an increase in porosity and a degradation of material hardness (Farrugia et al., 2015). Since medical device costs are closely related to shelf life longevity, it is essential that materials stability with age and more importantly packaging stability and sterility with age be maintained so as not to increase the cost of products to the consumer. Care should be taken to conduct shelf life and aging tests in environments similar to those in which they will be stored and usually these tests are conducted using accelerated aging models.

Safety Testing and Validation After Sterilization

For a device with significant sterilization material compatibility challenges, a robust understanding of sterility concepts and associated patient safety issues may be the key to discovering a cost-effective sterilization solution. At one end of the spectrum of sterilization options is overkill terminal sterilization. This approach has for decades served the industry well for devices with limited material compatibility concerns. The other end of the spectrum includes liquid chemical sterilization of biologics and aseptic processing of combination devices, relatively costly options from many perspectives. Between these extremes are creative terminal sterilization validation methodologies and terminal sterilization to nontraditional specifications. Without the ability to skillfully navigate this continuum of options, the biomaterials scientist may not be able to cost effectively bring a product to market.

Terminal sterilization is hugely advantageous in enormously reducing microbial contamination of fully packaged products with high process control to meet regulatory sterility requirements. However, it should be noted that the definitions of "sterile" and "sterilization" are based on the complete absence of viable microorganisms (ISO/TS 11139, 2006). These definitions are problematic, as they imply an absolute condition. Sterilization processes are based on microbial inactivation, which is exponential in nature in most cases and follows first-order kinetics. Therefore both the process parameters of sterilization as well as the design of appropriate validation procedures in terms of indicators or number of samples to be tested can be determined quantitatively.

This section begins with a review of sterilization-related product and patient safety issues. This is followed by an overview of validation of sterility and maintaining sterility over time through sterile barrier packaging.

Patient Safety: FDA Recall Classifications: Class I, Class II, and Class III

Public notices from the Food and Drug Administration (FDA) and the Centers for Disease Control (CDC) regarding infections resulting from medical device-related infections and product recalls indicate very few instances related to inadequate industry terminal sterilization practices (Favero, 2001). Therefore it appears the existing standards and medical device manufacturers, and associated contractors, are providing safe and effective devices in terms of product sterility. The majority of patient safety issues do not come from nonsterile, aseptically processed products, or from improperly sterilized products, regardless of the delivered SAL. Patient safety issues develop from the introduction of foreign materials into the body during patient treatment at hospitals. In 2015, there were approximately 687,000 hospital-acquired infections in the United States translating to a prevalence of 4% of all hospital patients (CDC, 2020). Of these, 22% were pneumonia, 22% surgical site infections, 20% lower respiratory tract infections, 17% gastrointestinal infections, 10% bloodstream infections, 16% skin and soft tissue infections, and 17% related to other issues (Magill et al., 2017). The following case studies provide perspectives on where the industry safety concerns may lie by examining a few sterilization-related incidents with subsequent patient infections or injury.

As can be seen from these examples, patient safety goes well beyond the ability to provide a sterile product. Nonetheless, the validation of product sterility is an absolute must and part of the regulatory submission and approval process. Principles of terminal sterilization validation are the next topics covered.

Biological Safety Verification

The typical SAL for most devices distributed in Europe and the United States is 10^{-6} (EN 556-1; Table 3.1.4.1). Alternatively, if the biomaterials scientists, the microbiologists, and sterilization personnel cannot demonstrate that the device is compatible from a product performance perspective with any sterilization process, they may need to move the product to an aseptic process where contamination rates

CASE STUDY II

Between 2012 and 2014, at least nine US sites disclosed clusters of patients infected by carbapenem-resistant Enterobacteriaceae, and over 250 patient-to-patient transmissions of infection and over 20 deaths attributable to such complications were reported worldwide. Endoscopes, or more precisely the insufficient cleaning and reprocessing of endoscopes, was found to be the cause for this transmission between patients. These outbreaks were reported across multiple sites in the United States and across the world despite clinical facilities following manufacturer-recommended high-level disinfection. Not only were the reported cases of infection distributed geographically, but they were also distributed across multiple medical device designs and manufacturers of the duodenoscopes; the infections included both drug-resistant as well as antibiotic-sensitive bacteria. The infection transmission findings (CDC, 2014), and successive safety alerts (US FDA, 2015) and guidance (FDA, 2019b), suggested that post-market surveillance of device use in terms of observing real-world re-processing sterilization procedures was necessary to generate updated disinfection and sterility testing protocols.

The risk of transmission and susceptibility for devices such as endoscopes, which do not breach the tissue barrier, stems from close contact with the epithelial mucous membrane, which has a relatively high bioburden (10^9–10^{12}), and from that level, the nine orders of magnitude reduction achieved in washing and cleaning after use still leave a significant challenge to achieve an SAL of 10^{-6}. Additionally, these cases of transmission revealed that the design of the endoscopes that allowed for flexibility of the device, including neck regions that could kink and internal channels and conduits to allow specimen collection or house cables and wires, made the devices especially difficult to clean and disinfect during reprocessing at clinical sites. The reports of infection transmission led to new guidance in terms of not only selective culture to validate SAL through improved biological surveillance, but also recommended enhanced EO or chemical liquid sterilization intermittently based on clinical use.

EO, however, has fallen out of favor in part because of extensive controls required to avoid its carcinogenic and teratogenic risks. In addition, the use of EO adds a significant instrument turnaround time after reprocessing, reducing adoption in clinical facilities. Liquid chemical sterilants such as peracetic acid might provide viable alternatives once validated as a reprocessing technique for endoscopes and approved as such by the FDA. The number of procedures using duodenoscopes exceeds 650,000 in the United States annually, and even the lowest reported defect rates would expose over 4500 patients to risks that are relatively preventable with good disinfection and maintenance practices (Petersen et al., 2016. Gastroenterology 151, 46–50).

may not be greater than 0.1%. However, terminal sterilization processes are clearly the preferred choice for regulatory agencies. With either of these scenarios, it must also be shown that the benefits of the device for the target population outweigh the risks (potential harms and severity of these harms to the patient) associated with the use of the device. Biological safety validation is typically carried out using a biological microorganism soil separate from the product batches being sterilized; this initial bioburden is representative on potential soil on the device, and ensuring that the spores in this sample are not active after a culture test post-sterilization is an effective validation step. The biological validation challenge chosen must be a standard bug known to be among the more resistant to the method of terminal sterilization being used (for example, *Bacillus pumilis* [E601 strain] for irradiation sterilization, with *Streptococcus faecium* and *Micrococcus radiodurans* also being more resistant to radiation; and *Bacillus atrophaeus* for EO sterilization). Another major perceived concern for a greater sterility assurance level is the potential use of the device on elderly patients, immunocompromised patients, those with HIV, transplant patients, burns patients, newborns, and children. This perception is countered by the fact that these high-risk patients are routinely treated with aseptically processed products, and clinical facilities where devices are prepared for reuse routinely subject them to overkill sterilization.

Maintaining Sterility: Packaging and Shelf Life

The product packaging and sterile barrier system is critical to maintaining the safety and integrity of the sterilized product. Device packaging must maintain product sterility throughout the expected shelf life. Packaging failures represent one of the most common reasons for product recalls. Examples of possible causes of such failures include pinholes worn into the sterile barrier from device protrusions, cracks in rigid packaging components, dislodged devices such as open seals from the packaging fixtures, product damage or wear, and dust generated by device components rubbing against other materials. Compromised packaging jeopardizes the integrity of the sterile product, and becomes a patient safety concern. The standards for packaging validation provide the industry with the requirements for validation of device packaging (ISO 11607-1 and AAMI TIR 22; Table 3.1.4.1).

Packaging materials used for the sterilization of gaseous sterilants must allow for the ingress of the sterilant to the device surfaces, while packaging for irradiated products can be a vapor barrier. A breathable package may be desirable for irradiated products, as some materials (polyethylene, polyvinyl chloride, and polyurethane used in tubing, drapes, and gowns) tend to generate gases during radiation sterilization. If the gases are trapped within the package, they may present potentially offensive odors when opened. Odor generation may be reduced by incorporating antioxidants or by using higher MW materials and breathable packaging materials (Hemmerich, 2000). For product material compatibility purposes, and to protect the product from the environment (i.e., water vapor, oxygen, etc.), one may have to provide packaging with a very low rate of gas transmission. Product and packaging are typically subject to an accelerated aging program, simulation of the transportation environment, and then inspected for packaging failures to ensure that sterility and product integrity are maintained.

Sourcing, Quality Systems, and Manufacturing Controls

To put terminal sterilization and sterility assurance levels in perspective, it is useful to compare terminal sterilization with

aseptic processing. In aseptic processing there is no inactivation of the product bioburden. These products are not exposed to a sterilization process in their final packaging. Aseptic processing is defined as "handling of sterile product, containers, and/or devices in a controlled environment, in which the air supply, materials, equipment, and personnel are regulated to maintain sterility" (ISO 13408-1, 2008, amended 2013 and under development in 2019). Aseptic processing includes compounding, filtration, and filling. Through simulations or media fills of the aseptic process, the manufacturer must demonstrate the effectiveness of the controls over the risks of contamination associated with each step of the process. Control over potential contamination in an aseptic process results in a frequency of a nonsterile unit occurring of less than one in 1000 (0.1%). The sterility of the final product is based on filter efficiency and integrity, lack of available contamination in the surrounding environment, and controlling a series of operations to "maintain" sterility.

Since better process control and patient safety is achieved through terminal sterilization processes, the current regulatory environment requires medical device manufacturers to demonstrate that a product cannot be terminally sterilized before it can convert to an aseptic process. The required parameters and risk assessment methods of such a demonstration are detailed in ISO 13408-7:2012 for processes in which process simulation (per ISO 13408-1) cannot be applied (ISO 30061,2012). Liquid chemical sterilization and aseptic processing are relatively expensive options that may not provide as high a level of process control as terminal sterilization. It is therefore hoped that the biomaterials scientist will explore creative sterilization validation to ensure that the sterility assurance specification can be appropriately met.

In the majority of sterilization validations, the sterilization process delivers a significantly greater amount of lethality than is actually required. Typically, for devices composed of materials and packaging that are compatible with the sterilization process, the sterilization scientist uses a sterilization process that is easy to validate, such as high or extreme standard sterilization doses, also referred to as the "overkill" approach, which often delivers SAL values of 10^{-12}, and often values lower than 10^{-20}. If product and/or package functionality are a potential issue, one should explore options of minimizing terminal sterilization processes to assure material compatibility.

Since the dose used takes into account the initial bioburden in addition to product configuration and sterilization method efficacy, one method to reduce dose or duration is to reduce the initial bioburden on the product and innovative techniques such as the use of specialized sterilization to specifically target internal, relatively inaccessible parts of the product geometry.

New radiation sterilization validation methods have been developed (Table 3.1.4.1: Method VD_{MAX}, AAMI TIR33; Modified Method 2, AAMI TIR40) that allow for the lowest possible doses to be achieved for a given product. Along with optimizing the minimum sterilization dose, which reduces sterilization time, recently there have been multiple applications for regulatory approval for biological indicators with shorter read and culture times, for example, reducing validation of EO sterilization from as long as 24 to 4 h after aeration. Reducing sterilization dose can also be leveraged to potentially take advantage of lower temperatures or humidity if maintaining material mechanical integrity is the greater concern.

The development of fully modular, closed-loop manufacturing systems that ensure not just cleanliness but sterility is a critical requirement to enable the translation of biological or tissue-engineered products. Such systems would enable quality assurance as well as quality control that matches regulatory requirements and accelerates the development of novel technologies such as 3D printed regenerative medicine implants or personalized medical devices to clinical application.

Sterilization Standards

Confidence in terminally sterilized products comes from a robust system of process control, standardization, testing, and validation. This is critical since sterilization processing efficacy cannot be demonstrated by routine testing. For instance, an SAL of $10–^{6}$ can only be truly demonstrated by testing of approximately one million products and finding no more than one positive. Since this is neither possible nor practical, validation and assurance of sterilization processes through standards is chosen instead. The standards used in the medical device and pharmaceutical industries, in conjunction with regulatory authorities, have been provided in Table 3.1.4.1 as a reference for biomaterials scientists. As is clear from the list, the standards are comprehensive in terms of definition of terms, processes, calculations of dose, measurement of delivery, validation of processes, and clearly defined stepwise sequences not only for sterilization processes, but also for validation, materials testing, and packaging and shelf life. Increasingly, the different professional organizations responsible for producing technical standards as well as for providing the governmental regulations for medical product safety are aligning their standards requirements and providing consensus standards documents or guidance (such as the ANSI/AAMI/ISO standards in Table 3.1.4.1).

Sterilization equipment and the process must be qualified and validated. The first considerations are termed "Product Definition" and "Process Definition." For a radiation process this includes defining product families, establishing the maximum acceptable dose (the highest dose the device can withstand and still function properly), and establishing the sterilization dose (the validated minimum dose the device can receive to ensure sterility). The considerations for an EO process include defining product families, confirming that the product design allows EO and humidity to penetrate the product and package, defining the hardest-to-kill location within the product, and determining the microbial rate of inactivation.

Sterilization processes must undergo Installation Qualification (IQ), Operational Qualification (OQ), Performance Qualification (PQ), and some form of intended dose mapping specific to the sterilization process and the product batch. IQ is defined by the verification of documents to meet users and manufacturer requirements. OQ verifies that regular settings such as environmental conditions, energy level for sterilization, and cycle length are met, while PQ demonstrates that the machines work reproducibly and that this can be documented and tracked. As the last step, intended dose mapping (for example, radiation sensors for irradiation, EO strips for EO, and temperature mapping for thermal methods) includes the verification of distribution data loggers and penetration data loggers to meet SAL requirements within the product batch. This includes ensuring proof of lethality value and that three successful fully dosed product loads are tested with less than an anticipated level of sterility failures to indicate that the appropriate controls are in place. This level of qualification and testing allows some distinct benefits, such as testing only a limited batch of samples (usually 20–50) to assure a high SAL and ensuring batchwise documentation of doses and failures to create trends as well as predictive data for maximum safety. Thus even in the case of deleterious outcomes, manufacturers and contract sterilization providers can pinpoint concerns.

Summary and Future Challenges

The medical device industry has been well served by well-validated and dependable terminal sterilization technologies, radiation, and EO, in addition to many other technologies that meet custom needs. The important processing parameters and mechanisms of microbial kill are well established. Patient safety is ensured by terminal sterilization as a result of the very high assurance of sterility specifications utilized, strong process control, and robust sterilization validation methodologies that have been incorporated into the regulatory framework.

The challenge for the biomaterials scientist is to skillfully apply terminal sterilization technologies to as many products as possible, especially the more recent combination devices. Examples include drug delivery systems with active biological agents, bioresorbable temperature-sensitive polymers, and radiation-sensitive electronics. The ability to find terminal sterilization solutions to avoid aseptic processing will allow the device industry to provide these innovative therapies at the lowest price and with the highest associated process control and patient safety. As new generations of biomaterials are developed for drug delivery, such as nanoparticles, greater caution needs to be exercised to ensure effective sterilization, especially for contaminants such as endotoxins while not changing the properties the particles are designed for. Similarly, the advent of new manufacturing processes such as 3D printing requires detailed consideration be given to which type of sterilization techniques are employed and in the case of 3D bioprinting to consider which aspects should be used after terminal sterilization and which have to employ aseptic techniques.

The solutions to challenges in sterilization arise from multiple quarters: the biomaterials scientists developing robust materials that can withstand terminal sterilization; improved process control and good manufacturing and clinical practices to ensure cleanliness and reduction of biological fouling where possible; microbiologists identifying improved pathways to combat microbes without using solutions that pose personnel or societal risk; and robust validation and testing, which paired with packaging and storage controls ensures that sterile medical devices can be made available with confidence to patients and clinicians. Increasing interactions between the biomaterials scientists, product engineers, and relevant regulatory authorities and industry forums is leading to both the development of new methods of sterilization, to meet the need for newly discovered concerns (such as prions and endotoxins), and the development of new validation testing standards that increase throughput in sterilization processes and keep costs low.

Chapter Exercises

1. How is bioburden on a material or device typically determined? Is this different from "soil" that is observed in clinical settings? How do the two affect each other and the processing of the material or device for use or reuse?
2. What is the SAL? What is the generally accepted value of SAL? Are most medical devices sterilized at, above, or below the SAL and how is that choice rationalized?
3. What are the advantages of EO sterilization and conversely under what conditions may EO sterilization not be the appropriate choice?
4. Gamma irradiation may not be feasible with many polymeric biomaterials. Which polymers must special consideration be given to in this regard?
5. Processing of biological samples or materials containing encapsulated cells are limited in how they may be processed for sterilization. What are the considerations for each category of biological material and how can sterilization and safety needs be addressed alternatively?

3.1.5

Verification and Validation: From Bench to Human Studies

JOSH SIMON

Spiral Medical Development, Lansdale, PA, United States

Introduction: Focusing on Commercial Medical Device Development

Transitioning a medical device idea from an academic to a commercial setting requires a change in focus and objective. For academic projects, the objective is often to explore new phenomena or physical laws and derive solutions to scientific questions. This work may extend or build upon previous questions and/or prior experience. It may even take place for its own sake with the primary driving forces being curiosity and the thirst for knowledge. Overall, the process is open ended and exploratory. Conversely, commercial development of medical devices focuses on a defined end-point: the release of a product onto the market and its subsequent distribution to patients. As such, projects that deal with medical devices in the commercialization process usually employ concepts that are relatively well tested and explored in comparison with the novel concepts of academia. Commercial projects also have more highly defined timetables because they involve increasingly different types of stakeholders (customers, employees, physicians, distributors, government officials, etc.) with their own deadlines and requirements.

Corporate considerations for producing products used in human subjects often do not appear in purely preclinical or nonclinical academic research. As an example, corporations can have private or public ownership, which in both cases highly anticipates the yearly financial profit and loss numbers. These numbers control strategy and planning for the next fiscal year and beyond, while allowing the companies to adjust their course by making decisions on what projects to continue and what products to discontinue. This stressor of a year-end deadline drives much of the pace for medical device development. A year-long or multiyear-long project has a specific anticipated impact on the profit and loss of the company, so the deadlines and requirements that spring from that anticipation place constraints on the device project. By contrast, an academic project may indeed have deadlines for funding through grants that have specific dates for turning in proposals. These grants may in turn fund the academic research of a faculty member and secondarily provide revenue to the university or institution that employs the researcher. However, once the grant is issued, the researcher may direct the pace of the project as desired, with considerations to milestones or additional grant payments. Though these requirements do not always present the researcher with total freedom to schedule projects, there is considerably more leeway than the corporate situation.

A full description of the medical device development process necessarily implies the foregoing considerations, and throughout this chapter the focus will automatically assume the commercial perspective. This chapter will start off with a quick overview of the initial steps of a medical device project and then quickly progress to introducing verification and validation. The concepts of regulatory constraints and risk management will receive some attention as well throughout the chapter, because they integrate thoroughly with all medical device development steps.

Starting a Medical Device Project

The initialization of a new medical device project is a multidisciplinary event that requires expertise from several skillsets, such as project management, marketing, preclinical and clinical research, and regulatory knowledge. Foremost among the drivers for the creation of a project is determination of a need for the device. All successful medical device projects address conditions or injuries that are documented to exist and require treatment. Without a commercially viable driving force to support the development and production of the medical device, there is little incentive to create it.

Finding the need is not trivial. In fact, much of the initial work that takes place before a project ever starts involves assessing the need for the device and answering questions about the clinical condition, its prevalence, its progression, the consequences if it is not treated, and alternative treatments that are already available. A clinical condition, such as a bone fracture, for example, may be common and

serious, but there may also be several cheap and easy treatments available for it already. In cases where the condition is not an injury but instead a progressive physical degeneration, like rheumatoid arthritis (RA), the alternative treatments will follow a sequenced progression from early to late disease stage. A given solution proposed for treating cases of RA would need to address which stage of the disease it treats, and how the treatment is better than the other currently available treatments for that stage. If the condition currently has no known treatments, the task is somewhat easier because describing the need for the medical device only must take into consideration the alternative consequences of not treating the condition at all.

Meeting a clinical need is primary for selecting a project, but it is not something to consider in isolation. For every treatment using a medical device, there are associated risks. At some point, every medical device on the market will fail in someone. Failure represents the manifestation of a known or unknown risk, and the consequence of that failure is the harm. The extent of the harm to the patient is weighed against the potential clinical benefit received from the medical device. This comparison is called a **risk/benefit analysis** and it helps govern the potential and actual success of a device both before and after it arrives onto the market. If a proposed device has a high **risk/benefit ratio**, it may not be prudent to develop it because such an analysis would show that the benefit is not great enough to offset the risk. For most projects in the initialization phase, the question of a preliminary risk/benefit ratio will help determine whether the project moves forward.

Research data from academic and commercial laboratories often help with this determination if there are no known clinical data on the device. The purpose of these data is to thoroughly vet the concept and show that it is viable and reliable. Published (and sometimes unpublished) research data along with data on the market size, the clinical condition, unmet need, and risk/benefit are pivotal for consideration of whether to allow the project to proceed. If the physical or scientific concept proposed for the product is still unknown or preliminary and the target patient population is not clear, for example, it will be less likely for the project to receive approval by the company.

Once the preliminary assessments just discussed are complete, a project proposal takes place that consolidates all that information and presents it to some managing authority within the company. The managing authority can take the form of a special project selection committee, a **project management office**, a designated group of people, or a single person giving the approval. In either case, the approval signals the start of the commercialization and development of the proposed device. Management selects a project manager, who in turn helps select a project team and the project is officially started with a "kickoff meeting."

The first task of the project team is to more clearly define the project parameters and the characteristics of the device with greater detail. This part of the process has both a business-oriented and engineering-oriented side, and both parts are initially led by the marketing team member(s). For the commercial side, the marketing team member's responsibility is to create or solidify a **business assessment model** that will clearly delineate the intent of how the product will generate revenue and reach its target customers. On the engineering side, the marketing team member is responsible for the collection of **design inputs**, which are broad, high-level descriptions of what the device must do and how it will meet the customer's needs. The reason why marketing usually leads both initial endeavors is that the marketing department is usually the one with the broadest amount of direct customer contact and the most awareness of the overall unmet needs. Often, the marketing team will seek the help of the sales department to gather even more detailed knowledge of this information at regional and individual levels. In fact, it is generally a best practice to include a sales team member on the project team from its inception.

Design Controls for Medical Device Development

Prior to 1996 in the United States, medical device development took place differently in every company and there was generally little regulation of the process. All devices had to conform to **good manufacturing practices** and meet certain requirements depending on their device classification under the Food and Drug Administration (FDA), and so long as those requirements were met the device would receive clearance or approval for sale. Few of the requirements dealt with how the development of the device proceeded, and instead focused on whether the device was safe and effective. What became apparent over time was that the safety and efficacy of devices was strongly linked to how their development took place, and the method of device clearance or approval was not enough to effectively reduce recalls and failures. In response, the FDA created the **quality system regulation** (QSR) (21 CFR 820) (Quality System Regulation, 2019), which applies to all medical devices in the United States except certain Class I exempt device types.

The QSR implements a process known as **design controls**, which fulfills the regulation by establishing, maintaining, and documenting the process of medical device development in a company (Quality System Regulation, 2019). Aside from ticking a box on fulfilling a regulation, however, design controls really represent a more coherent process for conceiving a device and checking its design before bringing it to market. Even in the production of device components, which do not require design controls, this process can act as a system of checks and balances during the design and increase the chance of error detection. Quite simply, this is because the process calls for a repeated review of itself at each major step and traces each input from the beginning conceptualization to a specification and then to an output that can be tested against the original input under both simulated and realistic conditions. Originally the format for design controls came from ISO 9001 and contains nine parts in its present form under the QSR (Table 3.1.5.1).

TABLE 3.1.5.1 Nine Parts of Design Controls

Planning	• Describes how design and development take place • Describes responsibilities and interfaces • Describes how approvals and updates of documents take place
Input	• Requires procedures on how to run the input process • Requires inputs to address measurable needs and requirements • Requires review and approval of documented inputs
Output	• Requires procedures for dealing with Outputs • Requires Outputs to be measurable and definable • Requires essential Outputs to be labeled as such • Requires review and approval of documented outputs
Review	• Requires a review at the end of each Design Control process • Requires successful review and approval to proceed to the next stage • Reviews the adequacy of inputs or requirements at each stage • Identifies any problems with design or process
Verification	• Requires establishment of Verification procedures • Confirms through measurements that Inputs = Outputs • Requires overall review of successful testing before proceeding
Validation	• Requires establishment of validation procedures • Confirms through measurements that Inputs meet User Needs • Requires testing under realistic actual or simulated conditions • Requires overall review of successful testing before proceeding
Transfer	• Requires procedures to correctly transfer device from development to manufacturing
Design Changes	• Requires procedures to identify, document, verify, validate, review, and approve any design changes before market release
Design History file	• Requires creation of a compilation of records that describes the design history of a finished device

The bulk of a medical device development project revolves around which step of the design controls process is taking place, along with a parallel process that develops the manufacturing process once the design has reached maturity. Though the QSR regulation is specific to the United States, medical device companies outside the United States that wish to market products under the FDA follow the process. Other national regulatory frameworks, like the regulations in Brazil, specifically call for design controls as well. The same applies to organizations that use ISO 13485 (International Organization for Standardization, 2016), which is a standard for developing and maintaining a quality system used to design and produce medical devices: the 2016 version of this standard calls for a process that mirrors design controls. The ISO 13485 standard (International Organization for Standardization, 2016) requires supporting, checking, and maintaining the results of the design process in a similar way. The new European Medical Device Regulation (MDR) does not explicitly call for design controls. However, it does require medical device producers to have a quality management system (QMS), and the generally accepted standard for a QMS is ISO 13485, which calls for design controls (International Organization for Standardization, 2016). Thus through this series of chained regulations and standards that involve one another, manufacturers in the European Union must also now develop products through a design controls process, and indeed this is now true of any medical device company using the ISO 13485 standard for its QMS.

Overlaid on top of the design controls process and taking place simultaneously from before the project proposal is approved until long after the device is released onto the market is the **risk management** process. Covering this process in full detail would require at least one other chapter dedicated solely to it. However, it is important to note that the risk management process is integrated with design controls and part of project planning. Once the team has created a plan of how to find, categorize, and address risks, this plan runs alongside of the **design development plan** that comes from the planning requirement within design controls (Table 3.1.5.1). Like most plans associated with the QSR, the **risk management plan** is a "living document," meaning the document undergoes continual change and revision throughout the lifetime of the project, and ultimately throughout the lifetime of the device. Each risk uncovered and characterized by the project team is evaluated at least for severity and probability of occurrence. For risks that require mitigation or other forms of addressing as per the risk management plan, the methods used to address that risk and their results must undergo verification and/or validation, which feeds directly into the design controls process. After design controls are complete and the product releases to market, this same risk management process continues, and new risks are addressed, if necessary, and those methods for addressing them are verified and/or validated outside of design controls.

Toward the beginning of the project, as the marketing team coordinates the collection of **design inputs**, several vague descriptions for the device will take shape and these will need further detail and clarification to become **design specifications**. Each design input will lead to one or more design specifications. Moreover, there are different kinds of

TABLE 3.1.5.2 Example Design Inputs and Their Associated Design Specifications

Design Input	Design Specification
The handle of the instrument should be red	Instrument handle must be colored as Pantone color number 185 C
The handle should fit comfortably into the surgeon's hand even if the surgeon has small hands	Handle radius of curvature for each of three handle conforming curves must be 0.85 ± 0.04 cm Handle conforming curves must be spaced 0.5 ± 0.01 cm apart
The handle of the surgical instrument should be at least 6 inches (15 cm) long	Instrument handle must be 15.4 ± 0.01 cm long from end to end at longest dimension along front-end curve
The handle of the surgical instrument must be made from a durable nonslip coating over metal	Instrument handle must be constructed from surgical grade 316 stainless steel Instrument handle must be coated with MEDCT4387 Red Epoxy adjusted to the Pantone color number above

design inputs that describe different aspects of the device and these give rise to different kinds of design specifications. Some design inputs talk about the look and feel of the device. Examples of this input for a surgical instrument would be, "The handle of the instrument should be red," and "The handle should fit comfortably into the surgeon's hand even if the surgeon has small hands." Other inputs might talk about size: "The handle of the surgical instrument should be at least six inches (15 cm) long." Design inputs can also specify that the product must be sterilized before use and that it must conform to certain regulations or standards. Material requirements are also common such as, "The handle of the surgical instrument must be made from a durable nonslip coating over metal." Notice that these inputs are not precise enough for an engineer to build the device. While the marketing team member's job is to collect these inputs, it is the engineer's responsibility to interpret them and create design specifications from them that are more precise and testable. See examples of how an engineer could interpret these design inputs and create some resulting specifications in Table 3.1.5.2.

Specifications derived from design inputs can be numerous, and many companies use a document called a **design specification document** (DSD) or "spec" to collect them. Specs can be many pages long even for deceptively simple devices because they describe at great length and in detail each aspect of how the device will look and perform. Unlike design inputs, specs directly dictate how to construct the first prototype devices, which then undergo testing. Since the specs are precise, it should be possible to construct tests for each design specification to show whether the device meets the spec. This is not always the case with a set of design inputs.

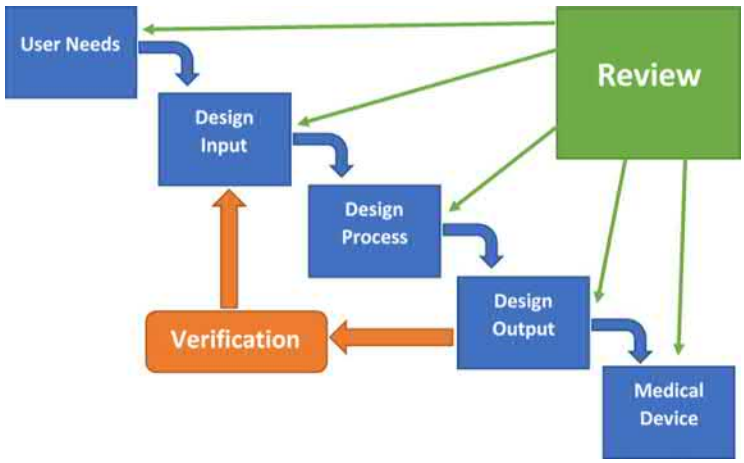
Design specifications can go through many iterations before the project team approves the final DSD. In this sense, the DSD is a living document during the beginning of the project as the team works out conflicts between the specifications. However, at some point the DSD receives approval in its final form and all the design specifications are agreed and set. This is known as **design freeze**, because from that point on in the project, the design of the medical device is not supposed to change. Any disturbance to the spec after this point will be costly, and the further along in the project at which point the disturbance occurs, the costlier it will be to change it.

While specifications are testable descriptions of how to build the medical device, the specifications themselves are not what is tested directly. **Design outputs** are tested. New team members working on medical device projects often have some confusion over design outputs and what they are. Simply put, a design output is the result of a design specification. Since there are different kinds of design specifications, there are also different kinds of design outputs. Some design outputs, for example, can be drawings. In the case of Table 3.1.5.2, the outputs of the specifications that talk about curvature radius and spacing will have drawings as outputs. The drawings will show that the plan is to create a device according to how the features are shown. Other types of design outputs can be documents like instructions for use or surgical technique guides. Pieces of the device can also be considered outputs, such as parts of a certain color. Of course, a prototype of the device is also a design output.

As a rule, every design input must have one or more design specifications, and one or more design outputs, because the whole intent of the design controls process is to track the progress of these inputs through to fruition and to document the decisions and rationale behind them. In some companies, a **design matrix** document is created, though it goes by different names depending on a company's traditions and naming conventions (i.e., functional requirements matrix, requirements and testing matrix, input-output-verification-validation matrix, etc.). Whatever name is used, the document accomplishes the task of assembling and tracking each design input and its associated design specification, design output, and later its verification and validation testing, which is discussed next. Due to the ever-increasing amount of information generated by a medical device project, this is a frequently updated living document. Some companies even combine this document with the DSD to track everything in one place and cut down on the number of documents to control.

Verification of Medical Device Design

Once the project achieves design freeze, verification can take place. In the simplest sense, verification checks that design inputs equal design outputs. This is why it is important to generate testable outputs from the design specifications, because verification should involve rigorous and scientifically



• **Figure 3.1.5.1** Verification's place in the waterfall design process (FDA, 1997).

sound testing of the outputs to ensure they are created according to the inputs. In a specific sense, verification ensures that the medical device in development is being designed according to its specifications. The graphic in Fig. 3.1.5.1 is adapted from the FDA guidance document entitled "Design Control Guidance for Medical Device Manufacturers" and shows the place of verification within the larger scheme of design controls, which is displayed as a "Waterfall Design Process" to show the relationships of the processes to one another. Without verification, there is a much greater chance that unplanned or unanticipated changes to the product design will inadvertently filter into the project. This in turn could create new and unanticipated hazards for the device if it releases without the verification process.

Although design controls, their specific requirements, and associated FDA guidance documents are United States centric, it is still important to note that the practice of verification and application of its principles are not solely United States-based requirements. Regulations under the QSR reflect the FDA's thinking on the medical device as a product demonstrating safety and efficacy based not only on its most current risk and benefit data, but also on its entire design process from beginning to end. This thinking is shared by some other regulatory bodies outside the United States but not others. Nevertheless, verification is still a part of virtually every regulatory system and is called out specifically in the European MDR (Medical Device Regulation, 2017) and the ISO 13485 standard (International Organization for Standardization, 2016), which are two of the most important regulatory structures used outside of the United States.

In the case of ISO 13485, verification is mentioned where the standard talks about planning and documenting the medical device project and says that verification activities must receive consideration ahead of time during this planning stage (International Organization for Standardization, 2016). Additionally, the standard prescribes the collection of inputs and the creation of outputs, which will later serve as a basis for verification testing. Once there is a verification plan in place and the inputs and outputs are complete, the standard explicitly requires verification testing to ensure the outputs meet the inputs, and that this testing should have thorough documentation. As a rule, there is much more leeway in how ISO 13485 is applied to a project, and companies each have their own ways of doing this, as opposed to some of the more specific requirements laid out in the QSR and its accompanying guidance documents. Nevertheless, the objectives between the two systems are virtually the same regarding verification.

The MDR is still a new regulation as this book is published, and as time goes on there will be guidance documents issued by European authorities that make the processes required in the regulation clearer. However, as it is written, the MDR does not call for a specific type of quality system or means of verification. Instead, it places the responsibility of building a quality system on the medical device manufacturer and a type of organization called a notified body, which is contracted by government organizations in individual countries called competent authorities to carry out the assessments of documentation from the medical device manufacturers. A notified body will audit the quality system of a medical device manufacturer to make sure it has effective verification processes in place. If the medical device manufacturer so chooses, it may opt to use ISO 13485 to model the basis of its quality system, which the notified body can then audit for compliance. A device manufacturer could also opt to use the QSR for the same purpose or in combination with ISO 13485. By staying compliant with both the QSR and the ISO 13485 standard for its verification processes, a company will have an easier time developing devices simultaneously for the US and EU markets.

Types of Verification Testing

Since different kinds of design inputs produce different types of design specifications that lead to design outputs, there are many different possible types of verification tests to compare the myriad types of inputs and outputs. Describing every possible type of verification test and assessing their scientific validities could indeed fill the contents of an entire course. A few types of testing will receive a more in-depth analysis

TABLE 3.1.5.3 Some General Types of Verification Tests

Verification Test Type	Input/Output Type
Tolerances	• Dimensions of an object • Durability/toughness constraints • Deformation constraints • Number of uses • Amount of work done • Amount injected
Appearance	• Color • Shape • Ergonomics • Presentation of parts
Biocompatibility	• Cytotoxicity • Hemocompatibility • Sensitization/Irritation • Carcinogenicity/Genotoxicity • Implantation (animal) • Other biocompatibility measures
Sterilization	• Effects on tolerances • Residuals • Bioburden • Endotoxin testing • Other sterility measures
Packaging	• Packaging integrity • Shipping integrity
Labeling Review	• Wording of product labels • Regulatory compliance of labels
Software	• Bug squashing • Software assurance

in other chapters of this book, while Table 3.1.5.3 gives a short list of several types of general kinds of verification tests, which is by no means exhaustive. In the verification test type column of Table 3.1.5.3, there are several forms of verification testing listed that are associated with the second column, input/output type, which suggests some design inputs/design outputs that would fall under that type of testing.

Tolerance testing is an extremely common type of verification test. For example, every medical device has some dimensions that must remain in a certain range for that device to function or even to remain in storage. The simplest type of tolerance test measures length, width, diameter, curvature, etc. using physical instruments like calipers or digital versions of measuring devices. If a design specification calls for the length of a catheter to be 1 m long, and a catheter is manufactured that is 1.01 m long, that device would fail inspection. It is "out of spec." To avoid this from happening, specifications always give a range, which is usually wide during the earlier parts of the project and narrows during the later parts. Thus, in the catheter example, a more realistic specification would be a length of 1 ± 0.05 m. If a catheter came off the manufacturing line and measured 1.04 m in length, it would pass because it is considered "in spec". Another catheter off the same line measuring 0.98 m in length would also pass. Essentially, when a drawing is made for a device as an output, there are ranges of acceptable dimensional characteristics listed on the drawing for every dimension. Each one in turn is verified by taking a sample of prototype devices and measuring all the dimensions to ensure they are in spec for a statistically significant number of devices, preferably for all devices.

Other physical parameters must undergo verification testing in the same manner: a spec with a range is given, and all devices must measure within that range. Aside from dimensional characteristics, devices have durability, toughness, and deformation requirements that specify how much force the device can take before breakage or how far it can bend/stretch before fracture. These requirements usually consider how the device will perform in the real world, and to what conditions the users will likely subject it. Tolerances also extend to the number of uses or cycles a device can withstand. These can be physical cycles or other kinds. If a device must inject a material into the body or some other vessel, the volume of injection will also have a tolerance measure that is necessary to verify. For example, a syringe device that injects exactly 23 µL of a protein solution could have a spec stating that it must inject 23 ± 2 µL, which is important for ensuring the correct dosage given to the patient. Finally, another common type of tolerance test involves mating parts that are supposed to fit together every time. There needs to be assurance that if both parts are manufactured at the extreme opposites of their individual specifications they can still fit together. This would involve creating such parts and measuring the fit.

Perhaps the easiest sort of verification testing is appearance verification. When a physical characteristic such as color or the wording printed on a surface is specified as an input, the outputs are the drawings featuring the characteristic and the prototype devices displaying them. Another possibility is a list of parts that fit together to form the device, which requires making sure all of them are present. Essentially, to verify such parameters, someone simply needs to review the drawing and prototype(s) to double check that the physical characteristics are exactly as specified. Similar and related to this form of verification is labeling review, which checks that the labeling fulfills all regulatory and marketing requirements as written.

One of the largest and most important sets of verification data is regarding biocompatibility. Not only for new biomaterials, but also well-known biomaterials must undergo verification in every device. The extent of verification differs between the two, with the newer biomaterials going through more stringent testing. Old biomaterials (>20 years) that have seen decades of use can sometimes escape major testing via creation of a biocompatibility rationale that explains the long usage of the material in similar devices as well as literature references that document the usage. This method is outlined in the ISO 10993-1 standard, which is like the requirements in the QSR and also forms the basis of European and most other biocompatibility standards. For newer biomaterials it is

generally not possible to skip the basic biocompatibility tests outlined in Table 3.1.5.3, along with others, depending on the invasiveness, type of tissue contact, and length of usage. The more invasive and longer the usage, the more testing is required. Devices that directly contact vital tissues such as brain tissue, bone tissue, and heart tissue also require more extensive biocompatibility testing. These tests will include standard tests outlined in ISO 10993 as well as appropriate animal tests in models that show their safety.

Chief among the concerns for newer biomaterials are risks posed by the products released through degradation and leaching. As time goes on, regulatory bodies move more toward treating these releasing substances much the same way that they regulate drugs, with stricter standards and higher demands for knowledge of how the substances are absorbed, degraded, metabolized, and excreted. Risks for new biomaterials also differ depending on application, because the implantation site and duration both have large effects on the leaching and degradation properties of the material. For this reason, it is often the case that new biomaterials must undergo brand new biocompatibility testing for every new device that uses them, at least for the first couple of decades of usage. Even after that point, new applications are likely to require new biocompatibility testing, because biomaterials are not cleared or approved directly by regulatory authorities. The regulatory authorities clear and approve devices, not materials, and there is generally no guarantee that a material's performance would be the same in two different situations or device types.

One of the largest and most important sets of verification data comes from sterilization testing. Naturally, for nonsterile medical devices like tongue depressors and stethoscopes, this portion of verification testing is much abridged. For sterile devices, the four most common types of sterilization are ethylene oxide (EtO), gamma irradiation, autoclaving, and hydrogen peroxide vapor. Each sterilization method has its own benefits and drawbacks, which are built into verification testing. The largest consideration for each method is how it will affect the biomaterial. For example, as a rule, all polymers will lose some molecular weight with any of the four methods, but the exact amount depends on the chemistry of the polymer. Certain polymers, like polymeric fluorocarbons, are highly resistant to most of these sterilization types for a single cycle, whereas other polymers like many alpha-hydroxy esters would not stand up well to autoclaving at all, even for a single cycle. To verify whether the sterilization method is viable, it is necessary to track the molecular weight loss effects on the device. Tracking the effects on the device and not a coupon of the bare material is key. When materials are fashioned into devices, they go through various processing steps that will affect the condition of the material and its molecular configuration. To test the true effects of the sterilization, the device in its final form (and final packaging) must go through verification testing for sterilization.

After understanding the basic effects of the sterilization method on the biomaterial as used in a final device prototype, other aspects of sterilization become important. Certain methods of sterilization, such as EtO, can leave residual material behind in the device, especially if the device contains an absorbent polymer. These residuals can create clinical problems later. Specifying a maximum level of acceptable residuals and then testing to ensure the device is in spec by having fewer residuals than the upper limit is another important verification step. Finally, assuring the device is truly sterile is one of the last pieces of sterilization verification. For example, **bioburden testing** is a method that measures how much bacteria reside on the surface of a device before sterilization. This helps engineers to set a sterilization dosage specification to achieve something called a **sterility assurance level**, which is the probability that one bacterial cell has survived the sterilization process, and is usually set at a probability of 1 in a million (10^{-6}). For all these processes, it is important to have consistent sterility results and products in specification for sterility, and important to remember that these processes are for devices in full final packaging, not loose individual devices. More information on this is discussed in other chapters of this book.

When conducting for verification testing, the process looks at the device when "fully loaded." This means it includes not only the device itself, but also all the packaging and accessories that come with the device. Thus throughout the project the packaging and other accompanying components are specified via inputs that proceed through the output and verification phases. For packaging, two main aspects are the most important: **packaging integrity** and **shipping integrity**. Most packaging specifications require that a package will remain sealed and sterile over the shelf life of the device, which can be anywhere from weeks to years. Testing how the package behaves over time requires aging studies. After aging the product in an accelerated aging scenario (usually along with a concurrent real-time aging test, which of course takes longer), the package is subjected to seal strength and sterility barrier testing. These will determine how strong the package is after aging and if it has successfully excluded bacteria over the period.

Shipping integrity is slightly different, but similar in that it requires the package to remain intact; however, instead of remaining intact over long periods of time on a shelf, shipping integrity looks at conditions through which the package travels and their effects. This usually involves simulated testing of travel conditions, such as vibrations, package compression testing, and drop testing. It can also involve shipping the package from one extreme place to another, such as a location with a high- or low-temperature climate, and/or a location that is distant.

The types of verification testing discussed in this section are by no means exhaustive. Other types, such as software verification, are applicable to specific kinds of devices and are becoming more common. Additionally, more verification tasks often appear in a project due to the parallel risk management process that occurs. When a risk is determined to require mitigation, for example, the changes made to the device design needed to mitigate that risk will require verification testing.

The aim of this section is to help convey the understanding that verification testing ensures that inputs equal

outputs, and that the company can create a prototype device in spec. Overall, this involves creating one or more tests for every specification and scientifically evaluating the results to prove that the specification is met. Some companies assemble the plans for all the testing that will take place into a large document called a **verification protocol**, and then group all the resulting test reports into another large document called a **verification report**. These documents both become part of the **design history file** of the device, or the **technical documentation** if it is a device aimed at the EU market. The concept of moving from a protocol to a series of tests to a report is often repeated in other processes, as will become apparent in the discussion on design validation.

Validation of Medical Device Design

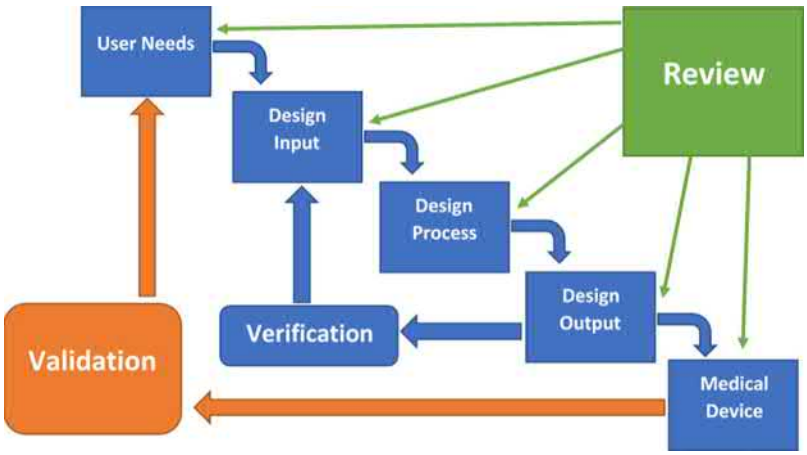
Design validation is a process to check that design inputs equal **user needs**. This reflects all the way back to the original purpose of the medical device project, to fill a clinical need by creating a device. In a specific sense, validation checks that every input that came about due to a user need is translated to one or more specifications, which are later verified and then validated as fulfilled user needs. The graphic in Fig. 3.1.5.2 is adapted from the FDA guidance document entitled "Design Control Guidance for Medical Device Manufacturers" and shows the place of validation within the larger scheme of design controls that is displayed as a "waterfall design process" to show the relationships of the processes to one another. Without validation, the manufacturer cannot be certain that it is providing what the customer is requesting or that it is meeting the need demonstrated by the market. This in turn could lead to lesser adoption of the device, and in certain cases increased risk to the patient or user.

The regulatory basis of design validation follows much the same reasoning and standards as that of design verification. Validation is required as part of design controls under the QSR and is referred to in the ISO 13485 standard (International Organization for Standardization, 2016). The MDR in turn requires validation of medical devices and leaves the choice of exactly how to do that up to the device manufacturer, which has the option to do it under a quality system based on the QSR, ISO 13485, or both. If a manufacturer decides to choose some other type of quality system, it would still need to fulfill the requirements in the MDR, which generally expects a minimum of adherence to ISO 13485. Other foreign regulatory systems require design validation in a similar fashion, often referring to the use of ISO 13485 along with additional requirements imposed differently by each country.

With a focus on connecting design inputs to user needs, design validation can take different forms and comprises different sorts of tests to achieve this. Table 3.1.5.4 illustrates some common types of validation testing but is not limiting.

TABLE 3.1.5.4 Some General Types of Validation Tests

Validation Test Type	Input/Output Type
Human Factors—health Professional	• Part compatibility or connection • Product handling • Office logistics • Operating room logistics • Ease of use • Learning curve • Cosmetic appearance • Color coding
Human Factors—patient	• Patient comfort • Ease of use • Use logistics • Learning curve • Cosmetic appearance • Color coding
Clinical Validation	• Clinical safety • Clinical efficacy • Clinical performance • Clinical benefits
Software	• Ease of use • User interface specifics • System compatibility • Security



• **Figure 3.1.5.2** Validation's place in the waterfall design process (FDA, 1997).

The format of validation testing is also quite similar to verification testing: a **validation protocol** collects the plans and lists the experiments that will proceed. Execution of the experiments produces results that are collected in a **validation report**. Examination of the results determines if they "pass" by successfully meeting user needs or "fail" by some deficiency in the results, in which case there will need to be further dissection of the problem. Whether the testing evaluates human factors, clinical validation, or other user needs, this format is generally the same, though the extent of planning and execution will vary greatly.

Human factors testing for medical professionals addresses how much the physician and medical staff like the product. Tests involve surveys and workshops where the professionals can comment on the device and/or simulate use to give feedback. For a device to be successful, it must fit into the routines and procedures of the target customer's operation. For a dental office, these needs differ significantly from an urban emergency room, as an example. Most devices are also geared toward a primary user, and that user is not always the physician. Nurses, technicians, and medical assistants also employ devices to do their jobs and the best practice is to give them input into the creation of these items.

Human factors testing for patients is similar but takes the perspective of the target patient population. Is the device targeted toward an older population or a younger one? Are the members of this population impaired in any way? Do they have special needs for accessing a device? Questions like these are evaluated in similar fashion with surveys and focus groups where the patients can simulate use and make comments. The logistics of using the product and the comfort the patients experience while using it are of primary importance among user needs for patients. If one or both things are lacking, patients will not comply with prescribed usage and their conditions will not receive optimal treatment.

It is extremely important when conducting human factors testing to avoid straying into the realm of clinical validation. The line between the two exists where simulated use stops and medical treatment begins. Human factors testing simply looks at comfort and measures opinions held by medical professionals and patients. It does not diagnose or treat injuries, conditions, or diseases. Crossing that line requires a clinical trial, which is another form of validation testing. Running clinical trials subjects the project to several other regulations beyond the typical QSR requirements for design controls, quality management systems, and documentation. Clinical trials are subject to 21 CFR 812 in the United States and the International Conference on Harmonization Guidelines as well as certain ISO standards like ISO 14155 outside the United States. All of these begin with some common tenets of modern clinical research: patient consent and safety.

Only devices of a certain risk level will require clinical trials in the United States (i.e., for all Class III devices and some Class II). In the European Union, all devices of Class III require a clinical trial unless they meet one of several possible exemptions listed in the regulation (Medical Device Regulation, 2017). In general, a clinical investigation for an implantable device containing a new biomaterial would require a way of implanting the device into human patients before the device received approval by any regulatory authority. This "first in man" trial would require provisional permission for use in a limited number of patients. In the United States, an **investigational device exemption** (IDE) is a submission reviewed by the FDA to determine if the clinical trial with the new biomaterial can move forward. In addition, FDA regulations under 21 CFR 56 require **institutional review boards** to provide oversight of the clinical trial after submission of the IDE. In the European Union, notified bodies review trial proposals and competent authorities authorize the trials under relevant requirements from a board called an ethics committee, which makes determination of whether the trial can go forward and provides oversight.

It is necessary to maneuver through these regulatory hurdles because testing novel devices on human beings can carry great risk. The regulations exist to assure clinical safety and efficacy of the device. Under the FDA this is done by directly showing safety and efficacy through clinical and nonclinical data, with specific methods depending on risk level and device class. Under the MDR, devices must meet general safety and performance requirements, which take the form of a checklist that device makers must fill out for each product or product family. The individual boxes on the checklist call for more specific requirements on clinical performance, verification, validation, safety, and human factors.

Verification Versus Validation

A major difference between design verification and design validation is that not all design inputs must go through design validation. Sometimes an input does not translate directly to a user need. Instead, it may simply be there as a necessity for the device's structure or function. For example, an input can refer to a placement of an internal screw that holds a handle in place but is unseen by any user. The resulting specification can give tolerances for the screw hole position, but that input and the accompanying spec would not need validation because they do not translate directly into a user need. They are only there to hold the device together. A user would be unlikely to care about the exact placement of the screw so long as it did not interfere with function. For validation testing documents, a brief rationale for not including any validation would suffice. Meanwhile, in the case of inputs and verification, all inputs must undergo design verification.

For the risk management process, there is a similar situation. Risk mitigations that deal directly with user needs must receive both verification and validation testing, while mitigations that do not deal directly with user needs only need verification testing. Often the most important risk data comes from clinical trials, which are part of design validation.

Concluding Remarks: Design Transfer Beyond Human Studies

Moving from benchtop through human studies is an important achievement under a project team's belt, which often takes several years. Lower-class devices tend to have shorter timelines to market because the regulatory clearance process is easier, at least in the United States. The MDR, which is still new in the European Union, is producing a shift in comparative difficulty between the European Union and the United States for placing new devices onto the market. Before the MDR, companies sought the EU market as a test bed and a quicker route to clinical use, while the United States was a more difficult but lucrative market to achieve after gaining the right to sell the product in the European Union. However, now the MDR imposes clinical evidence requirements on nearly all device types, which will require clinical trials on devices that have no prior data in the literature, in clinical registries, or in equivalent devices owned by the same company. The regulation does allow for two companies to share data on similar devices and use each other as equivalent comparators to fulfill the clinical requirements, but this is extremely unlikely to happen since most companies in this situation are competitors.

Nevertheless, this supposed ending to medical device development is just a beginning. Products spend their initial development phases under design controls, but to flourish on the market, design controls must end and production must begin. The process of transitioning from design controls to production is called **design transfer**.

The goal of design transfer is to translate all the documentation created during design controls into actionable directions and records that allow a company to manufacture the device on a larger scale. During this phase, the transfer team generates a document called a **device master record**, which serves as an index of all the documentation needed to manufacture and distribute the device. The team also generates the first version of the **device history record**, which is a document accompanying each device, lot, or batch to help track it through the manufacturing process.

Along with these documentation tasks, the product should also receive regulatory approval around that time, which will lead to training of the sales force and launching of the product. In fact, product training and launch planning begin before receiving regulatory approval and even before design transfer in some cases, so they can be ready to go when everything comes together.

The first sales of a product kick off new phases of medical device development, such as postmarket surveillance, complaint handling, and vigilance. For medical devices, these processes are usually conditional and unique per each device clearance and approval, as dictated by the FDA, although there are definite requirements for complaint handling and adverse event reporting. In the European Union, a lion's share of the MDR deals with this postmarket phase and the requirements to track the clinical performance of a medical device not only during its development and launch, but over its entire lifetime of use both in every patient and on the market as a whole.

Chapter Study Questions

1. For each of the items listed here, determine if it is a design input or a design specification, and explain your choice.

Item	Input or Specification?	Explanation
The diameter of the catheter must be 4 ± 0.1 cm		
The catheter must be slippery enough to fit through small blood vessels of the brain		
The catheter must comply with ISO 10993 standards for biocompatibility		

Answer:

Item	Input or Specification?	Explanation
The diameter of the catheter must be 4 ± 0.1 cm	Specification	This is a specification because it is specific about a size and has a tolerance range. Inputs are generally not as specific as this.
The catheter must be slippery enough to fit through small blood vessels of the brain	Input	This is an input because it talks about a user need without giving specifics on how slippery. This input would likely translate into a specification on the coefficient of friction, with a tolerance range.
The catheter must comply with ISO 10993 standards for biocompatibility.	Input or specification	This one is tricky. Input documents often give lists of what standards the device needs to observe. In that sense, this is an input. However, the specific tests within ISO 10993 are more detailed in regard to what constitutes passing or failing. In that sense, this is a specification. A DSD may use the line just as is for the specification, or it may break each ISO 10993 test into a separate line to create multiple specifications out of this one.

2. Consider a bone plate made from a novel polymeric biomaterial. One of the specifications for this device says that the "Bone plate shall be constructed from said novel polymer with a molecular weight between 100 and 150 kDa after a standard 12-hour EtO sterilization cycle." Describe the setup of one or more verification tests that would address whether or not the prototypes are in spec.

Answer:

The first thing to realize from this question is that it must use a sterilized prototype because it is asking for a device's molecular weight after sterilization to be within a certain range. Any experiment created to verify this spec would need to start with a sterilization cycle called for in the spec, i.e., a "standard" 12-h EtO cycle.

Of course, sterilizing one sample is probably not a good idea. There will need to be a number of samples that show that the prototype manufacturing process can create these samples consistently in that molecular weight range. For tests like this, having 10 or more samples is a good idea. Having those samples created on different days by different people on different equipment would be a better idea.

Subjecting 10 prototype samples to the sterilization cycle and then using some method of molecular weight measurement, such as gel permeation chromatography, would be a good start. The results would look at whether all 10 samples met the spec, and if not how many failed. As a bonus, it would not be a bad idea to also include measurements of nonsterilized samples as a control to get a better clue on how much the sterilization process affects the molecular weight.

3. For each of the items listed here, determine if it is describing a verification test or a validation test and explain your choice.

Item	Verification or Validation?	Explanation
Having people wear a brace for 10 h and then filling out a survey on its comfort		
Measuring 20 specimens of a device for their length, averaging the measurements, and calculating the standard deviation of the lengths		
Running a clinical trial on a novel polymeric bone screw to determine its Kaplan–Meier survivorship at 3 years		

Answer:

Item	Verification or Validation?	Explanation
Having people wear a brace for 10 h and then filling out a survey on its comfort	Validation	This test is expressly looking at User Needs, probably based on some Design input that talked about comfort requirements
Measuring 20 specimens of a device for their length, averaging the measurements, and calculating the standard deviation of the lengths	Verification	This test is looking at a Design specification for length, not a User Need. In general, User Needs are not concerned with tolerances and specific numerical length ranges. For a User Need, dimensions just need to be "enough to do the job."
Running a clinical trial on a novel polymeric bone screw to determine its Kaplan–Meier survivorship at 3 years	Validation	This one is tricky. The item talks about Kaplan–Meier survivorship, which is a statistical measurement of how long the implant functions in patients before failure. That could be interpreted as a specification, but in fact this statistic is usually not a required specification for devices. Instead it is considered a user need: a device needs to be "State of The art," meaning it needs to last as long as all the other modern devices in the industry that do the same thing. Each implant has a typical expected lifetime in the industry according to technology and patient need. Theoretically, this statistic could be listed as a device specification but then it would subject the device to a lengthy clinical trial to prove it, which would delay the device's entry onto the market.

4. Consider polymer microspheres with a small amount of temporary radioactivity that are loaded into a syringe and injected precisely into a cancerous tumor. The microspheres are supposed to deliver high doses of intense radiation to a small area within the tumor for a limited amount of time, after which they rapidly become less radioactive and resorb to be eventually excreted through the kidneys and lungs. Contrast the verification and validation testing for such a device.

Answer:

Since verification testing checks that inputs = outputs, the verification testing of these polymeric microspheres would check all the specifications and make sure they are functional and in range. This would involve looking at the size ranges of the microspheres. The amount of radioactivity and the pace of its dropoff would also be specifications of concern.

The other important component of this device is the syringe because it delivers the microspheres. Testing the volume of injection, rate of injection, and other aspects of the syringe function would be important. It would also be necessary to make sure that the syringe material can withstand the radioactivity under storage. It would not be good if the plastic syringe became brittle and shattered after storing the device on the shelf for a few weeks!

Meanwhile, validation testing would be concerned with patient needs. Does this device perform safely? Is it efficacious? A clinical trial or perhaps multiple clinical trials would be necessary to prove how well it functions in decreasing tumor size and/or increasing patient survival. Of course, these would all be set in the indications for use, which are not specified in this problem, nor is the type of cancer it would treat. A device like this would likely treat a specific type of cancer in a specific type of patient.

Aside from patient needs, validation would also look at physician needs, if the physician is the one injecting the treatment. How hard is it to push the plunger? How long does that take? How hard is it to attach a Luer lock to the end of the syringe if that is what the physician wants to do? Is such a thing even recommended? These questions would be answered by consulting with physicians who would use the device and collecting the results.

5. Consider a design input document that has 23 design inputs listed. How many design specifications and design outputs will that yield?

Answer:

It is not possible to tell from the number of design inputs how many specifications will wind up proliferating from them. Often, a single design input will yield multiple design specifications. A single design specification can sometimes yield multiple design outputs. A thoughtful answer to this question might be "at least 23 specifications and 23 outputs," but that is also not always the case. Sometimes it is possible for multiple design inputs to feed into a single specification, so one specification covers more than one design input. In such a case, there could actually be fewer than 23 specifications and outputs stemming from the inputs, but it would be rare.

3.1.6

Commercial Considerations in Medical Device Development

SETH J. GOLDENBERG

Veeva Systems, Pleasanton, CA, United States

Introduction

The medical device commercialization process requires a strong team with regulatory, quality, clinical, reimbursement, and sales expertise to bring a product to market. Convincing today's stakeholders of a medical device's value is harder than it was in the past (Richards, 2015). Previously, a company could launch and sustain a medical device's market share by focusing on a few regulatory clinical endpoints, procedure-based billing, and marketing just to clinicians. Real-world clinical data were an afterthought. Today, the variety of stakeholders participating in a product's success has increased (Llewellyn et al., 2015). Stakeholders may include patients, clinicians, government regulators, hospitals, and payers such as private insurance, Medicare, and Medicaid. Each stakeholder has a unique perspective to determine a device's value (Llewellyn et al., 2015). Every stakeholder requires distinct data to make their purchasing decisions. Lastly, global marketing strategies are much more complicated than launching products restricted to the domestic market (Lee et al., 2011). Each country has its own constellation of stakeholders that must be satisfied.

Early planning to capture the data desired by all the various stakeholders is essential. This is called a value-differentiated product. It includes a detailed plan on how to create that value during the product's lifecycle. This is in contrast to a product that launches with a simple clinical claim and a one-dimensional marketing message. Companies that plan for the components of a value-oriented product from the very beginning can be rewarded with an offering that is attractive to multiple value-focused stakeholders, and lower costs to develop clinical data that go beyond regulatory claims (Hartford, 2016).

Traditional Model of Product Development

Those investing money and resources to develop an expensive medical device concept want to lower their risk, reduce the time to regulatory approval, and have the broadest possible market commercialization for the highest possible profit margin. A survey of over 200 medical device companies estimated a total cost of US$31 million to bring a low- to moderate-risk device (i.e., Food and Drug Administration [FDA] 510(k) product) from concept to market. Makower et al. (2010). In comparison, high-risk devices (i.e., FDA Class III Premarket Approval products) averaged US$94 million, not including the cost of obtaining reimbursement approvals or sales and marketing-related activities (Makower et al., 2010) In addition, it was found that only one in four venture capital-funded medical technology startups ultimately found success (Makower et al., 2010).

Product development at smaller companies often follows a linear stage-gate approach as shown in Fig. 3.1.6.1. According to one report, 88% of medical technology companies fail to deliver significant return to their investors. (PWC/NVCA, 2015) < Focusing on traditional "phases" or "gates" may be one reason why this approach is failing. Companies have become hyperfocused on regulatory approval milestones without planning at the outset how they will move beyond "safe and effective" in a timely and cost-effective way.

Larger companies may have dedicated new product development (NPD) teams that develop new product plans. These teams usually incorporate a more robust consideration of the potential market, perhaps including general analyses of reimbursement, market size, and potential gaps in the market. However, the plans generated in this situation do not often detail the problem of *exactly* what to do, *exactly* when to do it, and *exactly* who does it. Without these details the product and plan may flounder due to communication issues (Medina et al., 2011). Without a detailed plan, each corporation silo is left to make decisions from the perspective of their own departmental culture and often narrowly defines processes without knowing the downstream effects of those decisions. They also have to reinvent the process each time, adding to the total time and cost (Goldenberg and Gravagna, 2018).

As software is becoming a larger part of medical devices, less traditional forms of product development are being

• **Figure 3.1.6.1** Linear stage-gate approach to medical device development. *CMS*, Centers for Medicare and Medicaid Services; *FDA*, Food and Drug Administration.

tested. Agile product development is the lead trend of new product development methodologies. This approach began in the 1970s and entails assessment of the project all throughout the product development lifecycle. One key feature of agile development is that work is conducted by the members of the product development team on a regular basis (Tan, 2016). Each round of development is called a sprint or iteration. Every aspect or phase of the development process is continuously revisited and reassessed throughout the development lifecycle (Tan, 2016). These lead to shortened development times and constant improvements, but this approach can be challenging in a regulated environment where validation is needed (Tan, 2016). It can be successful if the core regulated parts of the product are maintained where the unregulated interfaces or displays are modified more frequently.

Determining Market Opportunity

Determining market opportunity was historically done by determining overall market size and dollars spent on a product. In some cases, firms buy market assessment reports. The report is typically at a high level. A company needs to look at their total market size and their addressable market in detail, ideally from a bottom-up approach. In addition, one needs to look at the addressable market, or how much one can really capture with a new product (Kalorama Information, 2018). While market assessment reports are still a valuable process, today's need for understanding market opportunity really needs to look at the overall value a medical device is providing to the market.

If an organization has not considered how their product's value will be seen by different stakeholders in a global market, their product could fail to be successful even if it meets its clinical goals. For example, an implantable medical device that improves the cardiac output of a patient with heart failure is of clinical value, but

- Can it also lower the overall cost of care in the heart failure population for a payer like Medicare?
- Can it reduce 30-day rehospitalization rates?
- Can it improve the efficiency of clinics managing heart failure patients?
- Can it improve the quality of life for the patient?
- Will it improve or hurt the clinicians' practice and profitability?

Anticipating these potential benefits of a product can move the product from "low value" (i.e., single clinical benefit targeting single stakeholder population) to one of "high value" (i.e., diverse array of benefits targeting diverse stakeholder populations). Although it is the same product, the low-value marketing strategy is risky because it depends on adoption by a single customer (clinicians), whereas the high-value scenario spreads its risk by appealing not only to clinicians, but also to payers, hospitals, clinics, and patients. Anticipating these benefits enables a company to plan for and collect needed data for value creation earlier in the process rather than later. Pairing the data collection for stakeholders with studies for regulatory required endpoints allows medical companies to appeal to stakeholders faster and at a fraction of the cost of doing later studies.

A medical device's potential value can be defined more broadly than the "safe and effective" bar set by governmental regulatory agencies if one considers the many stakeholders that are key to a device's success in the marketplace. How differing stakeholder populations determine value for medical devices is a topic of intense research. ISPOR 1, ISPOR 2, Institute of Medicine (US), 2010. However, to reach beyond the threshold of "safe and effective," we will briefly discuss general value perspectives for patients, hospitals and integrated healthcare systems, payers (private and government run), and governmental healthcare agencies (Goldenberg and Gravagna, 2018).

For patients, value may mean more choice, lower out-of-pocket costs for devices and related clinical services, and/or a better quality of life. Patients have become savvy consumers as they have online access to information (correct and incorrect) about health data. They also have online platforms to share reviews that can drive brand preferences (Brinton et al., 2013).

For hospitals and integrated healthcare systems, value may mean lower product and service costs, and fewer complications (e.g., infections, repeat hospitalizations, or long and complicated procedures). To evaluate a device, hospitals will often use documented improvements in clinical outcomes and clinical processes, and/or an analysis of the total cost of a product. The total cost analysis might consider the difficulty of its implant procedure, or clinical data on post-surgical infection rates. Hospitals have expanded the scope of a medical device's value beyond simple features and benefits to encompass the entire healthcare ecosystem affected by its use (Hartford, 2016; KASCOPE).

For payers, value may mean lower product and service costs, better health outcomes for entire patient populations, and lower overall delivery costs per patient. For certain products, payers continue to need data to support if a product is "reasonable and necessary" and how it impacts long-term patient health.

For governmental healthcare agencies, value means balancing cost with improving health service delivery and outcomes at a national scale. They evaluate this using health economics data and strategies such as alternative payments, formal value analysis, and efficiency tracking systems. NPD teams will need to anticipate these data requirements to support health economic claims (Table 3.1.6.1).

TABLE 3.1.6.1 Criteria Used to Define Medical Device Value Varies by Stakeholder

	Patients	Providers	Payers
Health outcomes	X	X	X
Choice	X		
Total cost		X	X
Out-of-pocket cost	X		
Complications	X	X	X
"Reasonable and necessary"			X

What is common among stakeholders is the need for data and communications that addresses their needs. An efficient NPD plan would secure data that supports regulation and marketing needs *before* launch. This requires that value propositions are rooted not only in regulatory clinical endpoints but also broad population-based health outcomes, clinical and procedural efficiency, and patient quality of life improvements KASCOPE. These data are critical to building an integrated customer engagement roadmap. NPD teams must start with this end in mind.

Medical Device Reimbursement

Reimbursement is often one of the first elements a company will consider when developing a product. Companies may assume that medical need will ensure reimbursement. However, since the Affordable Care Act (ACA) switched reimbursement from procedural to outcome based, stakeholders need more data on how the device impacts the entire healthcare ecosystem. A reimbursement strategy is often the first step that companies formulate in determining how to successfully market their product. An analysis of the current reimbursement landscape is imperative. In the current regulatory and reimbursement climate, clinical studies alone fall short of what is needed to bring in actual sales. Companies need to develop a strategy for how their product will be paid for. Coverage, coding, and payment are the three pillars of reimbursement.

The need for clinical data is a common theme in obtaining reimbursement and generating sales of a medical device. Both Class 1 data and Class 2 data are necessary. Class 1 data consist of randomized controlled trial (RCT) and Class 2 data include prospective registries, longitudinal studies, and case control studies. "Real-world" Class 2 data are becoming more valuable. While Class 1 data can provide the scientific validity of device safety and efficacy, the rigorous oversight and strict patient selection criteria are often not representative of real-world patient populations. Conducting Class 2 studies provides greater insight into the costs, benefits, and patient outcomes a new device may have. Too often, companies fail to plan for health outcomes studies. Mandated postmarket surveillance should not be the only reason companies have for collection of postapproval data. The need for postmarket surveillance can typically be leveraged into valuable health outcomes and value proposition data if properly considered.

Coverage via a national coverage decision (NCD) or a local coverage decision will only apply to new medical procedures and technologies that are not currently defined in the regulations. An NCD applies only to a fraction of new devices and requires a significant amount of clinical data. At least one publication of an RCT is required. The FDA approval process is quite different from the process of meeting America's Centers for Medicare and Medicaid Services (CMS) guidelines to qualify for reimbursement by insurance companies. The FDA stresses safety and efficacy, while the CMS focuses on superiority of a product relative to the gold standard. This difference makes it challenging for a company to achieve both clearance and coverage. Essentially, the FDA makes decisions on a predicate device and CMS looks for novelty. A parallel path initiative was implemented in 2011 where companies meet with the FDA and CMS to determine clinical requirements for approval and reimbursement simultaneously.

Coding is the language of CMS, private payers, facilities, and physicians. Coding translates into payment. Without a proper code, procedures and products are not paid for. Codes include information on the type of medical facility, medical professional, and medical equipment used to treat the medical issue. The majority of companies focus on coding when they do a reimbursement analysis for cleared products. Determining how and where your product fits into the coding landscape can be a complicated and sensitive matter requiring thorough analysis. Creating a new code or obtaining an add-on code for additional payment to an existing procedure is an avenue many companies pursue. This strategy can be very successful but requires a good body of clinical data, usually peer-reviewed journal publications of Class 1 (RCT) and Class 2 (prospective registries, longitudinal studies, case control studies). Notably, a new code does not always result in payment. There are numerous codes that have a value of zero.

Payment is the coup de grâce of all the hard work and effort that it took to get a product cleared for commercial sale. After coverage determination and coding hurdles have been crossed, the amount a hospital or physician practice will be paid for your product determines sales. However, successful sales strategies can come not only from reimbursement, but also from a well-defined value proposition. Under the new ACA rules, many medical devices are used as part of medical procedures that are covered by a single payment to the hospital for the procedure (via Diagnosis-Related Group or Ambulatory Payment Classification code). Hospital systems are incentivized to lower cost and improve quality to stay financially viable. Companies often create a value proposition for direct purchase of devices that reduce length of stay, readmission, and/or procedure time. Physician advocacy and clinical data are usually required to create this value proposition for the hospital.

Dissemination of data needs to be planned and carefully considered early in the product development process.

Publication planning will ensure the necessary data are released in an ethical and timely fashion while reaching your desired audience. Peer-reviewed journal publications are the preferred method of disseminating clinical data regarding a new medical device. Journal publications provide a level of credibility that cannot be realized by internal white papers. CMS, private payers, hospitals, and physicians expect data to be presented in the form of journal publications. Release of abstracts and podium presentations at medical society meetings are also valuable dissemination tools. Including publication planning, authorship considerations, and medical writing early in the process of product development will result in maximum use of clinical data. Early planning also helps determine the role of key opinion leaders and other physicians in the dissemination of data. In addition, proper publication planning can identify the key journals and conferences to effectively reach your targeted healthcare providers. Beginning this process early is crucial for success, as the type of clinical trial design and prospective data analysis performed may limit your access to top-tier journals.

The necessary relationship between physicians and medical device companies is of vital importance, but also creates additional regulatory considerations once a device is cleared for sale. Acceptance of your product within the medical community is necessary to drive sales, regardless of reimbursement. The best way to achieve broad acceptance of your device is by having your product presented at medical society meetings and outcomes data published in medical journals. To do this, you need physicians to support your data collection efforts. While physicians are not allowed to be paid for authorship, companies can pay expenses for meeting attendance, time for steering committee or advisory committee involvement, and device development work. If you are fortunate to have your product reimbursed by CMS, be aware that you are required to report all physician payments under the Sunshine Act (Hartford, 2016).

Postapproval data generation is also a new reality for most medical device companies. This can be through postmarket clinical studies that are similar to premarket studies or it can be through clinical registries. A clinical data registry records information about the health status of patients and the health care they receive over varying periods of time. Clinical data registries typically focus on patients who share a common reason for needing health care. They allow health care professionals and others to see what treatments are available, and how patients with different characteristics respond to various treatments. These "real-world" data are increasingly important to payers and even regulatory bodies (FDA, 2019). They show the true value of a product in the wild.

Securing Intellectual Property and Funding

Intellectual Property

Once a regulatory and reimbursement path has been defined, one can begin to seek investment. Prior to making an investment, most investors will want to ensure that intellectual property (IP) is strong for the medical device. There are many types of IP protection, including trademarks, copyrights, trade secrets, and multiple types of patents (Teska, 2007). This section will cover the key parts of patents and how they impact the overall business. Before a medical device patent is considered, or any large commercial investment, an IP analysis should be done to ensure that no infringement would occur in the future (Teska, 2007). These patent costs can be high, with initial provisional patents costing up to $10,000 and the full patent prosecution can be up to $30,000 in many cases (Teska, 2007). There is also the cost of defending the patent and keeping it current, which can raise costs significantly. Entrepreneurs who are just starting out need to take all this into consideration, especially if they are entering a space with larger companies that employ full-time legal teams. Patents should also be filed not only in the United States, but also in the European Union and key countries where their new medical device could have commercial opportunities.

There are several patent types that can be filed in the United States and around the world. Design patents and utility patents are the most common patents that are utilized by medical device companies. A utility patent may be sought on "any new and useful process, machine, manufacture, or composition of matter" (35 US Code 101, 1959). An invention may be protected with a utility patent if it is novel, nonobvious, and useful. Subject to some exceptions, the term of a utility patent in the United States is 20 years from the earliest US filing date of any nonprovisional patent application to which the patent application claims priority (Teska, 2007). While obtaining a utility patent can be expensive, the benefits of filing are numerous. Issued patents enjoy a presumption of validity in legal proceedings. Additionally, patents can be a major source of income, as the rights to use the technology may be licensed to competitors or be kept for competitive advantage.

Design patents protect the novel ornamental features of a patented design. Like a utility patent, a design patent allows the patentee to exclude others from using the patented aspect of the product. While the utility patent term is 20 years from the filing date, the term for a design patent is 14 years from the date of issue. Most patents granted today are improvement patents. These patents protect the differences between a new product and previously existing products and services of the same kind. Improvement patents can be further broken down into "addition" or "substitution" inventions. Patents can also be issued for a new use, for example, a device was only used arterially, but now can be used in venous therapies (Teska, 2007).

In some cases, keeping the information about a technology as a trade secret can make the most sense. All patents require disclosure of how the technology works. While most companies believe that IP is best, if reverse engineering a technology is very challenging a trade secret could make the most sense. As the name suggests, trade secret law protects information that derives economic value from being "kept secret." Under

the Uniform Trade Secrets Act, trade secrets are different from trademarks, patents, and other forms of IP in that, by their very nature, they are not disclosed to the public.

Securing Funding

Venture investment in the medical device sector was a $5 billion industry in 2014 (Evans, 2016). The bar for new investments has increased significantly as accelerators and incubators are supporting companies to improve their pitches and coach them on what investors are looking for. Today's investors are considering total value, so products that reduce costs and improve outcomes are getting the most funding. While these investment trends will change over time, the process of raising funds has been consistent. Less complex products that go through 510(k) pathways will require fewer rounds of investment and milestones than more complex products that will need large clinical studies. The milestones and narrative to investors should reflect key points in a company's lifecycle such as prototype development, preclinical testing to show a product works as planned, initial FDA engagement for a clinical trial or testing needed to complete a regulatory submission, and finally scaling up for commercialization with manufacturing, sales, and marketing (Evans, 2016).

The first type of investors that a company will work with are angel investors. Angel investors are most often individuals (friends, relations, or entrepreneurs) who want to help other entrepreneurs get their businesses off the ground, and earn a high return on their investment. Usually they are the bridge from the self-funded stage of the business to the point that the business needs true venture capital (Evans, 2016). Angel funding can range from $150,000 to a few million dollars. Angle investors typically offer expertise, experience, and contacts, in addition to money. Medical device companies may also seek nondilutive funding (where they retain all their equity) through government grants like the Small Business Research Initiatives from the National Institutes of Health. Small research businesses who are partnering with nonprofit organizations such as research hospitals or universities are also eligible for Small Business Technology Transfer grants.

After initial investors are convinced, companies need to begin doing preclinical or bench testing to finalize their device. This is when a "seed" investment may occur. These investments are typically directed toward product development, market research, building a management team, and a business plan. Seed-stage investors' funds will typically participate in later investment rounds with other equity players to finance business expansion costs such as sales and distribution, parts and inventory, hiring, training, and marketing.

Once the medical device is ready for final testing for FDA submission, a Series A round is likely to occur. This Series A refers to the class of preferred stock that the investors receive. It is usually the first series of stock after stock has been issued to company founders, employees, friends and family, and angel investors. These early series of investments, even if more than one (i.e., Series A, B, and C), will be focused on reaching a regulatory and clinical milestone. This can put pressure on companies to reach these milestones, so it is crucial firms always understand the final commercial goals and do not sacrifice these for short-term gains. For example, companies frequently go for easier regulatory claims to meet investor requirements, but these claims may not allow for longer-term commercial success.

Future series of investments will be focused on what is needed for commercial success. These steps include building a sales team, investing in manufacturing to produce the product in large enough quantities and at a price point where a profit can be achieved, and in some cases postmarket clinical studies to show health economic impact beyond what was required for regulatory approval.

Commercial Operations: Sales and Marketing

Commercial success of a medical device is dependent upon a complex team from diverse backgrounds. The team should be an integrated, collaborative, flexible, cross-functional team that incorporates core strategic functions (i.e., clinical, regulatory, legal, R&D, reimbursement, engineering, sales, and marketing). Depending upon the device, additional or specialized functional areas may be needed, such as software engineering for an app-enabled smart device, or patient support/technical services if the device is consumer oriented and will require after-market care and support. Thus this core team represents all key business functions that will touch the device and the expectation is that its members are responsible for, and dedicated to, the development of the new product. They are empowered and incentivized to drive toward success efficiently. With the core team approach, the new product has a champion within each functional area to shepherd it through obstacles or translate specific operational needs that are important within the broader context of commercial success.

When developing a sales and marketing strategy, medical device companies need to determine whom the key stakeholders are who will purchase their products. This is constantly shifting. Physicians currently have less influence over which products they can use, while administrators have joined one or more group-purchasing organizations and use their combined purchasing power to make decisions and negotiate rates (Hartford, 2016). A common sales and marketing technique to communicate with the many healthcare stakeholders is a claims matrix. It also ensures medical salespeople are fully compliant about the claims that they make about a product.

Clinical claims reflect a primary clinical endpoint claim in a study, such as improving cardiac output of heart failure patients by 15%. There may also be secondary clinical claims about lower infection rates postdevice implant or reduced rehospitalization rates. The claims can also include population health outcome claims, such as reducing overall rehospitalization rate of heart failure patients by 8%.

Increasingly, economic claims are very important to purchasers. They now talk about the overall health reductions for a procedure. This will be about the cost savings or reduction in overall cost of care for patients. They can also take the form of efficiency claims, where more patients can be treated in the same amount of time or with the same amount of staff.

Procedural claims can touch not only on the speed of a procedure, but also on safety. Now that hospitals are increasingly required to pay for the whole lifecycle of a treatment, readmittance, infection rates, or other improved safety measures have a clear financial impact. Devices that allow for more accurate procedures are also appealing to decision-makers.

The largest increase in claims that can support sales and marketing are patient quality of life claims. Patient advocacy groups, insurers, and healthcare providers are all making decisions about which products to use based on quality of life (QOL) data. While these studies may have significant variability between patients, capturing these data during other studies can be very important for commercial success (Doward et al., 2010). QOL data capture patient compliance with a therapy and also speak to the patient's ability to enjoy normal life activities.

Summary

Having a detailed plan for data collection is an essential part of the medical device development process. There are many good reasons to consider what each stakeholder values early on. It is more economical and time efficient to plan for Class 2 data collection during the regulatory process and postapproval monitoring. Providing data to back up economic and QOL claims, in addition to clinical outcomes, provides a product that is attractive to investors and decision-makers. This gives a new medical device the best chance of commercial success.

Student Questions

1. What are some of the recent changes that affect the success of a new medical device?
2. What are some of the differences between linear development and agile product development?
3. Give an example of Class 1 and Class 2 data.
4. How do medical device companies fulfill different stakeholder needs?
5. What are some of the skills needed for a successful product development team?
6. Can you speculate how product development for emerging markets might differ from the product development process in developed markets?
7. Explain the differences between FDA approval and CMS approval and how it affects the success of a medical device.
8. During which stages of development does a company secure funding for their idea?
9. What are the four marketing claims a product can make? Which do you think is the strongest?

3.1.7

Regulatory Constraints for Medical Products Using Biomaterials

ELAINE DUNCAN[1,2]

[1]Paladin Medical, Inc., Stillwater, MN, United States

[2]Joseph Halcomb III, MD. Department of Biomedical Engineering, College of Engineering, University of Kentucky, Lexington, KY, United States

Introduction and History in the United States

The Congress of the United States of America was determined to introduce control over medical device safety in response to various notorious medical device calamities, but the Dalkon Shield[1] can be credited for galvanizing action in the early 1970s. According to a historical account of medical device legislation produced by the US Food and Drug Administration (FDA),[2] it was not until the Federal Food, Drug and Cosmetic (FD & C) Act of 1938, when a definition of a medical device was added to the existing law, did the FDA have any authority to "bring charges in court" against a defective medical device. It was not until the 1976 Medical Device Amendments to the FD & C Act that the FDA was given explicit oversight of new devices entering the market. The "risk-based" structure of these regulations is attributed to the work of the Cooper Committee organized when President Richard Nixon endorsed medical device legislation. The Cooper Report recommended three categories of devices: (1) those "so well recognized as safe and effective" that neither standards nor premarketing approval was needed, (2) those that could be regulated by standards, and (3) those "new and unproven critical devices that are at the leading edge of technological innovation and biomedical explorations" and that require premarketing review.[3] Committees were formed from representatives on the basis of certain clinical specialties who essentially voted on the designation of risk classification within their respective clinical specialty. When finalized the 1976 Medical Device Amendments established the authority of the FDA to:

- Provide reasonable assurance of the safety and effectiveness of medical devices;
- Authorize the FDA to ban devices;
- Create a three-class, risk-based classification system for all medical devices;
- Establish the regulatory pathways for new medical devices to get to market:
  - Premarket approval (PMA);
  - Premarket notification (510(k)) for devices that were not on the market prior to May 28, 1976, or had been significantly modified;
  - Creation of the regulatory pathway for new investigational medical devices to be studied in patients (Investigational Device Exemption [IDE]);
- Establish several key postmarket requirements:
  - Registration of establishments and listing of devices with the FDA;
  - Good manufacturing practices (GMPs);
  - Reporting of adverse events involving medical devices.

Global Premarket Assessment Methods

The outcome of the FDA regulation established a scheme of device classification that reflected knowledge of certain devices at the time of classification but did not necessarily represent a

[1] Dalkon Shield was a contraceptive intrauterine device developed by the Dalkon Corporation and marketed by the A.H. Robins Company. Many accounts attribute the adverse events of septicemia to a porous, multifilament string upon which bacteria could travel into the uterus of users.

[2] Medical Device and Radiological Health Regulations Come of Age, FDA Consumer magazine, The Centennial Edition/January–February 2006 by Carol Rados: https://www.fda.gov/downloads/AboutFDA/WhatWeDo/History/ProductRegulation/UCM593521.pdf.

[3] Institute of Medicine (US) Committee to Study the Use of Advisory Committees; Rettig R.A., Earley L.E., Merrill R.A., editors. Washington (DC): National Academies Press (US); 1992: https://www.ncbi.nlm.nih.gov/books/NBK236081/.

logical hierarchy of risk analysis or a method to guide future device classification. Not until the introduction of the European Medical Devices Directive[4] was there a medical device classification following a formal hierarchal "risk-based" system reflecting the vulnerability of the human body and taking account of the potential risks associated with the devices in their intended use. This approach allowed the use of a set of criteria, combined in various ways to determine classification, e.g., duration of contact with the body, degree of invasiveness, and local versus systemic effect, to have overriding influence on the regulation of the device. As medical device technology and subsequently knowledge of risks associated with medical devices have changed, Europe has revised the regulations, now known as Medical Device Regulations (MDRs),[5] and increased the number of classification "rules" from 18 to 22, including a separate "rule" for devices incorporating or consisting of nanomaterial.

Regulators throughout the world have sought harmonization of MDRs, yet the major jurisdictions continue to apply different methods to assess the risk of medical devices with biomaterials. To appreciate the similarities and differences between US and EU classification methods of a biomaterial used as a medical device, the difference in classification and quality control scheme for Gutta-Percha, one of the oldest known implantable biomaterials, should be examined. According to US FDA 21 CFR 872.3850, Gutta Percha points are made from coagulated sap of certain tropical trees. The Gutta Percha point is softened by heat and inserted into the root canal where it hardens as it cools. Gutta Percha points are Class I in the US FDA regulations and not considered an implant. They are not subject to premarket clearance (510(k)) but are subject to quality systems and thus potential FDA manufacturing inspection. In contrast, under the European Medical Device Directives classification, Gutta Percha points follow Rule 8 because these are surgically invasive, long-term use, implantable devices. However, since these are put in teeth (rather than any other part of the body) this device has a lower Class IIa designation (considered a medium risk device). The IIa category in the European Union requires verification of a quality system by a notified body, compliance with ISO 10993 for biocompatibility testing prior to CE marking. Although arrived at differently, the historic use of the material and its accepted safety have allowed the material to be subject to moderate controls in both jurisdictions although the regulatory threshold in the European Union is much more expensive and elaborate. Some patients could react to the natural latex component of the material and at least one study has found some versions of the material to be mildly toxic, apparently due to inorganic fillers.[6]

A brief survey of the regulatory schemes of a few of the World Biomaterial countries find similar risk-based structures for medical device marketing authorizations, although any specific device may carry a slightly different classification and thus different premarket challenges. For example, in Japan's system, Class I devices only require registration via the Todokede process; most Class II devices, and a few Class III devices, follow the Ninsho pathway but Class II products that do not hold, or comply, with the Ninsho Certification Standard can be approved via the Shonin pathway. Most Class III devices and Class IV devices require the Shonin process.

According to the Canadian Guidance[7] the following indicators of risk posed by a given device were used to create the Canadian classification rules: degree of invasiveness, duration of contact, body system affected, and local versus systemic effects. The risk classification system takes into consideration the duration of use of a medical device. The use of a medical device is either long term or not. Long-term use implies continuous use for a period of 30 or more days. Continuous use is understood to be uninterrupted use for the intended purpose.

The Therapeutic Goods Administration of Australia also maintains a risk-based method for medical device assessment and has been open to recognizing many aspects of prior review by originating country regulatory authorities. At this writing the Australian Regulatory Guidelines for Medical Devices are under review and some components have been superseded by new guidance or regulatory amendments.

For the United Kingdom, BREXIT[8] has opened a chasm of uncertainty for medical device regulatory authority. The United Kingdom previously had its own medical device regulatory process before adopting the EU regulations and can again if an agreement cannot be reached. A US company with a CE mark issued by a notified body chartered in the United Kingdom may wonder what will happen to their permission to market. The UK-based notified bodies are working to help develop a suitable mechanism to provide the United Kingdom with continuity of access to the wider EU trade area after the transition period. It is estimated that 70% of non-EU-based manufacturers use UK notified body services as a springboard into the European Union.[9]

Toss into this Shepard's Stew the major change to the EU MDR that was published in the Official Journal of the European Union on May 5, 2017. This new regulation[10] will consolidate two existing legal provisions and replace both the current Medical Device Directive (93/42/EEC) and the Active Implantable Medical Device Directive (90/385/EEC). It takes effect on May 26, 2020 unless there is an extension.

Global medical device regulations are complex and ever changing. Cultural differences and differences in

[4] Medical Devices Directive 93/42/EEC and some high-risk implantable products followed the Active Implantable Medical Devices Directive 90/385/EEC.

[10] Regulation (EU) 2017/745 of the European Parliament and of the Council of 5 April 2017 on medical devices, amending Directive 2001/83/EC, Regulation (EC) No. 178/2002 and Regulation (EC) No. 1223/2009 and repealing Council Directives 90/385/EEC and 93/42/EEC.

perception of acceptable risk make a major impact on the regulation of medical devices and thus the scrutiny given to biomaterials-based devices. When a country has perceived unfavorable past experiences with experimental medical devices or when a country aligns with a regional regulatory group, even established medical devices may undergo more rigorous premarket review. The most important point is that when a medical device is brought to a different country with different medical practices and stakeholders (different "voices of the customer") where there may be different support structures, e.g., health insurance schemes, determining that the device is safe and effective may be assessed with different criteria.

Premarket Assessment Requirements

Developing a medical device dependent upon biomaterials requires a series of assessments that must start early. Design control and review requirements were ushered in with the Safe Medical Devices Act of 1990 with modifications to the Quality System Regulations 21 CFR 820, formerly known as Good Medical Practices. These rules require that the development team produce certain elements that include a project plan, periodic reviews, design inputs and outputs, and documented verification and validation of the product. An early hazard analysis and risk assessment is crucial to developing a safe medical product and for proper risk management over the lifecycle of the device. As product inputs are established, assessing the potential hazards of the new product, should the device fail to meet the design requirement is the bedrock of premarket assessments.

Risk analysis worksheets will guide the developer to the proper risk mitigations and the criticality of those mitigations. There are many examples of how the various standards work hand in hand with medical device risk mitigation, but the two most important assessment processes for a device with biomaterials are the ISO 10993 Part 1 and ISO 14971. These two standards help to guide the biological risk assessments necessary for development of a safe medical device. ISO 10993 and all its various parts establish a baseline for the assessment of biocompatibility. But standardized toxicity assays do not supplant the need to understand in vivo device performance.

Understanding the performance of a biomaterial in a medical device, particularly when the biomaterial is the medical device, will necessarily involve an understanding of actual performance of the product "in life." It may be possible to incorporate standardized protocols from the ISO 10993 recommended assays with the "in-life" testing of the device in an animal performance model, but the specific goal in a large animal model is to model device function, not just tissue compatibility. Frequently referred to as "preclinical" studies, device studies in a functional animal model must be carried out following many regulations (21 CFR Part 58), standards, and guidance documents. In fact, the data from these animal studies may be audited by the FDA when the data are pivotal for demonstrating device safety. As part of a sound scientific study, a protocol for the conduct of the study and the postmortem analysis of specimens must be carried out by well-trained and knowledgeable experts under strict rules controlling traceability of specimens. A performance study for a new material for an implantable heart valve, for example, could involve a number of large animals implanted with the valve and serial sacrifice to examine the mechanical behavior of the valve and any thrombogenic sequelae downstream. In contrast, prior to the pivotal performance study, exhaustive extraction studies of the valve materials under ISO 10993 would ensure that construction materials and material preparation processes do not introduce unexpected toxic elements, which could affect tissue healing at the sewing cuff or blood compatibility of the leaflets.[11]

Device failure analysis should be considered as part of the premarket assessment to arrive at potential hazards that might harm the patient as the device may age in vivo and also when the device is subjected to sudden loads or stresses. History has shown that the potential that wear particles could be released, that coatings could delaminate, or that surface passivation might not be sufficient to preclude release of toxic metals are all typical biocompatibility concerns associated with implanted biomaterials but which require mechanical testing to help to determine how the device performs over time.

Design verification is a term associated with the process that a device manufacturer will undertake to assure that certain design requirements have been met. Devices to be delivered sterile to the operating theater must undergo sterilization validation following approved methods and standards, but it is also necessary to assure that the sterilization process did not affect the performance of the device or affect the biocompatibility of the materials. For new packaging systems or new devices in existing packaging systems, standardized ship testing is required to ensure the device arrives intact and the contents are still sterile. Standardized test methods abound and are too numerous and diverse to include in this discussion, but medical device manufacturers routinely turn to recognized and standardized test methods for safety evaluation. Discussed elsewhere in more detail, systematic assessment to ensure the device can perform as intended is a basic requirement in all regulatory jurisdictions.

Design validation typically focuses on those product attributes that cannot be verified. Validation techniques are also used to assess whether or not the device has met its user needs. This may take the form of usability assessment but can involve cadaver studies (for example, to ensure surgeons can use instrumentation to properly place an implant) and could involve simulation testing with animals or phantoms. In other circumstances, full design validation will require a clinical study. The typical difference between a validation study and verification testing is the scope of the evaluation; validation should always be planned through a detailed, preapproved protocol, and may involve several assays in series to fulfill the validation requirements.

Discussion of clinical trial design is beyond the scope of this chapter, but such trials when required are complex, require one or more protocols, and require compliance with numerous regulations, guidance documents, and standards. When planned properly the clinical trial can provide data to support

[11] ISO 5840 Parts 1 and 2.

the safety and effectiveness of the device and provide physician and patient satisfaction information. For the United States, clinical trials are subject to FDA regulation 21 CFR 812, even if the study is considered "nonsignificant risk" (NSR). The difference between a significant risk study and an NSR trial is that the NSR study does not require prior FDA application, known as an IDE. All studies, regardless of risk category, require Institutional Review Board oversight and approval of the informed consent for participating subjects. Implanted devices are subject to IDE application, which must assure that risks to patients in the study are clearly defined and balanced by the benefit to the patient. Even the best clinical trials cannot anticipate all real-world potential hazards, particularly once the device moves beyond the idealized clinical trial environment. Recognition that implanted devices and novel medical materials may require long-term surveillance has pushed regulators to attempt to implement more active surveillance methods, including postmarket studies and device registries.

Instructions for use and certain diagnostic technology differences should be considered before launching a new device in a different country to assure the device can be deployed for the proper indication for use. Implanted medical devices seeking approval in the European Union will be required to present clinical data prior to awarding the CE mark. It is not uncommon that certain regulatory jurisdictions will require at least one clinical study to be conducted within the country or associated countries prior to granting market approval.

For US premarket applications, suppliers of biomaterials have begun to take advantage of a provision known as a Device Master File (MAF). Although not an approval mechanism, the MAF has enabled a mechanism whereby the biomaterial supplier (including component suppliers) can provide confidential material formulations and manufacturing methods for review by the FDA but not disclosure to the premarket review applicant. Such information as the chemistry of processing aids and cleaning methods are often proprietary and the FDA recognizes that disclosure of these proprietary methods even to a customer can be detrimental to business. To allow the FDA to access the supplier's Master File, the applicant receives permission from the supplier by way of a letter that is provided to the FDA identifying the MAF by number and which sections are appropriate for the review. A MAF might include material composition, biocompatibility test reports, reports concerning degradation by-products, effects of sterilization, and general quality controls for material production.

Premarket Clearance and Approvals

As previously discussed, the 1976 Medical Device Amendments to the FD & C Act gave the FDA explicit oversight of new medical devices entering the market. The law established the regulatory pathways for new medical devices (devices that were not on the market prior to May 28, 1976 or had been significantly modified) to get to market. With the evolution of technology and the difficulty of determining that a device was on the market prior to 1976, the regulations were again modified in 1990 to clarify:

> *For purposes of determinations of substantial equivalence … the term "substantially equivalent" or "substantial equivalence" means, with respect to a device being compared to a predicate device, that the device has the same intended use as the predicate device and that [FDA] by order has found that the device—*
>
> (i) has the same technological characteristics as the predicate device, or
> (ii) has different technological characteristics and the information submitted that the device is substantially equivalent to the predicate device contains information, including clinical data if deemed necessary by [FDA], that demonstrates that the device is as safe and effective as a legally marketed device and
> (iii) does not raise different questions of safety and efficacy than the predicate device.

Little by little, clarifications and guidance documents attempted to make it clear that *new* devices are Class III unless the foregoing provisions can be established. But then it made little sense to make *all new* medical devices Class III and thus require full PMA applications if the devices were simply not substantially equivalent to an existing device, but which were otherwise moderate risk. The de novo determination was crafted to allow low to medium risk devices to be reviewed by the FDA without the full and formal processes associated with a PMA application. Gradually, guidance documents evolved,[12] and as new devices have been cleared under the de novo process, more modern technologies have entered the market without full PMA applications.

As already stated, the PMA process for a new medical device is typically necessary to evaluate the safety and effectiveness of Class III medical devices.[13] PMA is the FDA process for scientific, clinical, and regulatory review. Class III devices are those that support or sustain human life, are of substantial importance in preventing impairment of human health, or which present a potential, unreasonable risk of illness or injury. The review of a PMA application is a four-step review process consisting of administrative and initial scientific review by FDA staff to determine completeness (acceptance and filing reviews), in-depth scientific, regulatory, and quality system review by appropriate FDA personnel (substantive review), review and recommendation by the appropriate advisory committee (clinical panel review), and final deliberations, documentation, and notification of the FDA decision. There are many elements to a PMA and the review can require years. Clinical data to support the efficacy of the new device are necessary, although the FDA has made provisions for acceptance of clinical data from outside the United States.

[12] https://www.fda.gov/downloads/MedicalDevices/DeviceRegulationandGuidance/GuidanceDocuments/ucm080197.pdf.
[13] https://www.fda.gov/MedicalDevices/DeviceRegulationandGuidance/HowtoMarketYourDevice/PremarketSubmissions/PremarketApprovalPMA/default.htm.

Prior to the changes proposed for the new European MDRs to take effect in 2020, it was possible to draw parallels between the approval process for a "me-too" (Class II) device for the US market and to obtain the CE mark for most IIa and IIb devices in Europe. For both jurisdictions, moderate risk devices put forth general safety information such as standardized testing and labeling for the product. Documentation in the Technical File for the European Union was similar to the content in the 510(k). As the requirements for the MDRs begin to take shape it is possible that the differences between the two systems will increase. The FDA has made it clear that the scrutiny of new medical devices in the Unite States will also undergo changes.[14] The FDA stated the desire to see that new devices that come to market under the 510(k) pathway should account for advances in technology and meet modern safety and performance criteria. FDA's Center for Devices and Radiological Health has leveraged the risk-based paradigm and wants to adopt a more modern process. It is clear that the new medical device review process for so-called "me-too" devices will undergo drastic changes in both of the two largest markets for medical devices. At least some of this impetus for change has been motivated by public criticism that the FDA has allowed older technology to be used in new applications without the proper level of scrutiny. Some of those devices have been biomaterials-based devices.

Medical device manufacturers face significant testing and controls when biomaterials play a major role in their function. There are fewer available medical-purposed materials at higher costs and most that are available have been known in the market 20 years or even much longer. Even attempts at tissue-engineered devices gravitate to known biomaterials for their substrates. With fewer materials to work with, device manufacturers attempt to improve performance by modifying the existing materials with chemicals and processes (including drugs and texturing), which then may require more biocompatibility testing. Even minor differences in clinical applications may require clinical trials if the material is used in a new intended use, raising concerns that new risks may lurk within the new application. Advancing technology for testing can detect extracted chemicals at lower and lower thresholds, which can cause anxiety, where before there was no perception of risk. And, of course, the cost of doing any testing continues to rise while the health care delivery industry is constrained by cost controls and risk reduction. In fact, it can sometimes be many years after the FDA approves a new product that a health care third-party payor (insurance company) will reimburse for the use of the device in the operating room. Yet the world is now faced with an aging population with increasing demands to remain not only mobile but physically active. The increasing demand for better medical products is worldwide, even as each emerging market seeks to ensure that their constituents do not become the practice field for emerging technologies and experimental materials.

[14] https://www.fda.gov/newsevents/newsroom/pressAnnouncements/ucm626572.htm.

Manufacturing and Material Supplier Controls

For several decades global regulatory specialists have sought a harmonized approach to quality systems management of manufacturing and material supplier controls. Although idealized as an international quality system, ISO 13485 has struggled for universal adoption. One reason has been the constraint of the US FDA to maintain the 21 CFR 820 regulation as the quality system for US medical devices.

As of this writing the US FDA has posted a "regulatory agenda" under RIN:0910-AH99 titled "Harmonizing and Modernizing Regulation of Medical Device Quality Systems,"[15] which states:

> *FDA intends to harmonize and modernize the Quality System regulation for medical devices. The revisions will supplant the existing requirements with the specifications of an international consensus standard for medical device manufacture, ISO 13485:2016. The revisions are intended to reduce compliance and recordkeeping burdens on device manufacturers by harmonizing domestic and international requirements. The revisions will also modernize the regulation.*

Because ISO 13485 is a copyrighted standard it is difficult to imagine the mechanism of adoption because this would supplant a public regulation with a commercial standard. Furthermore, the standard is scheduled to be revised every 5 years and reissued, subject to change by delegates to the ISO over whom neither Congress nor the FDA will have any control.

For the present time, developers of medical products using biomaterials based in the United States are required by law to conform to 21 CFR 820. Compliance with this regulation is self-determined with the FDA conducting audits on site on a no-fee basis (other than the annual registration and listing fee). Thus startup companies and those not immediately seeking an international marketplace are prudent to develop their initial internal quality procedures in alignment with FDA regulations.

Comparing and contrasting ISO 13485:2016 to US FDA CFR 820 for the means to maintain manufacturing and materials controls gives an insight into the difference in approach but similarities of requirements. (This comparison is limited to these specific subtopics and do not represent a complete comparative analysis of the two quality systems.) Because the two programs have approached the organization of quality information differently, one should be familiar with the entirety of both quality program structures before attempting to create a harmonized internal compliance system. Neither quality system approach would appear to have a better method for materials control than the other. Both take turnabout with more or less detail on how to fulfill the quality objective. A side-by-side analysis gives the best illustration of how these two systems differ and correspond (Tables 3.1.7.1 and 3.1.7.2).[16]

TABLE 3.1.7.1 Manufacturing Controls (Does not Include Environmental and Equipment Controls)

21 CFR § 820	US Quality System Regulation	Corresponding ISO 13485:2016	Differences
820.70(a) Production and Process Controls, General	Each manufacturer shall develop, conduct, control, and monitor production processes to ensure that a device conforms to its specifications. Where deviations from device specifications could occur as a result of the manufacturing process, the manufacturer shall establish and maintain process control procedures that describe any process controls necessary to ensure conformance to specifications. Where process controls are needed, they shall include: (1) Documented instructions, standard operating procedures (SOPs), and methods that define and control the manner of production; (2) Monitoring and control of process parameters and component and device characteristics during production; (3) Compliance with specified reference standards or codes; (4) The approval of processes and process equipment; and (5) Criteria for workmanship which shall be expressed in documented standards or by means of identified and approved representative samples.	7.5.1 Control of production and service provision	In this clause, ISO 13485:2016 specifies requirement that may align with other 21 CFR § 820.70 requirements beyond 21 CR 820.70(a). For example, in clause 7.5.1, ISO 13485:2016 specifies "b) qualification of infrastructure"; whereas, this requirement appears in "820.70(f) Buildings" of 21 CFR § 820.
820.70(b) Production and Process Changes	Each manufacturer shall establish and maintain procedures for changes to a specification, method, process, or procedure. Such changes shall be verified or where appropriate validated according to 820.75, before implementation and these activities shall be documented. Changes shall be approved in accordance with 820.40.	4.1.4 Quality management system	No significant difference in requirements.
820.75(a) Process Validation	Where the results of a process cannot be fully verified by subsequent inspection and test, the process shall be validated with a high degree of assurance and approved according to established procedures. The validation activities and results, including the date and signature of the individual(s) approving the validation and where appropriate the major equipment validated, shall be documented.	7.5.6 Validation of processes for production and service provision 7.5.7 Particular requirements for validation of processes for sterilization and sterile barrier systems	21 CFR § 820 specifies the documentation of the date and signature of the individual(s) approving the validation.
820.75(b) Process Validation	Each manufacturer shall establish and maintain procedures for monitoring and control of process parameters for validated processes to ensure that the specified requirements continue to be met. Each manufacturer shall ensure that validated processes are performed by qualified individual(s). For validated processes, the monitoring and control methods and data, the date performed, and, where appropriate, the individual(s) performing the process, or the major equipment used shall be documented.	8.2.5 Monitoring and measurement of processes	ISO 13485:2016 clause 8.2.5 specifies the expectations for monitoring and measurement of processes. 21 CFR § 820 specifies that the monitoring and control methods and data, the date performed, and individual(s) performing the process, or the major equipment be documented.
820.80(e) Acceptance Records	Each manufacturer shall document acceptance activities required by this part. These records shall include: The acceptance activities performed; the dates acceptance activities are performed; the results; the signature of the individual(s) conducting the acceptance activities; and where appropriate the equipment used. These records shall be part of the DHR.	4.2.5 Control of records 7.1 Planning of product realization 8.2.6 Monitoring and measurement of product	Although both require records, 21 CFR § 820 specifies specific record content requirements.

TABLE 3.1.7.2 Provisions for Materials Control

21 CFR § 820	US Quality System Regulation	Corresponding ISO 13485:2016	Differences
820.50(b) Purchasing Data	Each manufacturer shall establish and maintain data that clearly describe or reference the specified requirements, including quality requirements, for purchased or otherwise received product and services. Purchasing documents shall include, where possible, an agreement that the suppliers, contractors, and consultants agree to notify the manufacturer of changes in the product or service so that manufacturers may determine whether the changes may affect the quality of a finished device. Purchasing data shall be approved in accordance with 820.40.	7.4.2 Purchasing information	ISO 13485:2016 specifies "The organization shall ensure the adequacy of specified purchasing requirements prior to their communication to the supplier." ISO 13485:2016 specifies "To the extent required for traceability given in 7.5.9, the organization shall maintain relevant purchasing information in the form of documents (see 4.2.4) and records (see 4.2.5)."
820.60 Identification	Each manufacturer shall establish and maintain procedures for identifying product during all stages of receipt, production, distribution, and installation to prevent mix-ups.	7.5.8 Identification	ISO 13485:2016 specifies more detailed requirements, including the documentation of procedures to ensure medical devices returned to the organization are identified and distinguished from conforming product.
820.65 Traceability	Each manufacturer of a device that is intended for surgical implant into the body or to support or sustain life and whose failure to perform when properly used in accordance with instructions for use provided in the labelling can be reasonably expected to result in a significant injury to the user shall establish and maintain procedures for identifying with a control number each unit, lot, or batch of finished devices and where appropriate components. The procedures shall facilitate corrective action. Such identification shall be documented in the DHR.	7.5.9 Traceability 7.5.9.1 General	ISO 13485:2016 requires procedures for traceability based on regulatory requirements. 21 CFR § 820 specifies the types of devices that require traceability.
820.70(e) Contamination Control	Each manufacturer shall establish and maintain procedures to prevent contamination of equipment or product by substances that could reasonably be expected to have an adverse effect on product quality.	6.4.2 Contamination control	ISO 13485:2016's specified requirements are "as appropriate" unless relative to sterile medical devices. However, as stated in ISO 13485:2016 0.2: Clarification of concepts, when a requirement is qualified by the phrase "as appropriate", it is deemed to be appropriate unless the organization can justify otherwise. For sterile devices, ISO 13485:2016 specifies "… the organization shall document requirements for control of contamination with microorganisms or particulate matter and maintain the required cleanliness during assembly or packaging processes." 21 CFR § 820 is not this specific.

(Continued)

TABLE 3.1.7.2 Provisions for Materials Control—cont'd

21 CFR § 820	US Quality System Regulation	Corresponding ISO 13485:2016	Differences
820.70(h) Manufacturing Material	Where a manufacturing material could reasonably be expected to have an adverse effect on product quality, the manufacturer shall establish and maintain procedures for the use and removal of such manufacturing material to ensure that it is removed or limited to an amount that does not adversely affect the device's quality. The removal or reduction of such manufacturing material shall be documented.	7.5.2 Cleanliness of Product	ISO 13485:2016 specifies conditions that would require documentation of cleanliness requirements.
820.80(a) Receiving, In-Process, and Finished Device Acceptance, General	Each manufacturer shall establish and maintain procedures for acceptance activities. Acceptance activities include inspections, tests, or other verification activities.	7.1 Planning of product realization 8.2.6 Monitoring and measurement of product	No significant difference in requirements.
820.80(b) Receiving Acceptance Activities	Each manufacturer shall establish and maintain procedures for acceptance of incoming product. Incoming product shall be inspected, tested, or otherwise verified as conforming to specified requirements. Acceptance or rejection shall be documented.	7.4.3 Verification of purchased product	No significant difference in requirements.
820.120(e) Control Number	Where a control number is required by 820.65, that control number shall be on or shall accompany the device through distribution.	7.5.8 Identification 7.5.9.2 Particular requirements for implantable medical devices	ISO 13485:2016 does not require control numbers, although it does specify requirements for UDI (when required) and traceability for implantable medical devices.
820.184 Device History Record	Each manufacturer shall maintain device history records (DHRs). Each manufacturer shall establish and maintain procedures to ensure that DHRs for each batch, lot, or unit are maintained to demonstrate that the device is manufactured in accordance with the DMR and the requirements of this part. The DHR shall include, or refer to the location of, the following information: (a) The dates of manufacture; (b) The quantity manufactured; (c) The quantity released for distribution; (d) The acceptance records which demonstrate the device is manufactured in accordance with the DMR; (e) The primary identification label and labeling used for each production unit; and Any unique device identifier (UDI) or universal product code (UPC), and any other device identification(s) and control number(s) used.	7.5.1 Control of production and service provision	21 CFR § 820 specifies additional DHR content beyond that specified in ISO 13485:2016 (e.g., (a) The dates of manufacture; … (d) The acceptance records which demonstrate the device is manufactured in accordance with the DMR; (e) The primary identification label and labeling used for each production unit; and any unique device identifier (UDI) or universal product code (UPC), and any other device identification(s) and control number(s) used.)

Perhaps more important than the specific wording of the quality methods is the requirement for a vendor agreement or contract manufacturing agreement to be in place. According to QSR 820.50(b) "purchasing documents shall include, where possible, an agreement that the suppliers, contractors, and consultants agree to notify the manufacturer of changes in the product or service so that manufacturers may determine whether the changes may affect the quality of a finished device." Best practice evolved in recent years for contract manufacturing agreements is to include as a part of the agreement an index to the quality system that defines the responsibilities of the respective parties for pertinent quality systems.

Postmarketing Management of Risk and Product Performance

It is clear from the information presented thus far that medical device regulation, and thus the deployment of biomaterials, varies around the globe. The US FDA was the vanguard in postmarket surveillance but has not necessarily implemented the most effective methods to assure that a medical device continues to provide benefits that outweigh the risks over the lifecycle of the medical product. Although the 1976 MDRs established the requirement to report adverse events involving medical devices the implementation was less than ideal. With the amendments to the Act in 1990 the FDA issued 21 CFR 803 for mandatory reporting, providing definitions and mechanisms for the reports. In addition, this reporting system was now made open to reports by the user and the abridged reports were made public in a searchable database. Manufacturers were required to integrate the investigation process and report decision-making processes into the quality system management of complaints. Although a major step forward, compliance is not uniform and on various occasions nonmedical personnel swamp the system with unqualified reports, rendering the database useless for certain product categories. No remedy has been found for this dilemma.

Recognizing the shortcomings of the current Manufacturer and User Facility Device Experience Database and medical device reporting, the FDA has now implemented a surveillance network called the National Evaluation System for Health Technology and an independently run public/private coordinating center comprised of members representing the key community stakeholders, including patients and providers who have entered into agreements this year with 12 organizations that represent more than 195 hospitals and almost 4000 outpatient clinics with access to more than 495 million patient records, which will all be part of the early data network to provide real-world evidence to be used in pre- and postmarket decision-making. It remains unclear how this effort will affect the industry and device safety. Areas of interest announced by the FDA are knee replacement surgeries and intervertebral body fusion devices. The FDA noted in its recent announcement[17] that implementing this surveillance system required the implementation of the unique device identification system, which now allows implants to be tracked through distribution and patient use from its manufactured source.

In Europe the requirements for the CE mark had already required medical device manufacturers to reapply for the CE mark at periodic intervals, which in turn was cause for the manufactures to meet any updated product standards. However, since for the most part the updates to standards did little to remove an unsafe device that had managed to meet prior issuance of the standards, this mechanism has not had a significant impact on removing unsafe devices from the market but it has added to the cost for manufacturers. The Clinical Evaluation Report (CER) consists of analyzed clinical data collected either from a clinical investigation of the subject device or the results of studies and publications on equivalent devices already in the market. These reports were required to be submitted to the notified body as part of the Technical File. CERs were to be updated as part of the postmarket surveillance and vigilance activities (term for postmarket reporting of adverse events in the European Union). Through the years, CER requirements, including the qualifications of the author of such reports, have become stricter. One of the most significant advancements is the requirement of the CER, which will be emphasized even further under the new MDR, to integrate the risk management system with clinical evaluation. For Class III and implantable devices (of any classification), CERs will now be required to include clinical data derived from clinical investigations that were conducted under the supervision of a sponsor (in contrast to studies that are ad hoc collections of clinical experience). With a higher threshold for CER content for the initial CE mark it is expected that the quality of the postmarket surveillance of high-risk devices will continue to improve. The renewing applicant will be required to justify that the benefit of the device continues to outweigh the risks.

Surveillance of the quality of manufacturing of medical devices was the basic tool initiated with the original 1976 US FDA Good Practices regulation 21 CFR 820, which was also updated in 1990 to expand the authority in numerous ways, including the requirement for design control and review. Through fees for registration and listing the US FDA supports routine inspection by FDA compliance inspection officers for both initial quality inspection (PMA and Class III devices cleared under a 510(k)) and for routine periodic inspections of the facilities. These inspections not only assure the cleanliness and quality of the manufacturing and contract manufacturers for certain functions, but their purpose is to investigate how effectively the facility employees have implemented required quality procedures and documentation requirements. If a facility has significant noncompliance the company will receive a warning letter and can be fined for certain compliance failures. In the most serious circumstances, the facility can be closed until corrective actions have been taken. From time to time complaints from users resulting in postmarket reports have

[17] https://www.fda.gov/NewsEvents/Newsroom/PressAnnouncements/ucm626286.htm.

brought the inspectors to the door. Obvious unsubstantiated labeling claims are also an invitation for the inspectors to alert the manufacturer to misbranding, a common temptation for medical device companies. Although there are many training programs to assist startup manufacturers in the proper development of quality system regulations, reading from the FDA Warning Letter provides a limitless resource of motivation.[18]

Most of the World Biomaterials participating countries have either a similar inspection process or authorize an ISO registrar to perform the on-site inspections to certify that the manufacturer continues to conform to ISO 13485. In many circumstances the ISO registrar may also be the same firm engaged as the notified body for the medical device manufacturer. Failure to rectify quality system shortcomings can be a cause for withholding the quality certification such as the CE mark.

Registration, Device Listing, Licenses

The US FDA does not require a license on the facility to make or sell a medical device; however, for combination products a license may be required for the facility that is responsible for aspects of the biologic or drug constituent part. As new biomaterials technologies continue to push the definition of "medical device," any new medical device company may come under the jurisdiction of more than one agency in the FDA. These details are beyond the scope of this part of the chapter but for further reading, the FDA has issued guidance.[19]

Owners or operators of places of business (also called establishments or facilities) that are involved in the production and distribution of medical devices intended for use in the United Sates are required to register annually with the FDA.[20] This process is known as establishment registration. The amount of the fee varies from year to year and is the same for all, regardless of the size of the entity, and applies to US-based entities and importers. The registration fee does not differ by the number of products the entity may list. "Listing" is the process by which the FDA is notified by the responsible party of the type of medical device entered into interstate commerce. The current scheme for registration and listing can be quite complicated for a company attempting to complete the process for the first time. Timing of the initial fee payment, registration, and listing differ for Class I devices, which do not require premarket clearance. For devices under 510(k) or other premarket review, registration and listing does not occur until the device is cleared for US marketing. The process needs to be complete within 30 days of putting the Class I or 510(k)-exempt product into interstate commerce. Registration and listing is a very important part of the postmarket management of medical devices. The registration and listing public database is helpful to identify the responsible party for the product, although identifying a product's point of origin using this database is seldom straightforward.

Terminology differs for Canadian medical device licensing, as a license and paid fee are required for manufacturers submitting Class II, III, and IV medical device license applications, and license amendment applications will be charged a review fee. Fees are proportionate to the complexity of the application. As in the United States, this license fee does not apply to investigational devices, but unlike the United States this fee does not apply to Class I devices.

Australian medical device fees occur at various levels similar to the US scheme. An Australian manufacturing license is required and there is a fee for the inspection. Overseas manufacturers are responsible for an hourly fee for the inspection and reasonable costs and expenses for the inspector in addition to a GMP clearance application processing fee. Certificates of compliance have a fee. The annual fee (similar to the FDA registration fee) varies by class of device. Australia charges an "application fee," which is required to "include" a medical device in the Australian Register of Therapeutic Goods. As with other regulatory agencies around the world, Australia is also looking to make various updates to rules and requirements, including institution of a UDI.[21]

The complexity of "user fees" such as market application fees, fees for registration and inspection of a facility, fees for "listing" or "including" a device allowed for sale in a particular country, and other sundry fees and fines in the many World Congress of Biomaterial countries are far too numerous to mention in this textbook and will probably change even before the book goes to press. But with this understanding of the many differences between countries it is clear that when countries can band together to have a common jurisdiction, such as what has developed under the European Commission, the medical device industry and its stakeholders may benefit. In recent years, other common markets and shared regulatory schemes have evolved, such as the Association of Southeast Asian Nations Medical Device Directive, known as the AMDD, which has 10 member states recognizing the goal of creating a harmonization of trade for medical devices in the region. Not all "joint" efforts succeed, such as a proposed agency for both Australia and New Zealand called ANZTPA.

However, a more practical arrangement for a single quality system audit program may find broader acceptance. Known as MDSAP and proposed by the International Medical Device Regulators Forum the single auditor program would include Australia, Brazil, Health Canada, Japan, the European Union, and the FDA. The FDA, however, limits

[18] https://www.fda.gov/iceci/enforcementactions/warningletters/default.htm.

[19] https://www.fda.gov/downloads/RegulatoryInformation/Guidances/UCM429304.pdf; Guidance for Industry and FDA Staff: Current Good Manufacturing Practice Requirements for Combination Products FINAL GUIDANCE January 2017.

[20] https://www.fda.gov/MedicalDevices/DeviceRegulationandGuidance/HowtoMarketYourDevice/RegistrationandListing/ucm318796.htm.

[21] https://brandwoodbiomedical.com/regulatory-change-in-australia-tgas-wish-list-for-2019/.

the MDSAP audit reports as a substitute for routine FDA inspections. Medical device firms with activities related to the Electronic Product Radiation Control (EPRC) provisions of the FD & C Act will continue to be subject to FDA inspections for EPRC activities. Despite the attempt toward harmonization, it is clear from the FDA's stated limitations that MDSAP is not likely to be an umbrella shielding a medical device company from warning letters and "for cause" inspections.

Summary and Study Guide

Medical devices that rely on biomaterials that function in medium to high-risk applications are subject to strenuous global regulations. Various jurisdictions have embraced many common assessment techniques, such as biological risk assessment, but many different regulatory schemes persist. The perception of and evidence required for safe medical devices remain culturally based and require patience to navigate.

Chapter Questions: True or False

1. Medical device regulation is harmonized globally and therefore once a device is approved in the United States by the FDA it can be sold in any country.
2. A Class I device is not regulated in the United States.
3. Risk management standard ISO 14971 provides the requirements for determining how to conduct biocompatibility testing.
4. ISO 10993 says that prior human clinical use of the material reduces the risk of biomaterial toxicity and the prior use makes the material so safe no other testing is necessary.
5. Japan recognizes US PMA determination, so a product approved in the United States does not require a separate application for sale in Japan or Korea.
6. ISO 13485 quality requirements are identical to the US 21 CFR 820, so an ISO certificate means a US company will not be inspected by the US FDA.
7. Submission of the Clinical Evaluation Report to the notified body for the CE mark exempts a foreign company from needing to file a 510(k) in the United States.

3.1.8

Role of Standards for Testing and Performance Requirements of Biomaterials

CARL G. SIMON, Jr[1], LIISA T. KUHN[2]

[1]Biosystems Biomaterials Division, National Institute of Standards & Technology, Gaithersburg, MD, United States

[2]Department of Biomedical Engineering, University of Connecticut Health Center, Farmington, CT, United States

Introduction: What Is a Standard?

The word standard is used to describe a broad set of activities and entities. There are many types of standards developed through many different organizations using a variety of processes, but "there is nothing standard about standards" (Alocca, 2019). The Office of Management and Budget (OMB) Circular A-119 states that a "standard," or "technical standard" (hereinafter "standard"), includes all of the following:

(1) common and repeated use of rules, conditions, guidelines, or characteristics for products or related processes and production methods, and related management systems practices;
(2) the definition of terms; classification of components; delineation of procedures; specification of dimensions, materials, performance, designs, or operations; measurement of quality and quantity in describing materials, processes, products, systems, services, or practices; test methods and sampling procedures; formats for information and communication exchange; or descriptions of fit and measurements of size or strength; and
(3) terminology, symbols, packaging, marking, or labeling requirements as they apply to a product, process, or production method.

Standards can take the form of a material, data set, or document.

Reference Materials

Reference materials are physical objects or things that have stable homogeneous properties which are used to calibrate an instrument or as a test to confirm that a measurement system is operating correctly (Box 3.1.8.1). Reference materials are carefully prepared and tested and the reported values for reference material properties come with an estimate of the uncertainty. The uncertainty is the doubt about the measured value with regard to the true value and is described by a probability distribution (Possolo, 2015). Providing the uncertainty of the measured value is key for using the data to support decision making.

The National Institute of Standards & Technology offers a "Standard Reference Material (SRM) 2910b Hydroxyapatite" which is a 2-gram sample of well-characterized hydroxyapatite that comes with a Certificate of Analysis (www.nist.gov/srm). SRM 2910b was carefully prepared and tested to assure its composition. SRM 2910b can be tested alongside other preparations of hydroxyapatite and used to assess purity and composition. Hydroxyapatite is a biomaterial for which all three types of standards exist: reference material, reference data, and documentary standards. Hydroxyapatite reference data and documentary standards are discussed below.

The United States Pharmacopeia (USP; www.usp.org) also provides reference materials for biologics (http://www.usp.org/biologics/cell-tissue-standards). The "CD34+ Cell Enumeration System Suitability" contains human leukocytes, erythrocytes, and CD34+ cells that have been fixed and lyophilized (Catalog Number 1084292). It can be reconstituted in water and comes with a certificate stating the number of CD34+ cells per unit volume. It can be used to assess the flow cytometric enumeration of CD34+ cells.

The National Institute for Biological Standards and Control (NIBSC) makes a vascular endothelial growth factor reference material (VEGF 165, Product Number 02/286).

• BOX 3.1.8.1 Standards and Measurement Terminology

Measurand: "quantity intended to be measured" (International Vocabulary of Metrology, 2012)

Note: Measurements are conducted to collect information that will be used in decision making. For tissue-engineered medical products, these decisions are often related to safety, efficacy, and batch release. A measurand is the quantity that one intends to measure. The use of the word "intended" is important since the measurement may not be measuring what one intends to measure. Thus the word measurand is used to emphasize what one intends to measure even though it might be different from what is being measured.

Measurement: "Measurement is an experimental or computational process that, by comparison with a standard, produces an estimate of the true value of a property of a material or virtual object or collection of objects, or of a process, event, or series of events, together with an evaluation of the uncertainty associated with that estimate, and intended for use in support of decision-making" (Possolo, 2015)

Reference Material: "material, sufficiently homogeneous and stable with reference to specified properties, which has been established to be fit for its intended use in measurement or in examination of nominal properties" (International Vocabulary of Metrology, 2012)

Note: Reference materials are typically well-characterized materials that are used to calibrate a measurement system, or to assess the performance of a measurement system (quality assurance).

The VEGF reference material was made by recombinant DNA technology and the assignment of the activity in the ampule was determined by an international interlaboratory study (Robinson et al., 2006). It is intended to "facilitate the measurement of the potency and stability of therapeutic preparations of VEGF and inhibitors, and measurement of VEGF levels for diagnosis."

Reference Data

Reference data are carefully collected measurement data that can be used for comparison with experimental data to confirm that a measurement system is operating correctly, or to identify unknowns in a test sample. Reference data are often spectra or measurement values of material properties. An example is the X-ray powder diffraction file for "Calcium Phosphate Hydroxide, $Ca_5(PO_4)_3(OH)$, $Ca_5HO_{13}P_3$, Hydroxyapatite, synthetic" which can be obtained from the International Center for Diffraction Data (ICDD; www.icdd.com). Hydroxyapatite is an important medical material which is the focus of many standards. ICDD maintains a central collection of X-ray powder diffraction patterns. All data are critically reviewed and evaluated by the ICDD editorial staff using a multitiered process before being added to the collection. As technology improves, the quality requirements for reference data evolve and the reference data must be "continuously reviewed and upgraded for accuracy and quality." The data file for hydroxyapatite can be used to assess spectra from test samples to assess composition.

USP also provides examples of reference data. "Bovine Acellular Dermal Matrix Reference Photomicrographs" (Catalog Number 1535824) and "Scaffold Human Dermis Reference Photomicrographs" (Catalog Number 1535813) are images provided in a digital format. These reference micrographs can be used for comparison with images of test specimens of decellularized extracellular matrix intended for use as scaffolds for tissue-engineering applications.

Documentary Standards

Documentary standards are written documents that "provide requirements, specifications, guidelines or characteristics that can be used consistently to ensure that materials, products, processes and services are fit for their purpose" (www.iso.org). Several documentary standards for hydroxyapatite have been written by two of the major standards development organizations in the medical materials field: ASTM International (ASTMi; www.astm.org) and the International Organization for Standardization (ISO; www.iso.org), such as

- ASTM F1185 Standard Specification for Composition of Hydroxyapatite for Surgical Implants
- ASTM F2024 Standard Practice for X-ray Diffraction Determination of Phase Content of Plasma-Sprayed Hydroxyapatite Coatings
- ISO 13175-3:2012 Implants for surgery—Calcium phosphates—Part 3: Hydroxyapatite and beta-tricalcium phosphate bone substitutes
- ISO 13779-2:2018 Implants for surgery—Hydroxyapatite—Part 2: Thermally sprayed coatings of hydroxyapatite
- ISO 13779-3:2018 Implants for surgery—Hydroxyapatite—Part 3: Chemical analysis and characterization of crystallinity ratio and phase purity
- ISO 13779-4 Implants for surgery—Hydroxyapatite—Part 4: Determination of coating adhesion strength

ASTM F1185 provides an explicit set of chemical and crystallographic requirements for hydroxyapatite intended for surgical implants. ASTM F2024 describes how samples should be analyzed using X-ray diffraction in order to determine their hydroxyapatite composition. This assortment of documentary standards, reference materials, and reference data helps ensure that high-quality hydroxyapatite biomaterials are available for use in therapeutic devices.

Documentary Standards: Voluntary, Consensus

Documentary standards can be written by open, consensus processes and their use is often voluntary. Documentary standards from ASTM and ISO are generally considered voluntary, consensus standards. The American National Standards Institute (ANSI) accredits standards development organizations (SDOs) who use fair and open processes. The www.ansi.org website reports 240 accredited SDOs in the United States as of 2019. Accreditation signifies that the

SDO meets ANSI's requirements for (1) openness, (2) balance, (3) due process, (4) an appeals process, and (5) consensus. Standards that are created following these requirements are referred to as "voluntary consensus standards" (OMB Circular A-119, 2016).

- Openness: all interested parties are provided a meaningful opportunity to participate in standards development
- Balance: a broad range of stakeholders are involved with no single interest dominating the process
- Due process: documented policies and procedures, adequate notice of meetings, sufficient time to review documents, access to views of other participants, a fair process for resolving conflicts
- Appeals process: an impartial process is available for appeals
- Consensus: general agreement, but not unanimity; objections are considered by a transparent and open process

In some cases, use of standards is not voluntary and their development is not consensus. For example, regulatory agencies mandate the use of certain ASTM and ISO documentary standards in their regulations. Also, the governments of some countries have mandated the use of ISO documentary standards during product development. Some types of USP documentary standards are mandatory; for example, those that describe manufacturing requirements for well-established small-molecule drugs. In some cases, membership in the working groups that write standards is by appointment only and is not open to the public. This is the case for some committees that write documentary standards for USP.

Who Writes Documentary Standards?

There are many SDOs that have a stake in the medical device and regenerative medicine industries that use biomaterials (Standards Coordinating Body, 2019). The largest organizations in the world that publish medical product documentary standards include IEEE (Institute of Electrical and Electronics Engineers) with 423,000 members and ASME (American Society of Mechanical Engineers) with more than 130,000 members. Other major SDOs active in medical products standards, including those in the tissue engineering and regenerative medicine (TERM) industry, are listed in Table 3.1.8.1.

There are many benefits to standards, as listed in Box 3.1.8.2. A standard test method for a measurement process can enable comparability over space and time. This is especially important for measurements of the critical quality attributes of a medical product. When thousands of units must be reliably manufactured in different locations, on different equipment, and by different operators, a standard test method for assessing product quality is essential. Standards can streamline the regulatory process by providing well-characterized test methods for demonstrating safety and efficacy (Arcidiacono et al., 2018). When a product attribute is measured in accordance with a standard test method, then regulatory agencies have greater confidence in the reliability of the data. Standard

AAMI	Association for the Advancement of Medical Instrumentation
HESI	Health and Environmental Sciences Institute
AABB	American Association of Blood Banks
FACT	Foundation for the Accreditation of Cellular Therapy
ATCC	American Type Culture Collection
ASME	American Society of Mechanical Engineers
PDA	Parenteral Drug Association

• BOX 3.1.8.2 Risks and Benefits of Standards

Benefits of High-Quality Standards

- Improve consistency of manufacturing
- Streamline the regulatory process
- Provide high-quality, proven test methods, avoiding costly trial-and-error approaches
- Reduce manufacturing and testing costs
- Improve confidence in a product
- Enhance commerce and facilitate trade
- Improve product quality, safety, and effectiveness
- Help small enterprises compete with big companies
- Inform decision making
- Improve comparability and reproducibility of research conducted by academics and their students

Risks of Not Developing Standards

- Without standard test methods, each firm must bear the costly development of their own test methods
- Regulatory review is slowed since developers cannot follow accepted standards in their regulatory filings
- A source of best practices that has been vetted by many stakeholders and experts will be not available to product developers
- Consumer confidence may falter if performance standards are not available to assure quality of new products

Risks of Publishing Low-Quality Standards

- Impose overly burdensome requirements on manufacturers
- Requirements for inappropriate testing could stymie product development
- Costs of meeting unnecessary requirements passed on to the consumer
- Poor practices promulgated throughout the community
- Manufactured products may be less reliable

test methods can facilitate commerce by establishing consistent guidelines for assessing product quality (Sarkar et al., 2019). Ideally, when the properties of a product are assessed by a standard test method, then the quality of products from different manufacturers can be compared. Academic teams, including students, that employ standard test methods can improve the reproducibility of their research, the comparability of their results with results from other labs, and their posture in regard to translation and commercialization.

ASTM International (ASTMi, www.astm.org) is an SDO that was formed in 1898 by members in the railroad industry and now has more than 30,000 members. It is divided into 143 different topic-specific Technical Committees, with Committee F04 Medical and Surgical Materials and Devices being the home for many biomaterials standards. There are approximately 12,000 ASTM standards, with more than 300 of them from Committee F04. New committees are formed as technology is developed, with F42 on Additive Manufacturing being one of the newer ones, formed in 2009. The technical committees are divided into subcommittees with task groups formed to develop particular standards. ASTM has defined six types of standards as given in Table 3.1.8.2.

Another major SDO is the International Organization for Standardization (ISO; www.iso.org). ISO is an independent, nongovernmental, international organization with members from the national standards bodies of 163 countries with one member per country. Each member country has a Technical Advisory Group (TAG) which individuals from that country may join. Each country has one vote which is managed by the TAG. Technical committees lead standards development within ISO and there are 22,480 ISO standards to date. The first ISO technical committee was ISO/TC1 on screw threads and was created in 1947. ISO/TC150 on Implants for Surgery was formed in 1971 and has 158 documentary standards. There are several subcommittees (SC) of ISO/TC150 which include SC1 Materials, SC2 Cardiovascular Implants and Extracorporeal Systems, and SC7 Tissue Engineered Medical Products. The ASTM motto is "helping our world work better" while ISO's is "when the world agrees."

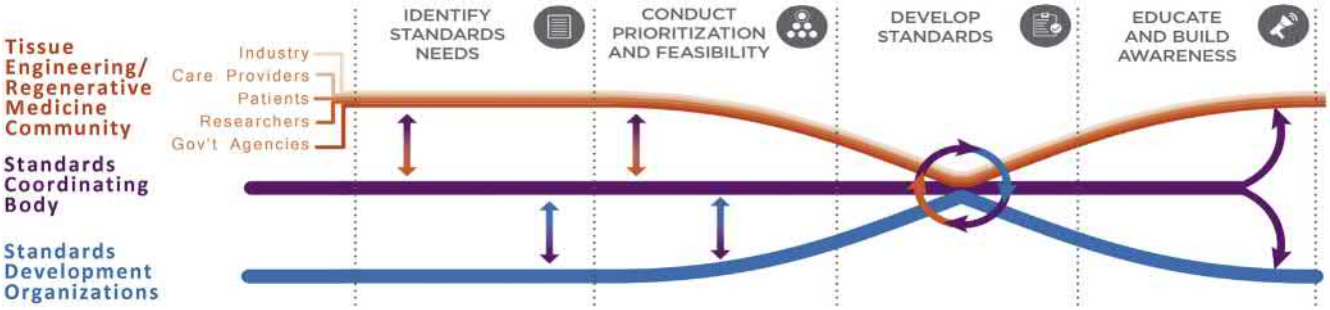
TABLE 3.1.8.2 The Six Types of ASTM Documentary Standards

Guide	An organized collection of information or series of options that does not recommend a specific course of action; typically provides a list of issues to consider when making a particular measurement, or a list of complementary measurements to consider when characterizing device properties.
Test Method	A definitive procedure that produces a test result; provides a detailed procedure for conducting a measurement including controls and how to analyze the data; may include acceptance criteria and tolerances.
Practice	A set of instructions for performing one or more specific operations that does not produce a test result, such as how to sterilize a device.
Specification	An explicit set of requirements for chemical, mechanical, physical, biological, and/or electrical properties to be satisfied by a material, product, system, or service.
Terminology	A document composed of terms, definitions of terms, descriptions of terms, nomenclature, and explanations of abbreviations, acronyms, and symbols.
Classification	Systematic arrangement or division of materials, products, systems, or services into groups based on similar characteristics such as origin, composition, properties, or use.

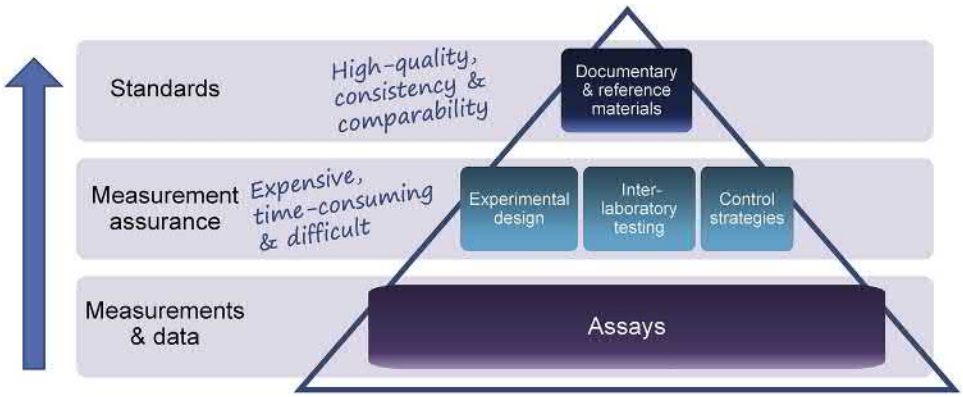
How Are Documentary Standards Developed?

The documentary standards development process involves a wide range of people within a scientific or technical community as shown in Fig. 3.1.8.1. Typically, researchers from industry, academia, or government identify an issue that is impacting product reliability and performance and convene for discussion. Discussion can occur through informal working groups, at regular meetings of SDOs, or at special workshops. Due to the substantial number of people interested in or impacted by standards and the many SDOs active in the field of biomaterials and TERM, a Standards Coordinating Body (SCB) has been established to help coordinate efforts in these areas (www.standardscoordinatingbody.org). The first step of identifying a need, an issue worthy of standardization, and figuring out how to address it, is the most important. Issues identified for standards development must be based on repeatedly observed, known results, and not on a new area of basic research that is still highly variable and undefined. Sometimes, there is no clear, standardizable way of performing the task and the best option is to wait until more research has been conducted and information obtained. Robust documentary standards are underpinned by measurement science (metrology) (Fig. 3.1.8.2). There can be a substantial lag time from when a new material is discovered, or a new technology is developed, to when a definitive standard can be written. For example, development of nanoparticle standards was deferred until specialized equipment to measure their properties became available. Standards can only be developed about a topic for which there is already a large body of knowledge.

The next step is to identify people with the appropriate expertise and willingness to develop the standard. Documentary standards are developed by volunteers who are not typically compensated for their time, travel costs, or laboratory expenses and who do not work for the SDOs. The timelines for developing standards are lengthy, typically 3–5 years. Standards do not provide authorship or citations to those that develop them. On the other hand, writing standards leads



• **Figure 3.1.8.1** Overview of the standards development process. People working in the field, such as tissue engineering or regenerative medicine, must work together to identify clear needs for standards. People who are interested in the standard or may be impacted by the proposed standard are known as stakeholders and must be recruited to develop the standards. Standards are developed within standards development organizations (SDOs), such as ASTM and ISO. SDOs provide training on the standards development process, hold meetings to convene stakeholders to work on the standards, provide the infrastructure for developing standards, and disseminate the standards. The Standards Coordinating Body (SCB) was formed in 2017 to help coordinate standards development among the many SDOs and regenerative medicine stakeholders, with tissue engineering being an important focus. (Courtesy of SCB, https://www.standardscoordinatingbody.org/.)



• **Figure 3.1.8.2** Standards and technology development are underpinned by measurement science (metrology). (Courtesy of Sheng Lin-Gibson.)

to a direct, positive impact on health care and new product commercialization and is nevertheless rewarding work. The highly interactive process builds a strong sense of camaraderie and lasting friendships are developed. The participants learn the best practices, caveats, and shortcomings of the technologies or measurements that are the focus of the standards.

After finding the right people, a working group or task force is formed that develops the draft documentary standard. This may involve teleconferences, face-to-face discussions at regular SDO meetings, literature reviews, writing assignments, or laboratory research. It is important to identify and include all stakeholders at an early stage to avoid having the standard disputed later in the process. Stakeholders are those that are interested in the standard or potentially impacted by the standard. Staff from regulatory agencies, such as the Food and Drug Administration (FDA), attend SDO meetings since they have a great interest in standards development due to the value of standards in streamlining the regulatory process. Academics participate in SDO meetings to learn what is important for the commercialization of new technologies and for the opportunity to share technological advances. SDOs provide a neutral forum for all stakeholders to meet and discuss the best path forward. SDO meetings involve teamwork and not competition. They are interactive and provide the opportunity for candid, open scientific discussion with key points becoming incorporated in the standards (see Case Study I). This may contrast with scientific conferences where the shortcomings of research results may receive less attention.

After the task group is in consensus that a draft documentary standard is complete, it goes to ballot where the membership of the SDO will vote. In ASTM, there is a tiered balloting process with a subcommittee vote first, followed by a vote at the highest technical committee level. Negative votes are rigorously discussed and often require a revision of the standard draft. The requirement for consensus from a majority of stakeholders during standards development reduces bias, leading to technically sound standards. If the draft successfully passes through the balloting process, then the draft becomes a standard and is published.

Within each SDO, efforts are taken to ensure balance among the voters. For instance, ASTM requires that the number of votes by "producers" (companies, manufacturers) must not exceed the sum of "users" (surgeons, dentists) plus "consumers" plus "general interest" (government,

CASE STUDY I: DOCUMENTARY STANDARDS ARE LIVING DOCUMENTS THAT MUST BE CONTINUOUSLY REVIEWED FOR QUALITY AND ACCURACY

When it was originally developed, ASTM standard F1581 Standard Specification for Composition of Anorganic Bone for Surgical Implants indicated that bone mineral was hydroxyapatite with characteristics that resembled the geologically formed mineral. The specification reflected current practice at the time which was the use of high temperature, aqueous processing conditions to produce anorganic bone that actually altered the native state of bone mineral to hydroxyapatite with reduced carbonate content. Some, but not all, companies used processing conditions that altered the native state of bone mineral, leading to high variability of anorganic bone products. Variable clinical outcomes were observed and equivalent product replacements were hard to make. Professor Melvin Glimcher, MD, an orthopedic surgeon and research director at the Children's Hospital/Harvard Medical School, was motivated to revise the ASTM standard based on his expertise in the physical and chemical structure of bone mineral. Dr. Glimcher had discovered the true structure of bone mineral by developing a low temperature, non-aqueous method to isolate bone mineral from the organic matrix. By using a variety of characterization methods, he and his team showed that bone mineral is a nanocrystalline, carbonated apatite with a unique crystalline array of atoms that is different than hydroxyapatite. Atomic vacancies and atomic substitutions of carbonate for phosphate make the native bone crystals more readily resorbed than highly crystalline hydroxyapatite. A consensus was reached to revise the standard. The F1581 specification now includes a description of anorganic bone as a bone-derived apatite and explains the importance of carbonate content and structure relative to dissolution and biological performance. This is an example of how standards must be continuously reviewed to reflect current knowledge and serves as a testament to the importance of clinician and academic input to the generation of robust standards.

academic). Further, in ASTM, each organization, company, or agency is only granted one vote. In ISO, each country is given one vote. In this way, one group of stakeholders cannot unfairly influence the voting outcome.

Documentary standards are "living" documents that can be revised or revoked by the balloting process. Often, new information relevant to the standard becomes available and triggers revision. All standards must be periodically updated and reballoted (every 5 years for ASTM) to assure their relevance continues. Documentary standards have a useful lifetime and are revoked when they become irrelevant.

Applications of Documentary Standards

Accelerating the Regulatory Process

Documentary standards can be a vital part of securing regulatory approval. When a standard test method can be used to assess a quality attribute of a product, then the review of these data is more efficient since the regulators will be familiar with the methods. The Center for Devices and Radiological Health at US FDA has a database of standards that it recognizes: https://www.accessdata.fda.gov/scripts/cdrh/cfdocs/cfStandards/results.cfm.

Furthermore, in 2016, the US Congress passed the 21st Century Cures Act (US Public Law 114-255) which

CASE STUDY II: DOCUMENTARY STANDARDS USED IN A SUBMISSION TO FDA—A LIVING EXAMPLE

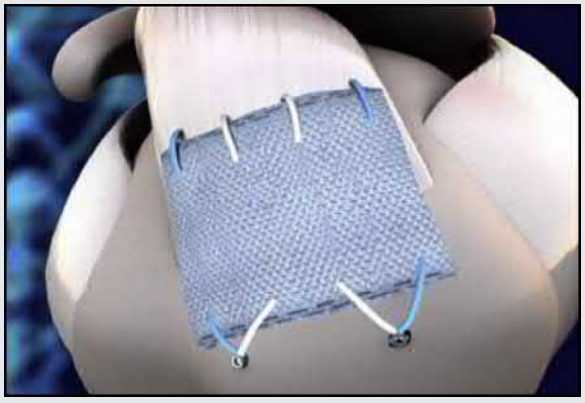
The documentary standards cited below were critical in the development and approval of X-Repair.

Product: X-Repair (Synthasome)

- Woven, degradable mesh (poly-L-lactic acid)
- Augments surgical repair of tendons and soft tissues
- Received 510(k) clearance in 2009

Standards that Were Used in the X-Repair 510(k) Application to FDA

- ASTM D3786 Standard Test Method for Bursting Strength of Textile Fabrics—Diaphragm Bursting Strength Tester Method
- ASTM D5035 Standard Test Method for Breaking Force and Elongation of Textile Fabrics (Strip Method)
- ASTM D5587 Standard Test Method for Tearing Strength of Fabrics by Trapezoid Procedure
- ASTM F1635 Standard Test Method for in vitro Degradation Testing of Hydrolytically Degradable Polymer Resins and Fabricated Forms for Surgical Implants
- ASTM F2211 Standard Classification for Tissue Engineered Medical Products (TEMPs)
- ASTM F2312 Standard Terminology Relating to TEMPs
- ASTM F2027 Standard Guide for Characterization and Testing of Raw or Starting Biomaterials for Tissue-Engineered Medical Products
- ASTM F2150 Standard Guide for Characterization of Biomaterial Scaffolds Used in TEMPs
- ISO 10993 Biological Evaluation of Medical Devices
- ISO 11135 Sterilization of Health-Care Products



Acknowledgement: Information courtesy of Anthony Ratcliffe, Synthasome.

requires the US FDA to facilitate the development of standards to enable "the development, evaluation, and review of regenerative medicine therapies and regenerative advanced therapies, including the manufacturing processes and controls of such products." An example of the essential role of standards in bringing a medical product from bench to bedside is described in Case Study II.

As mentioned above, the use of documentary standards is mandatory in some cases. Thus, it is important that documentary standards be carefully written to avoid inhibiting innovation and enabling their appropriate application to

multiple use cases, especially those that may be unforeseen. Verbs such as "shall," "will," and "must" should be used cautiously in standards, while words such as "may" and "can" are less restrictive and more compatible with innovation. It is difficult to set a specification in a standard that will apply to every product that may be developed. Specifications should be described with language that is conducive to innovation.

For these reasons, risk management approaches are being applied for tissue-engineered medical products: ISO 10993-1: Biological Evaluation of Medical Devices – Part 1: Evaluation and Testing Within a Risk Management Process. Risk management is a systematic approach to evaluating, controlling, and monitoring risk. Risks assessment includes "risk analysis in which risks are identified and estimated and risk evaluation in which risks are evaluated to identify those which require mitigation" (ISO 10993-1). It is not realistic to view documentary standards as a one-size-fits-all solution and the decision to use them should be based on the application and its risks. Risk management approaches enable the most important tests to be identified and performed for each product while avoiding the performance of unnecessary or irrelevant testing.

Specificity versus Universality

"Specificity versus universality" is a common debate during standards development. If a standard is written very broadly then it may not be useful, whereas as if it is written very narrowly, then it may only be useful to a small group of stakeholders. Finding the proper balance of being broad enough to have wide application, but being specific enough to still be useful, is a challenge. For this reason, the scope statement may be the most important section of a standard. The scope is the first section of both ASTM and ISO standards. The scope statement should clearly define the intent of the standard and what types of products or measurements are to be addressed. Defining the scope of a standard is a major task of any working group and may require extensive discussion to compose.

A Standard Test Method Does Not Necessarily Define the Best Measurement

It is important to realize that a standard test method does not necessarily describe the best way to measure a property of interest (Simon et al., 2015). Instead, a standard test method provides a reliable way to make a measurement, a way that has been vetted by experts and voted upon. Although there may be better or newer test methods, the value of a standard test methods lies in its reliability, since many experts have reviewed it and provided input. New approaches, or experimental test methods that are not well established, are not typically covered by a standard.

Clinical Relevance

Another common, and very challenging, topic for discussion when developing documentary standards is that of "clinical relevance" (also referred to as "biological relevance"). This is important when deciding what to measure and how to measure it. Although the desire is to measure the most important properties of a product (the properties that will influence its clinical performance), this is often difficult to achieve, particularly for tissue-engineered medical products. Very careful thinking is required to determine which properties are the most clinically relevant and should be characterized. These decisions are easier when the product has been rationally designed with a hypothesized mechanism of action (Bravery et al., 2013). In this way, measurements can be selected based on their ability to provide information about the product's ability to achieve the intended mechanism of action.

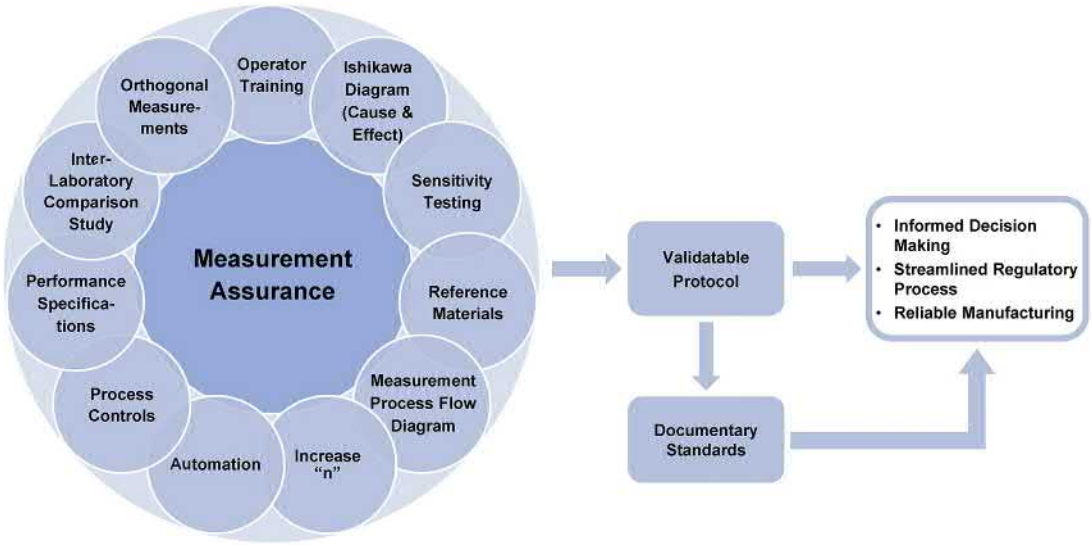
Some documentary standards focus on raw materials that are used in a range of other products or devices. Examples of materials-focused standards include "ASTM F75 Standard Specification for Cobalt-28 Chromium-6 Molybdenum Alloy Castings and Casting Alloy for Surgical Implants," "ASTM F451 Standard Specification for Acrylic Bone Cement" and "ISO Technical Specification 20,399-1 - Biotechnology — Ancillary Materials Present During the Production of Cellular Therapeutic Products — Part 1: General Requirements." Other standards may focus on devices, including design aspects, dimensions, materials used in the device, and laboratory-based tests of device performance. Performance testing evaluates the quality or capability of a product and aims to be a step closer to predicting clinical performance. Examples of documentary standards that describe device characteristics include F703 Standard Specification for Implantable Breast Prostheses and F623 Standard Performance Specification for Foley Catheter. ASTM F1926 Standard Test Method for Dissolution Testing of Calcium Phosphate Granules, Fabricated Forms and Coatings is a test method for a performance-related parameter. Many types of documentary standards are important for improving the quality and reliability of medical devices.

Measurement Assurance

Measurement assurance is the process of evaluating and reducing variability in a measurement to improve confidence in results for use in decision making (Simon et al., 2016). There are many strategies that can be used to achieve measurement assurance, as shown in Fig. 3.1.8.3. Test methods that have been improved by the application of these strategies may serve as the basis for writing a documentary standard.

Several strategies for measurement assurance are described below and in Fig. 3.1.8.3:

- *Reference materials:* Materials that are homogeneous and stable in regard to specified properties for use in calibration, to serve as a control or to serve as a reference point for comparability (described in more detail above).
- *Measurement process flow diagram:* A tool to formally map a measurement process so that each step can be considered for its contribution to measurement uncertainty.
- *Increase "n":* Increasing the number of replicate measurements (n) that are conducted enables more reliable statistical analysis and better modeling of the probability distribution function (histogram).
- *Automation:* When automation can replace human manual labor, the number of measurements can be increased, the variability in the process can be reduced, and human bias can be reduced.



• **Figure 3.1.8.3** "Measurement assurance is a structured process designed to ensure that measurements are adequate for their intended use" (Carey, 1993). This encompasses the strategies that one can use to improve confidence in a measurement. Identifying, monitoring, and mitigating the sources of variability in the measurement process lie at its core. Application of these strategies to a measurement process yields a protocol which can be validated for a particular application and which may serve as the basis for developing a documentary standard.

- *Process controls:* Procedures to monitor critical points in a measurement process to check that steps are performing according to specifications.
- *Performance specifications:* Specifications that must be met in order for the test results to be used in decision making; they are established by sensitivity testing and by tracking process control data over many runs.
- *Interlaboratory comparison studies (ILCSs):* When different labs conduct the same test and compare the results to assess measurement reproducibility; assesses measurement variability introduced by different operators in different labs using different equipment (discussed in more detail below).
- *Orthogonal measurements:* Confidence in a measurement result is enhanced when different measurement methods give a similar value of a material property; this is more convincing when the different measurements are based on different underlying principles.
- *Operator training:* Provision of suitable training to operators improves measurement precision and comparability between different operators and labs.
- *Ishikawa diagram (cause and effect):* A graphical tool to map sources of variability in a measurement and to attribute them to different steps or aspects of the measurement process; also called a "cause and effect" or "fishbone" diagram.
- *Sensitivity testing:* Identification of key measurement parameters that should be controlled in order to improve the reliability of the test results; may involve "design of experiment; " also called "ruggedness testing."
- *Design of experiment (DOE):* A systematic approach for assessing the effect of multiple experimental variables on the test results; uses a mathematical approach to determine the most efficient and statistically powerful approach for varying and combining the parameters.

Interlaboratory Comparison Studies

Interlaboratory comparison studies (ILCSs) are an especially important tool for improving the reproducibility and comparability of research (Horwitz, 1994). ISO defines an "interlaboratory comparison" as the "organization, performance and evaluation of measurements or tests on the same or similar items by two or more laboratories in accordance with predetermined conditions." ASTM requires that an ILCS be completed for all standard test methods that they publish. The first step in an ILCS is the formation of a working group of participants that work collaboratively to design the test method. A well-documented, carefully written protocol must be developed that precisely describes how the test will be conducted. A set of stable, homogeneous specimens is distributed to the participants who then conduct the test method on the specimens in their labs. The participating labs report their results to the organizing lab, and the data are analyzed to assess the reproducibility (intralab variability) of the method when conducted in different labs. This process reduces variability as the protocol is refined through successive testing iterations and yields a more reliable test method. New labs benefit since they can use this reliable protocol to conduct testing in their own labs and may reasonably expect their results to fall within the range observed during the ILCS. The use of standard test methods which have been refined through an ILCS enhances the comparability of data collected in different labs. Comparable test data are especially important when a company needs to assess the quality of products manufactured at different locations, by different operators, and/or on different equipment.

Looking Ahead

There are many interesting and challenging opportunities for future standards development. One example is data standards. Cell characterization data sets are getting larger, especially omics data sets (genomic, transcriptomic, metabolomic, proteomic, etc.), and standards for formatting, annotating, analyzing, and summarizing these data will be required as they are used to support regulatory filings.

Another useful advance may be the application of the principles of "engineering biology" to the development of biological reference materials. For example, precise genetic manipulations could be used to generate cells with precise characteristics that could be used as reference materials to calibrate cell measurements. For instance, cells with a tightly regulated and reproducible rate of division could be useful for calibrating cell-counting measurements. Cells that express a precise number of a particular cell surface marker on their surface could be used to calibrate flow cytometry measurements.

The ability of different systems, devices, or applications to connect, or interoperability, will be key for driving down development and manufacturing costs. However, this concept is relatively new for TERM since the common themes for successful TERM products are not yet clear. As the field matures, multiple products may come to market that use overlapping materials and processes, and standards to enable interoperability of these materials and processes will be needed.

Another area for potential standardization will be multivariate analytical methods and artificial intelligence. Regulatory filings contain many types of measurement data and relating these data to clinical outcomes is challenging. Standards for using multivariate methods and artificial intelligence for determining product quality from large and complex data sets will be required.

Standard approaches for weighing risks versus benefits of TERM products will be needed. Decision making must weigh potential benefits of the product against the likelihood and severity of adverse events. It may be appropriate for a terminally ill patient with a prognosis of months to live to take on greater treatment risks than a relatively healthy patient being treated for a nonlife-threatening musculoskeletal ailment. The ethical, cultural, and personal nature of these decisions could benefit from the open discussions of experts in a specialized working group which are part of the documentary standards development process. Institutional review boards (IRBs) could benefit from having documentary standards to assist in their decision-making process.

Conclusion

Despite the many standards that are already available, the translation of biomaterials and tissue-engineered medical products to clinical use is creating many needs and opportunities for standards development. There are many benefits to standards that make participation in their development a valuable and rewarding experience. Standards development remains an active and ongoing process that will likely influence your research in the future, if it has not already.

Homework Questions

1. Which one below lists all the types of ASTM standards?
   A. Classification and Test Methods.
   B. Classification, Guide, Specification, Terminology and Test Methods.
   C. Classification, Guide, Practice, Specification, and Test Methods.
   D. Classification, Guide, Practice, Specification, Terminology, and Test Methods.
2. Describe the differences between an ASTM specification standard and a test method standard.
3. Who uses standards?
   A. Manufacturers and Test laboratories
   B. Manufacturers, Consumers, Test laboratories, College professors and their students.
   C. Manufacturers, Test laboratories, College professors and their students.
4. Which below best completes this sentence? Compliance with a standard …
   A. is voluntary.
   B. is nonvoluntary.
   C. may be either voluntary or nonvoluntary.
5. What are the names of some standards development organizations (SDOs) that prepare consensus standards through voting (lists are not exhaustive)?
   A. AAMI, ASTM, ISO, and ADA
   B. AAMI, ASTM, ISO, and ANSI
6. Briefly describe the ASTM standards development process including words like task groups, subcommittees, and ballots.
7. Both the subcommittees and main committees of ASTM must be balanced between what categories of stakeholder groups?
8. How can domination by any one stakeholder or interest group be prevented during development of a standard?
   A. Only one vote per voting interest is allowed.
   B. Only one member per voting interest may join the SDO.
   C. Through discussion at working groups or task-force group meetings.
9. Should a standard be based on well-established technologies or on new areas of research? Circle one.
10. (A) Why are there so many different standards organizations, and (B) accreditation by what organization brings some measure of uniformity of process to the many SDOs in the USA?
11. Identify a standard within ASTM (www.astm.org) that covers the testing needed to establish the biocompatibility of a new material for a medical device.
12. Which type of testing below is an example of in vitro testing:
   A. in a cell culture plate
   B. implantation in an animal
   C. a simulation on a computer
13. Are materials proposed for medical use tested by direct contact, by using extracts obtained by soaking the implant in liquids that simulate body fluids or by both methods (search www.astm.org)?
14. What animal is skin irritation typically tested in (search www.astm.org)?
   A. Rabbit
   B. Dog
   C. Cat
   D. Mouse
15. Are guinea pigs used in testing for allergic reactions? Search the www.astm.org website to find out.
16. Search the www.astm.org website to find three examples of standards for biomaterials, biomolecules, cells and tissue-engineered constructs that apply to tissue-engineered medical products.
17. Standards development in the area of nanomaterials has been slow. Suggest possibilities for what has held up standards development in the field of nanotechnology.

Answer Key for Homework Questions

1. What are the types of ASTM standards?
   Answer: D. Classification, Guide, Practice, Specification, Terminology, and Test Methods.
2. Describe the differences between an ASTM specification standard and an ASTM test method standard.
   Answer: A specification describes chemical, mechanical, physical, and electrical properties of a material. A test method standard describes the test specimen to be used, the conditions under which it is to be tested, how many specimens and what controls are to be tested, and how the data are to be analyzed. Often, the reproducibility of test methods is assessed by "interlaboratory testing," meaning that several laboratories have followed the method and the results are analyzed to determine the degree to which they agree.
3. Who uses standards?
   Answer: B. Manufacturers, Consumers, Test laboratories, College professors and their students.
4. Which below best completes this sentence? Compliance with a standard …
   C. may be either voluntary or nonvoluntary.
5. What are the names of standards development organizations (SDOs) that prepare consensus standards through voting?
   Answer: A. AAMI, ASTM, ISO and ADA.
   Note: ANSI does not write standards but instead coordinates the activity of standards development organizations in the United States.
6. Briefly describe the ASTM standards development process including words like task groups, subcommittees, and ballots.
   Answer: This is a brief description of the ASTM standards development process: A standard work item can be proposed by anyone and then approved by the executive committee of a subcommittee based on a rationale and scope provided by the person or group initiating the standard. A task group is created that includes

5–20 stakeholders and they draft the standard. It is written using an ASTM template for one of the six defined types of standards. It is sent out for ballot at the subcommittee level first and then the main committee. Persuasive negative votes will stop the process and may require revision of the standard. If no negative votes are received at either subcommittee or main committee, then the item becomes a published standard.

7. Both the subcommittees and main committees of ASTM must be balanced between what category of stakeholder groups?
Answer: Producers and nonproducers.
Note: Nonproducers include users, consumers, and general interest.

8. How is domination by any one stakeholder or interest group prevented during development of a standard?
Answer: A. Only one vote per voting interest is allowed.

9. Should a standard be based on well-established technologies or on new areas of research? Circle one.
Answer: Well-established technologies.

10. (A) Why are there so many different standards organizations, and (B) accreditation by what organization brings some measure of uniformity of process to the many SDOs in the USA?
Answer: (A) Each SDO provides valuable standards for a particular area of technology and has the right stakeholders and experts to write these standards. (B) ANSI accreditation provides a measure of uniformity and consistency of process to the many SDOs.

11. Identify a standard within ASTM (www.astm.org) that covers the testing needed to establish the biocompatibility of a new material for a medical device.
Answer: There are many standards that could provide a correct answer. Some of them are listed here:
F748 Standard Practice for Selecting Generic Biological Test Methods for Materials and Devices Medical Devices.
F3206 Standard Guide for Assessing Medical Device Cytocompatibility with Delivered Cellular Therapies.
F813 Standard Practice for Direct Contact Cell Culture Evaluation of Materials for Medical Devices.
F1027 Standard Practice for Assessment of Tissue and Cell Compatibility of Orofacial Prosthetic Materials and Devices.

12. Which type of testing below is an example of in vitro testing:
Answer: A. In a cell culture plate.

13. Are materials proposed for medical use tested directly, by using extracts obtained by soaking the implant in liquids that simulate body fluids or both?
Answer: Both.
Note: Under ASTM Committee F04.16, see the following:
ASTM F749 Practice for Evaluating Material Extracts by Intracutaneous Injection in the Rabbit
ASTM F750 Practice for Evaluating Material Extracts by Systemic Injection in the Mouse
ASTM F813 Practice for Direct Contact Cell Culture Evaluation of Materials for Medical Devices

14. What animal is skin irritation typically tested in?
Answer: A. Rabbit.
Note: See ASTM F719 Standard Practice for Testing Biomaterials in Rabbits for Primary Skin Irritation.
Humans are also used. See ASTM F2808 Standard Test Method for Performing Behind-the-Knee (BTK) Test for Evaluating Skin Irritation Response to Products and Materials That Come into Repeated or Extended Contact with Skin.

15. Are guinea pigs used in testing for allergic reactions? Search the www.astm.org website to find out.
Answer: Yes.
Note: See ASTM F720 Practice for Testing Guinea Pigs for Contact Allergens: Guinea Pig Maximization Test.

16. Search the www.astm.org website to find examples of standards for cells and tissue-engineered constructs that apply to tissue-engineered medical products.
Answer: There are many standards that could provide a correct answer. Some of them are listed here:
ASTM F3259 Standard Guide for Micro-computed Tomography of Tissue Engineered Scaffolds
ASTM F2211 Standard Classification for Tissue Engineered Medical Products (TEMPs)
ASTM F2315 Standard Guide for Immobilization or Encapsulation of Living Cells or Tissue in Alginate Gels
ASTM F2739 Standard Guide for Quantifying Cell Viability within Biomaterial Scaffolds

17. Standards development in the area of nanomaterials has been slow. Suggest possibilities for what has held up standards development in the field of nanotechnology.
Answer: Standards for nanoparticles have been delayed due to the lack of high-precision methods required to ensure reliability of the results. It is not possible to standardize something that is not reproducible or reliably measured. A lack of reproducibility has also delayed standards for cells in the field of tissue engineering and regenerative medicine. Uncertainty with test methods and high variability in the results, and in the cells themselves, has made it difficult to define appropriate quality measures.

3.1.9

Medical Device Failure—Implant Retrieval, Evaluation, and Failure Analysis

MELINDA K. HARMAN

Department of Bioengineering, Clemson University, Clemson, SC, United States

Overview and Definitions

Medical Implants

The phrase "medical implant" can assume many definitions, depending on the context and intended purpose. Regulatory and public health agencies broadly define implants as types of medical devices that are: (1) intended for use in the diagnosis, prevention, treatment, or cure of diseases or other conditions; (2) intended to affect the structure or function of the body; and (3) do not achieve their intended purposes with chemical or metabolic action (FDA, 2017; WHO, 2003). Some implants can replace anatomic structures in part or in full, while others can deliver medication, monitor body functions, or provide support to organs and tissues. Implants can consist of processed tissues or synthetic biomaterials and can be placed permanently or removed after accomplishing their intended function. Modern medical implants gained widespread use in the mid-20th century and millions of different types are implanted in the United States each year (Table 3.1.9.1). It is estimated that 8%–10% of Americans are living with some type of medical implant (NIH, 2000).

For the purposes of this chapter, an implant is defined as a type of medical device that is placed inside or on the surface of the human body, as having an intended lifespan spanning months or years, as being made of biomaterials and penetrating living tissues, as having a physiological interaction in the human body, and as being retrievable (NIH, 2000).

Implant Retrieval

Modern medical implants are highly beneficial to patient health. Rapidly evolving technologies and ever-expanding indications for implant use demand continual development to improve their performance and extend their useful lifespan. Medical implants are also subject to failure.

Implant retrieval and evaluation (commonly, implant retrieval analysis or explant analysis) describes a method of scientific analysis for determining the efficacy and safety or biocompatibility of medical implants in vivo (Anderson et al., 2012). It is concerned with the documentation of problems that dictate modification of design, materials, or use of the implants in patients. In this manner, implant retrieval and evaluation encompass a total product life cycle approach, with analysis occurring during many of the major phases in the lifespan of a medical implant, from research and development activities, to design validation and preclinical studies, and after widespread clinical use (Table 3.1.9.2).

Postmarket Surveillance

It is globally recognized that basic regulatory programs for the safety and performance of medical devices depend on the critical elements of premarket review ensuring product control, postmarket surveillance ensuring safe and effective use, and product representation ensuring accurate advertising and public education to guard against misrepresentation of product claims (WHO, 2003). However, prior to 1976, there were no regulatory programs assuring that devices recommended to American patients by their doctors were monitored for safety and effectiveness (See Case Study: Intrauterine Contraceptive Devices).

The FDA defines postmarket surveillance as the systematic, scientifically valid collection, analysis, and interpretation of data or other information about a marketed device (FDA, 2018). A robust postmarket surveillance

TABLE 3.1.9.1 Prevalence of Medical Implants in the United States (McIntyre, 2011)

Implant	Procedure Volume[a]
Artificial eye lenses	>2,580,000
Ear tympanostomy tubes	>715,000
Coronary stent	>560,000
Knee replacement	>543,000
Orthopedic fracture repair	>453,000
Intrauterine device	>425,000
Spinal fusion/disc replacement hardware	>413,000
Breast implants	>366,000
Heart pacemaker	>235,000
Hip replacement	>230,000
Implantable cardioverter defibrillator	>133,000

[a]Estimated using 2011 National Health Survey data and other sources.

TABLE 3.1.9.2 Sources of Retrieved Implants and the Relevance of the Evaluation

Source	Relevance
Fabricated but unimplanted prototypes	To evaluate changes induced by the fabrication process
Specimens subjected to in vitro tests	To evaluate biocompatibility, durability of the biomaterials, or potential failure modes
Specimens removed from animal models following in vivo function	To evaluate biocompatibility, durability, implant–tissue interactions, or safety and effectiveness of the design
Specimens accrued in carefully controlled clinical trials	To evaluate implant–tissue interactions, or safety and effectiveness of the design for its intended use
Failed or functioning implants explanted in the course of general clinical use following regulatory approval	To evaluate underlying mechanisms contributing to implant success or failure during end-use conditions

strategy supports better management of the risk–benefit ratio throughout the life cycle of medical devices (Institute of Medicine, 2011). Postmarket surveillance is either passive (regulators depend on data provided by manufacturers and user facilities) or active (regulators seek information on adverse events, device malfunctions, and product effectiveness) and the FDA uses multiple platforms for postmarket surveillance of implants.

Passive postmarket surveillance is an important mechanism for monitoring medical device performance and potentially detecting adverse events associated with device use. Available since 1991, the Manufacturer and User Facility Device Experience (MAUDE) database at the FDA is the key platform for postmarket surveillance gathered through two reporting tools. First, the Medical Device Reporting (MDR) tool is a mandatory (for manufacturers and user facilities) and voluntary (for individual clinicians or patients) reporting mechanism designed to facilitate the capture of device-related adverse events, including death, serious injury, or malfunction. Second, FDA partners with approximately 250 healthcare facilities under the MedSun program to collect real-world information about medical device (generally, Class II) problems in hospitals, generating more reliable and higher quality reports than MDR alone (Daniel et al., 2015). MAUDE stores data reported through the MDR and MedSun programs.

Using these adverse event reports and other sources (e.g., device recalls or corrective actions, review of premarket or post-approval data, or review of scientific literature), the FDA can identify device issues appropriate for active postmarket surveillance. It has authorization (under section 522) to compel manufacturers to complete studies of an approved device if a safety issue has been identified (see Case Study: Metal-on-Metal Articular Bearings in Hip Joint Replacement). Manufacturers use implant retrieval and evaluation studies and various other assessments to investigate reason(s) for failure and identify failure modes, as required by these "522 orders." However, due to known challenges with meeting 522 orders, including inconsistencies in design and lack of a general framework for completing them, some have advocated for registry-based surveillance as an alternative approach (Daniel et al., 2015).

Goals for Implant Retrieval and Evaluation and Failure Mode Analysis

Implant designs, the biomaterials selected for them, and the protocols used to test them before use in humans, are all intended to minimize the possibility of device failure (Schoen et al., 2012). The majority of such devices serve their patients well, alleviating pain and disability, enhancing quality of life, and/or increasing survival. Nevertheless, some implants fail, often following extended intervals of satisfactory function. The clinical value of implant retrieval and evaluation is rooted in patient safety through detailed analysis of clinical complications associated with the implanted device and biocompatibility at the implant–tissue interface (Schoen et al., 2012). Irrespective of implant site or desired function of the device, the overwhelming majority of clinical complications produced by medical devices fall into several well-defined categories (Table 3.1.9.3).

There is a critical need for implant retrieval analysis in order to gain insights into the strengths and weaknesses of implant designs and their functional longevity and to understand the enduring consequences of implantation. The National Institutes of Health recognizes that "long-term data on the behavior of implanted devices and host

CASE STUDY I: INTRAUTERINE CONTRACEPTIVE DEVICES

Often cited as the device failure that helped prompt the Medical Device Amendments of 1976, which authorized the FDA to begin regulating medical devices, the problem of the Dalkon Shield intrauterine device (IUD) provides an instructive case history of biomaterials performance and failure modes uncovered by implant retrieval analysis, adverse event reporting, and clinical outcome studies.

What Problem Was Addressed?

IUDs are the most commonly used method of reversible female contraception, with over 168 million women users worldwide as of 2011 (Nelson and Massoudi, 2016). Introduced in the 1960s, early IUDs were a nonhormonal contraceptive benefitting from two mechanisms of action. The IUD biomaterials (polymers with small amounts of copper sulfate or stainless steel rings) created changes in the cervical mucus and uterine wall that made it difficult for sperm to fertilize eggs. The IUD's flexibility and shape provided for easy insertion into the uterine wall and effectively induced a chronic noninfectious inflammation in the endometrium to prevent implantation of any fertilized egg. Tail strings, consisting of monofilament polypropylene, attached to the distal end of the IUD facilitated removal.

One of the dominant IUDs designed in the late 1960s was the Dalkon Shield IUD. Its key design features included a large circular shape with a thin inner membrane for increasing surface contact with the endometrium and 10 plastic fins around the circumference for secure anchoring into the uterine wall, effectively preventing involuntary expulsion while in use and increasing the resistance to removal (Roepke and Schaff, 2014). Tail strings with higher tensile strength were added, using a nylon suture material (Supramid) having hundreds of inner fibers encased in a smooth outer sheath.

Following its introduction in 1971, there were 3.9 million Dalkon Shields sold over 3 years, capturing the majority (60%) of the US IUD market (Roepke and Schaff, 2014). However, by 1974, there were overwhelming clinical complications of pelvic infections, miscarriage, and deaths associated with this device (Tatum et al., 1975). Explant analysis performed in the years to follow revealed the multifilament tail string served as a wick for vaginal fluid and bacterial access inside the uterus, effectively bypassing the antibacterial actions of the cervical mucus (Bank and Williamson, 1983). Deterioration of the outer nylon sheath, especially in regions of high stress adjacent to the knotted attachment side, provided a route for bacteria to exit the sheath into the sterile uterine cavity and contributed to string breakage during attempted removal.

Following protracted legal challenges and denials of wrongdoing by the manufacturer, the absence of heat-sealed ends on the multifilament tail strings and deterioration of the outer nylon sheath were identified as contributing factors in the high infection rates with the Dalkon Shield (Roepke and Schaff, 2014). The FDA identified the multifilament tail string as a hazard for its role in the infections.

What Properties Were Required of the Biomaterial?

Modern IUDs incorporate tail strings meeting the following criteria (Roylance 1993):

1. Sufficient tensile strength to avoid breakage during IUD removal
2. Sufficiently small diameter to provide flexibility
3. Biologically inert material that does not undergo chemical or physical change during use
4. Hydrophobic monofilament fiber to avoid water absorption (and capillary transport)
5. Suitable attachment to the IUD body by a method that does not result in a loss of tensile strength
6. Capable of being sterilized, by either chemical or thermal means
7. Capable of being colored to aid in distinguishing it from surrounding tissue
8. Widely available material that is capable of being processed with consistently high quality
9. Material that has a proven history of safe and effective use in biomedical applications.

What Biomaterials Are Used?

The FDA regulates the IUD as a combination product, recognizing that the device has an additional function to delivery of the drug. There are two general types of modern IUDs, polymeric hormone-releasing IUDs and polymeric copper-releasing IUDs, and older generations of all-metal stainless steel IUDs primarily used outside of the United States. As of 2016, there are five IUDs with FDA approval for use in the United States, including three hormone-releasing (levonorgestrel, a progestin hormone and does not contain estrogen) IUDs and one copper-releasing IUD (Nelson and Massoudi, 2016).

Polymeric IUDs have T-shaped bodies fabricated from low-density polyethylene with added barium sulfate for opacity during imaging. The copper surface areas, in the form of solid collars or coiled wire, vary from approximately 200–380 mm^2. Highly drawn and oriented polyethylene, polypropylene, and nylon 66 monofilament fibers of approximately 0.25 mm diameter are considered suitable for use as tail strings (Roylance, 1993).

Technical specifications recommended by the WHO (WHO, 2016) include the following:

- Polyethylene material properties having a minimum tensile strength of 13 MPa and a 2% secant flexural modulus in the range of 133.5–180.6 MPa
- Minimum copper purity of 99.99% distributed over a 380 mm^2 surface area
- High-density polyethylene monofilament having a minimum tensile strength of 28 MPa to withstand a 9.5 N tensile load
- Monofilament pigmented with titanium dioxide and knotted to form two tail strings.

response are essential inputs to the development process" (NIH, 2000), yet systematic programs for implant retrieval and evaluation are rare. The general goals of implant retrieval and evaluation aim to fill this need by implementing a multidisciplinary strategy to document implant-specific and patient-specific parameters and underlying mechanisms contributing to implant success or failure during end-use conditions (Table 3.1.9.4). These goals address key factors for determining the outcome of a medical implant, including the biomaterials and implant design, patient-specific functional anatomy and pathology, and technical aspects of the surgical implantation.

Each type of in vivo condition and clinical use of the implant has unique implant–host interactions requiring

CASE STUDY II: METAL ON METAL ARTICULAR BEARINGS IN HIP JOINT REPLACEMENT

With implications for the current state of the 510k approval pathway at the FDA (Howard, 2016; Institute of Medicine, 2011), metal-on-metal (MoM) articular bearings for hip joint replacement provide an instructive case history of a historical design concept that was reintroduced using contemporary biomaterials. Used in total hip replacement and hip resurfacing, MoM implants quickly gained widespread clinical adoption, especially when coupled to larger diameter femoral heads (Hart et al., 2015). Despite promising laboratory results for the wear performance of MoM implants, clinical outcome studies and adverse event reporting revealed unanticipated problems with MoM implants and ultimately led manufacturers to stop marketing their devices. Implant retrieval and evaluation played an essential role in the characterization of volumetric wear rates for historical MoM implants (so-called first generation) and the failure mode analysis used to unravel and understand the causes of pervasive failures in modern MoM implants (so-called second generation). Detailed data gathered through mandatory postmarketing surveillance studies ultimately led the FDA to reclassify MoM as class III (higher risk) medical devices requiring premarketing approval applications containing sufficient valid scientific evidence to reasonably assure the safety and effectiveness of MoM implants for their intended use (FDA, 2016).

What Problem Was Addressed?

Since the introduction of total hip replacement in the 1960s, MoM and metal-on-polyethylene (MoP) articular bearings have been the most common implant biomaterials used to replace diseased articular cartilage. Although regarded as clinically successful, problems with wear of the polyethylene implants and late aseptic loosening limited the longevity of MoP designs. Careful implant retrieval analysis of historical first-generation MoM hip implants made of cast cobalt chromium alloys documented volumetric wear rates that were an order of magnitude smaller than the typical 50–100 mm^3 wear rates for conventional MoP implants (McKellop et al., 1996; Rieker et al., 1998; Semlitsch and Willert, 1997).

These observations fueled interest in alternative bearing materials to replace MoP designs and led to the introduction of modern second-generation MoM hip implants made of wrought cobalt chromium alloys. In vitro wear simulations of modern MoM bearing materials demonstrated significantly reduced volumetric wear compared to conventional MoP bearing materials (Barbour et al., 1999; Firkins et al., 2001; Fisher et al., 2004). However, those in vitro studies noted that alloy composition (low carbon), inadequate clearance between the metal femoral head and metal acetabular liner (deviation from nominal 0.2 mm), and load and motion profiles replicating more adverse and physiologically relevant inputs (higher load and elliptical contact paths) led to excessive MoM wear in some cases.

Initial clinical outcomes from second-generation MoM designs were promising, with >95% survival rates reported at 10-year follow-up for 28–32 mm diameter MoM bearings (Benjamin-Laing and Haddad, 2012; Eswaramoorthy et al., 2008; Grübl, 2007). Subsequent introduction of larger diameter femoral heads, which provide for additional joint stability, were cleared using the 510(k) FDA regulatory pathway by claiming substantial equivalence to the smaller diameter MoM bearings. MoM hip replacements were readily adopted by orthopedic surgeons and over one million were implanted worldwide by 2008, with approximately 35% of all hip implants in the United States including MoM articular bearings (Bozic et al., 2009).

Implant registries captured this widespread use of the MoM bearings and began to raise concerns regarding high revision rates after 5 years in vivo, which were approximately two to three times higher than other bearing material combinations (Jameson et al., 2012). Although there was some variability among different manufacturer brands, general trends indicated higher failure rates in women than men and with bearing sizes of 36 mm diameter or greater. Unacceptably high revision rates reported by two national joint registries called into question the regulatory approval process for MoM hip implants, particularly with respect to premarket data requirements to prove safety and effectiveness (Howard, 2016).

The consequences of nanometer-sized wear particles from the MoM bearings elicited a biological response with both local and systemic consequences largely due to a higher degree of biological reactivity in the metal debris compared to polyethylene debris from conventional MoP bearings (FDA, 2019). The substantially higher number of metal particles provided for a very large surface area for interaction with intracellular and extracellular fluids. Explant analysis and histological studies of joint tissues revealed failure mechanisms consistent with release of both wear particles and metallic ions from the articular surfaces and the head-stem trunnions in modular implants (Campbell et al., 2014; FDA, 2019). Local tissue reactions included osteolytic bone loss and soft-tissue masses (termed pseudotumors) evident in some patients with MoM implants, with histomorphology presenting macrophage-dominated and/or lymphocyte-dominated foreign-body reactions (Campbell, 2010; FDA, 2019; Hallab, 2013). Elevated measures of metal ion concentrations in blood serum and urine led to concerns of systemic effects from chronic exposure to metal ions.

Based on rising numbers of reported adverse events and accumulating evidence in clinical and explant studies, in 2011, the FDA issued 522 orders mandating postmarketing surveillance studies to all five US manufacturers of MoM hip implants. Detailed explant analysis from more than 2000 failed MoM hip implants determined that factors associated with release of higher metal ion levels and wear were: edge-loading of the metal acetabular liner, concurrent wear at the modular taper junction between the head and stem, larger head diameter, and acetabular cups designed with smaller cup coverage angles. The clinically failed hip implants exhibited more wear than was predicted by in vitro testing completed in mechanical hip joint wear simulators and used to support FDA premarket clearances of MoM hip bearings (FDA, 2019).

These results highlight the critical need for improved methods to measure wear and associated metal ion release at both the articular bearing surfaces and modular taper junctions. National and international standards committees are leading the development of additional "high-demand" and "adverse" hip wear testing protocols to better simulate wear conditions seen clinically. Detection of metal ion levels in body fluid (e.g., blood, serum, urine, and synovial fluid) lack sensitivity and specificity necessary for diagnostics and outcome predictions (FDA, 2019). The biological effects of wear and metal ion release in patients with MoM implants continue to present challenges for clinical management (FDA, 2019).

In 2016, the FDA issued a final order requiring manufacturers to submit a premarket approval application for MoM hip implants as class III medical devices (FDA, 2016). As of March 2019, there are no approved PMA applications for MoM total hip replacements. There are two MoM total hip resurfacing systems (Cormet Hip Resurfacing System, Corin; Birmingham Hip Resurfacing System, Smith & Nephew) cleared through the PMA process supported by nonclinical and clinical performance data.

CASE STUDY II: METAL ON METAL ARTICULAR BEARINGS IN HIP JOINT REPLACEMENT—CONT'D

What Properties Were Required of the Biomaterial?

Implant biomaterials used for joint replacement must be biocompatible and stable in vivo for longer than 10 years, present a low risk of mechanical failure, resist deformation under loading conditions that exceed body weight, and provide favorable tribological properties to endure one to two million or more gait cycles of loading each year. Desirable material properties for the bearing surfaces of total joint replacements include (Long and Rach, 1998; Rahaman et al., 2007):

1. High strength and toughness
2. High elastic modulus
3. High impact strength
4. High fracture toughness and fatigue resistance
5. High corrosion resistance
6. High hardness and good surface finish
7. High abrasion resistance
8. Good wetting behavior (low contact angle)
9. Low friction.

What Biomaterials Are Used?

Biomaterials used for articular bearings in hip joint implants include four classes of materials in clinical use or in development (Rahaman et al., 2007). These include:

1. Alloys of refractory metals (largely cobalt–chrome alloys, although stainless steel and titanium alloys were used in previous decades) (Long and Rach, 1998)
2. Refractory monolithic ceramic oxides (e.g., alumina, zirconia) or nonoxide ceramics (e.g., silicon nitride)
3. Ceramic composites (e.g., zirconia-toughened alumina)
4. Surface-modified refractory metals developed by oxidation (e.g., oxidized zirconium or zirconia) or surface deposition coatings (e.g., titanium nitride and diamond-like carbon).

According to the most recent data reported by the American Joint Replacement Registry (AJRR, 2018), ceramic biomaterials account for 52.3% of the femoral heads for hip joint implants, eclipsing the use of cobalt–chrome alloys in femoral heads for the first time. US surgeons overwhelmingly (>80% of cases) pair these femoral head biomaterials with highly cross-linked UHMWPE acetabular liners, and opt for 28 mm (14.0%), 32 mm (23.1%), or 36 mm (57.6%) diameter bearing surfaces.

TABLE 3.1.9.3 Patient–Implant Interactions Causing Clinical Complications (Schoen et al., 2012)

Thrombosis
- Thrombotic occlusion
- Thromboembolism
- Anticoagulation-related hemorrhage (owing to therapy to prevent thrombosis)

Infection

Inappropriate Healing
- Too little/incomplete
- Excessive tissue overgrowth

Structural Failure Due to Materials Degeneration
- Wear
- Fracture/fatigue
- Calcification
- Tearing

Adverse Local Tissue Interactions
- Inflammation
- Toxicity
- Tumor formation

Migration
- Whole device
- Embolization or lymphatic spread of materials fragments

Systemic and Miscellaneous Effects
- Allergy
- Heart valve noise

unique assessment protocols. Implant retrieval analysis makes use of systematic, multilevel assessment protocols documented in international standards (ASTM F561 and ISO 12891) and the medical/scientific literature. The standards generally describe relevant conditions to document at the time of explantation, methods for analyzing the tissue–implant interface and isolating particulate debris, and stages of progressively destructive analysis of the implant. Stage I analysis consists of routine device identification, documenting the device description, and macroscopic examination for any evidence of failure modes. Stage II analysis is more detailed and time consuming, and includes photography, optical microscopy, and nondestructive failure analysis. Stage III analysis includes material-specific techniques for metallic, polymeric, and ceramic materials, many of which are destructive.

Implant retrieval analysis provides a window into in vivo implant performance and corresponding host responses and plays a critical role in determining the cause(s) and mechanism(s) of implant failure, that is, failure mode analysis (Schoen et al., 2012). Interactions of the implant biomaterials with the surrounding tissues can be local or distant to the implant and deleterious biomaterials–tissue interactions can exist below detectable limits for extended periods of

TABLE 3.1.9.4 General Goals of Implant Retrieval and Evaluation (Anderson et al., 2012)

Determine rates, modes, and mechanisms of implant failure
Identify effects of patient and implant factors on implant performance and overall clinical outcome
Establish clinical and design factors that promote implant success
Determine dynamics, temporal variations, and mechanisms of tissue–biomaterial and blood–biomaterial interactions
Develop design criteria for future implants
Determine adequacy and appropriateness of animal models
Identify biomarkers of implant reactivity

TABLE 3.1.9.5 Combined Strengths of Implant Registries and Explant Analysis

1. Provide for meticulous and professional scrutiny while ensuring transparency through traceable datasets and reporting to all stakeholders (medical, industrial, scientific, and public sectors)
2. Documentation of the actual number of implant failures rather than underrepresentation as often occurs with passive surveillance
3. Reports of scientifically rigorous epidemiological data that link explant analysis with implant registries to aid early detection of specific implant failures
4. Rigorous analysis of implant degradation processes through time-related observations to help distinguish sporadic events from the general behavior
5. Establish standardized classifications that enable objective comparisons between different implant models of a given medical specialty to improve material selection, design, and manufacturing processes of implants
6. Enhance understanding of the in vivo behavior of modern implants not otherwise exposed to rigorous premarket assessment.

time before manifesting as complications in the patient (see Case Study: Metal-on-Metal Articular Bearings in Hip Joint Replacement). In addition to specific analysis protocols for the implant–tissue interface and implant biomaterials, unraveling a cause of failure usually requires systematic integration of clinical and laboratory information pertaining to the patient, and careful pathological analyses (Schoen et al., 2012). Evaluation of the implant without attention to the patient factors and clinical conditions will produce an incomplete evaluation, and limit understanding of the failure mode(s).

Implant complications are highly influenced by the clinical user (broadly used to include surgeon, interventionalist, or other medical professional) through the process of implant selection, implantation technique, and insertion procedure. This feature constitutes a key difference between implants and drugs, with the efficacy and safety of the latter generally not affected by the process of insertion (Schoen et al., 2012). In general, demographic, structural, functional, or physiologic factors relating to the patient (e.g., age, anatomy of the implant site, activity level, genetic predisposition to complications to thrombosis, allergies) and the implantation procedure (e.g., implant selection, technical aspects of the surgery, potential damage to the implant), are superimposed on the biomaterials and implant design and manifest failure modes (Schoen et al., 2012). Thus, implant failure in the clinical setting often involves multiple contributing factors (see Case Study: Prosthetic Heart Valves).

Medical Surveillance and the Role of Retrieval Analysis in Device Development

Explant analysis is complementary to both preclinical assessments and postmarketing surveillance. It challenges the scientific and medical community to consider what is normal function for medical implants and provides invaluable benchmarks for predictive models meant to simulate in vivo device performance. Quantitative endpoints generated from implant retrieval and evaluation and related failure mode analysis, as evidenced in the case studies presented in this chapter, aid the implant development process and contribute to patient safety.

Registry-based surveillance within regional or national healthcare systems provides an important context for implant retrieval and evaluation conducted within the context of routine clinical use. Studies from well-validated registries of large populations have the unique strength of reflecting the clinical reality (e.g., outcomes in routine clinical practice) and thus provide a high level of external validity (HerniaSurge Group, 2018). A major part of Europe's medical device regulations includes the European Database on Medical Devices (EUDAMED), which aims to help authorities conduct postmarket surveillance on medical devices using data obtained through vigilance and clinical investigations (SANCO, 2013). Integrating explant analysis programs into medical device registries and other intentional surveillance activities strengthens the total product life cycle approach, and advocates recognize several key strengths offered by this approach (Table 3.1.9.5) (Chakfe and Heim, 2017; FDA, 2013; MDRTF/MDEpiNet, 2015).

Medical devices and implants prioritized for registry development (Table 3.1.9.6) include high-risk devices and those in which device failure has serious implications for public health, devices using new technology whose long-term safety and effectiveness are not well understood, devices that have long in vivo durations, devices having many design variations and the potential for significant variations in outcomes, devices with outcomes that are highly dependent on the clinical user performance, and devices in which unanticipated problems with similar devices were identified through premarket review.

CASE STUDY III: PROSTHETIC HEART VALVES

Prosthetic heart valves have progressed significantly since the introduction of the first caged-ball valve in the 1950s, fueled by key advances in heart–lung bypass machines and thrombo-resistant biomaterials and the application of fluid mechanics for understanding blood circulation through the human heart. Often cited as the prototypical device failure analysis that contributed important clinical information, the problem of the Björk-Shiley tilting disk mechanical valve prosthesis provides an instructive case history.

What Problem Was Addressed?

The initial Björk-Shiley tilting disk mechanical prosthetic heart valve design, in which an acetal (Delrin) polymer disk and later a pyrolytic carbon disk was held in place by a wire superstructure composed of inflow and outflow struts, was associated with an unacceptable late failure rate owing to thrombotic occlusion. The inflow strut was an integral part of the valve base while the outflow strut was welded to the base ring.

In order to reduce the risk of thrombosis by improving valve flow, the company manufacturing the valve (Shiley, Inc.) redesigned the prosthesis to achieve opening angles of the disk of 60° or 70° from the plane of the valve base and rounded the surfaces of the disk ("convexo-concave" or "C–C"). However, clinical use of the redesigned Björk-Shiley C–C heart valve led to an unusually large cluster of cases in which the metallic outlet strut fractured in two places, leading to disk escape. The complication was fatal in the majority of patients in whom it occurred. In 2005, strut fracture was reported in at least 633 of the 86,000 (0.7%) valves of this type implanted worldwide during 1978–86. Clinical studies identified large valve size, mitral site, young recipient age, and valve manufacture date as risk factors for this failure mode (Blot et al., 2005).

Careful implant retrieval and evaluation elucidated the mechanisms of this catastrophic problem. Pathologic studies of retrieved Björk-Shiley valves, enhanced by scanning electron microscopy, demonstrated a pronounced wear facet at the tip of the outlet struts, and localized pyrolytic carbon wear deposits at sites where the closing disk contacted the strut (Schoen et al., 1992), providing a fatigue fracture mechanism that began on the inflow side of the outlet strut often initiated within a weld joint. The analysis suggested that the first strut leg fracture typically initiated at or near the point of maximum bending stress, was traced to a site of weld shrinkage porosity and/or inclusion in most cases, and was followed by fracture of the second leg. Occasionally, valves with only a single strut fracture were encountered. The underlying problem was metal fatigue failure, probably initiated by transient (<0.5 ms) outlet–strut–tip impacts due to overrotation of the disk during valve closure that produced almost 10 times the force of disc opening, leading to excessive bending stresses beyond the strut wire's fatigue endurance limit (Wieting et al., 1999). These stresses occurred at or near the welds joining the outlet struts to the housing, potentially coupled with intrinsic weld flaws.

Moreover, in subsequent animal studies in which Björk-Shiley 60–70° C–C valves were implanted in sheep and instrumented with strain gauges showed that impact forces varied greatly with cardiac activity, and that loads occurring during exercise were significantly elevated. This correlated with clinical data that showed that fracture often occurred during exertion.

The Björk-Shiley prosthetic heart valve case demonstrates that elucidation of a failure mode by detailed materials failure analysis can have a potential impact on patient management. Understanding this mode of failure has enabled the development of noninvasive testing modalities [via high-definition radiography (O'Neill et al., 1995) or acoustic characterization of strut status (Plemons and Hovenga, 1995)] to establish when one strut has fractured prior to the onset of clinical failure, to caution patients with these valves against vigorous exercise, and to consider rereplacement of properly functioning valves at high risk of fracture. Moreover, this case has reinforced certain principles of prosthetic heart valve testing which should occur before widespread clinical use of a new or modified prosthesis design (Blackstone, 2005).

What Properties Were Required of the Biomaterial?

Heart valve prostheses are devices intended to perform the function of the heart's natural valves. Historically, three general designs used for mechanical heart valves included the caged ball, tilting disc, and bileaflet designs. The ISO 5840 standard outlines appropriate qualification tests and methods for assessing the physical, chemical, biological, and mechanical properties of heart valve designs and relevant materials. Desirable performance characteristics for modern heart valve prostheses include the following (Dasi et al., 2009; Ghanbari et al., 2009):

1. Durable for extended intervals (i.e., low peak stresses throughout the cardiac cycle to minimize the potential for creep deformation or fatigue)
2. Easily and permanently inserted into an appropriate physiologic site
3. Suitable interface between prosthesis and patient for appropriate healing
4. Nonobstructive to blood flow (i.e., open at a minimum systolic transvalvular pressure differential with minimum resistance to forward flow)
5. Nonturbulent flow for limiting shear stress experienced by the blood cells and platelets
6. Provide prompt and complete closure (i.e., minimize backward flow)
7. Noise-free function
8. Biocompatible, with low platelet adhesion
9. Nonthrombogenic
10. Nonhemolytic
11. Infection-resistant
12. Chemically inert and resistant to biodegradation (e.g., from oxidation, acid hydrolysis, enzymatic pathways, etc.).

What Biomaterials Are Used?

Biomaterials used for prosthetic heart valves in clinical use or in development include:

1. Titanium alloys or stainless steel alloys for structure and struts
2. Polyester (Dacron) or polytetrafluoroethylene (Teflon) as synthetic fibers for the suture ring
3. Pyrolytic carbon for tilting disc and leaflet features
4. Various types of polyurethane (e.g., polyester urethane, polyether urethane, polycarbonate urethane) with alternate chemical structures incorporated into the PU backbone to improve hydrolytic and oxidative stability (Ghanbari et al., 2009).

8. Coronary stents
9. Robotic and other less invasive surgery
10. Ophthalmic procedures/devices
11. Surgical mesh

In summary, quantitative and systematic implant retrieval and evaluation bridges the gap between in vitro performance assessments and the effective clinical behavior of implants. It plays a critical role in the evolution of medical devices throughout the development process and clinical use. It informs the medical device industry through their corrective and preventive action (CAPA) systems for meeting FDA quality system regulation requirements (FDA, 2019b). It encourages technology development through identification of failure modes and mechanisms, providing a benchmark for assessing future improvements in implant performance and longevity. It provides an evidence-based approach for driving change in surgical techniques and implant biomaterials and designs. There will be persistent demand for quality data generated through implant retrieval and evaluation given that medical devices and implants prioritized for future registry development include high-risk devices, devices that have long in vivo durations, devices in which substantial design variations provide the potential for significant variations in outcomes (see Case Study: Surgical Mesh), and those in which device failure has serious implications for public health (Table 3.1.9.6).

CASE STUDY IV: SURGICAL MESH

Surgical mesh provides an instructive case study of a polymer biomaterial (polypropylene monofilament) attaining widespread dominance in two surgical applications (suture for wound closure and knitted mesh for hernia repair). The resulting "ancestral network" of surgical meshes cleared through the 510k regulatory pathway (Zargar and Carr, 2018) links a small number (11) of predicate surgical mesh implants to hundreds of subsequent products that are substantially dissimilar to their predicate designs. Moreover, this case study underscores the risk of claiming substantial equivalence to implants that are later recalled and the need for scientific evidence to support claims of substantial equivalence across various device categories (Zuckerman et al., 2014).

What Problem Was Addressed?

A hernia is defined as a protrusion or projection (prolapse) of an organ through the wall of the cavity where it is normally contained. Polymeric surgical mesh implants provide support for damaged or weakened tissues during hernia repair surgery. More than 1,000,000 Americans undergo hernia repair each year (Rutkow, 2003) and more than 90% of patients with certain types of hernias require repair with surgical mesh (Kingsnorth and LeBlanc, 2003). There have been several hundred unique surgical mesh products commercialized since the introduction of polypropylene monofilament fibers in the early 1960s for use as sutures for wound closure and as knitted mesh for hernia repair (Usher et al., 1962, 1963; Zargar and Carr, 2018). Polypropylene (PP), polyethylene terephthalate (polyester, or PET), and expanded polytetrafluoroethylene (ePTFE) are the most common materials for modern hernia repair mesh implants (Sanders and Kingsnorth, 2012).

Surgical mesh intended for use within the peritoneal cavity (so-called intraperitoneal onlay mesh, or IPOM) requires surgical mesh designs that combine more than one material into a composite mesh providing a smooth visceral side and a macroporous nonvisceral side. The visceral side incorporates a microporous sheet or barrier coating that is adhesion-resistant and nonabrasive to organs within the peritoneal cavity. The nonvisceral side consists of a structured knitted mesh surface for tissue ingrowth within the abdominal wall.

Introduced in 2000, the Composix Kugel surgical mesh is a self-expanding, nonabsorbable composite mesh implant that combines an ePTFE layer (visceral side) and two layers of knitted monofilament PP mesh (nonvisceral side) with a peripheral PET memory recoil ring. The memory recoil ring, formed by welding together the ends of approximately 1 mm thick PET fiber and secured within a sewn edge located within the two PP layers, keeps the mesh optimally expanded. These IPOM composite meshes are intended to bridge large hernia defects and were offered in sizes ranging from a 4.5 inch (115 mm) diameter circle to a 10.7 × 13.7 inch (275 mm × 350 mm) oval, with larger meshes having two concentric rings. Multiple transabdominal sutures provide initial fixation of this IPOM composite mesh.

An estimated 350,000 Composix Kugel meshes were implanted in the United States from 2000 to 2005 before an FDA class I voluntary recall was initiated due to risk of memory recoil ring breakage potentially leading to bowel perforation and/or chronic enteric fistula (Hope and Iannitti, 2009). Other associated clinical complications with the Composix Kugel mesh include abdominal pain, mesh bulging, cut-out of transabdominal sutures, wrinkling, and seroma (Hope and Iannitti, 2009; Wiegering et al., 2013). The incidence of ring breakage was reportedly 0.009% based on complications reported to the FDA, although this likely underestimates the overall complication rate due to an unknown number of unreported events.

Implant retrieval and evaluation of a limited number of explanted Composix Kugel meshes, including electron microscopy, chemical analysis (FTIR, DSC), and materials testing, elucidated the failure mechanisms (Costello et al., 2007; Cozad et al., 2010; Wiegering et al., 2013). The PET memory recoil ring was severely damaged in areas of wrinkling or buckling, with breaks typically occurring at the ring weld. Compared to unused controls, explanted PP had lower heat of fusion (indicating lower crystallinity) and FTIR absorbance spectra consistent with oxidation, whereas explanted ePTFE had FTIR absorbance spectra consistent with cross-linking (Cozad et al., 2010). Explanted PET memory recoil rings exhibited degraded mechanical properties (fatigue and loss of elasticity) in cyclic mechanical tests (Wiegering et al., 2013). The analysis suggests that excessive forces applied to the mesh from manipulation during mesh placement or tissue contraction in situ could contribute to weld failure on the PET memory coil ring.

CASE STUDY IV: SURGICAL MESH—CONT'D

What Properties Were Required of the Biomaterial?

Implant retrieval and evaluation of many types of surgical mesh reveals that prolonged physiological loading produces a distinct tissue response for different classes of mesh with different pore structures (Klinge and Klosterhalfen, 2012; Muhl et al., 2008). For example, class II meshes having small pores (<60% porosity) and no effective porosity (interfilament distance <1000 μm) are associated with high volumes of inflammatory cells and fibrous connective tissues bridging across mesh pores compared to class I mesh having large pores (>60% porosity) and a suitable effective porosity (interfilament distance >1000 μm). ePTFE has a low-intensity inflammatory and fibrotic tissue response and incites only loose adhesions when used in the visceral cavity. The analysis supports using mesh structure to guide implant selection and assuring designs and materials maintain effective porosity under a range of mechanical strains.

Surgical meshes are continuously subjected to cyclic stress from abdominal wall forces, which can mechanically fatigue and alter mesh materials (i.e., increased stiffness, decrease strength), along with oxidative stress that has potential to degrade the biomaterials. Defining ideal properties of surgical mesh for hernia repair requires products that provide for strength to reinforce weakened tissues along with suitable pore structure and biocompatibility to foster tissue ingrowth. These performance criteria must be balanced with requirements to meet clinical indications (e.g., hernia size and location) and surgical handling (e.g., open vs. laparoscopic surgical approach) techniques.

Desirable performance characteristics for modern surgical mesh used in hernia repair include the following (Sanders and Kingsnorth, 2012):

1. Easily and permanently inserted into an appropriate physiologic site
2. Reinforces tissues while allowing normal physiological function of the abdominal wall
3. Durable for resisting mechanical strains and maintaining adequate long-term tensile strength and flexibility
4. Chemically inert and resistant to biodegradation
5. Does not adhere to viscera
6. Biocompatible, produces a controlled/predicted biological response
7. Noncarcinogenic and nonallergenic
8. Infection-resistant
9. Maintains optimal effective porosity under a range of mechanical strains
10. Rapid integration into host tissues and resists migration/dislocation.

What Biomaterials Are Used?

The most common widely used nonresorbable polymer used for surgical mesh implants is polypropylene (PP), which has many advantages as a mesh material (Sanders and Kingsnorth, 2012). These include its high tensile strength and burst strength, its ease of manufacturing for braided or knitted constructs, its compatibility with connective tissue ingrowth, and long-term data supporting its use in vivo. Disadvantages of PP include an intense foreign-body reaction associated with mesh contraction and reduced compliance and adhesion formation when in contact with visceral organs. Other common polymers used for surgical mesh implants are polyethylene terephthalate (PET), expanded polytetrafluoroethylene (ePTFE), and polyvinylidenefluoride (PVDF) (Sanders and Kingsnorth, 2012). PET provides for infiltration of fibroblasts for rapid fixation to tissues and less contraction than PP, but some studies report higher infection rates and loss of mechanical strength over time. Microporous and hydrophobic ePTFE meshes elicit a minimal inflammatory reaction and poor tissue ingrowth, which are advantageous for contact with visceral organs as an IPOM composite mesh. However, ePTFE is more susceptible to infection than other materials due to its laminar structure. Absorbable materials used for surgical mesh include polylactide (PLA), polyglycolic acid (PGA), polycaprolactone (PCL), and polydioxanone (PDO).

Chapter Exercises (With Answers)

1. Identify the characteristics that define an implant, as recognized by the National Institutes of Health.
   Answer: An implant is defined as a type of medical device that is placed inside or on the surface of the human body, as having an intended lifespan spanning months or years, as being made of biomaterials and penetrating living tissues, as having a physiological interaction in the human body, and as being retrievable.
2. Define implant retrieval analysis and identify two general goals for it.
   Answer: Implant retrieval and evaluation (commonly, implant retrieval analysis or explant analysis) describes a method of scientific analysis for determining the efficacy and safety or biocompatibility of medical implants in vivo.
   General goals include:
   - Determine rates, modes, and mechanisms of implant failure
   - Identify effects of patient and implant factors on implant performance and overall clinical outcome
   - Establish clinical and design factors that promote implant success
   - Determine dynamics, temporal variations, and mechanisms of tissue–biomaterial and blood–biomaterial interactions
   - Develop design criteria for future implants
   - Determine adequacy and appropriateness of animal models
   - Identify biomarkers of implant reactivity.
3. Assume you are involved in characterizing biomaterials for the development of a new implant. Devise a preclinical testing plan that makes use of information gained through implant retrieval and evaluation.
   Answer: This question is open-ended and has many possible correct answers.
   A preclinical testing plan could include:
   (1) Inspection of unimplanted prototypes to evaluate changes induced by the fabrication process
   (2) In vitro testing of implant biomaterials followed by implant retrieval and evaluation to evaluate biocompatibility, durability of the biomaterials, or potential failure modes
   (3) In vivo animal models followed by implant retrieval and evaluation to evaluate biocompatibility, durability, implant–tissue interactions, or safety and effectiveness of the design.
4. Argue the advantages of integrating implant retrieval and evaluation programs into implant registries and other intentional surveillance activities.
   Answer: This question is open-ended and has many possible correct answers.
   Quantitative and systematic implant retrieval and evaluation …
   - Plays a critical role in the evolution of medical devices throughout the development process and clinical use
   - Informs the medical device industry through their corrective and preventive action (CAPA) systems for meeting FDA quality system regulation requirements
   - Encourages technology development through identification of failure modes and mechanisms, providing a benchmark for assessing future improvements in implant performance and longevity
   - Provides an evidence-based approach for driving change in surgical techniques and implant biomaterials and designs
   - Is a suitable tool for evaluating the safety and effectiveness of high-risk devices, devices that have long in vivo durations, devices in which substantial design variations provide the potential for significant variations in outcomes, and those in which device failure has serious implication for the public health.
5. What failure mechanisms did implant retrieval and evaluation reveal about early Björk-Shiley prosthetic heart valve designs? Describe the designs of modern heart valves that help to minimize the future risk of similar failures.
   Answer: The tilting disk mechanical prosthetic heart valve design was associated with an unacceptable late failure rate owing to thrombotic occlusion. The redesigned Björk-Shiley C–C heart valve had fatigue fracture of the metallic outlet strut initiated at or near intrinsic weld flaws and the point of maximum bending stress, leading to disk escape, pronounced wear at the tip of the outlet struts, and localized pyrolytic carbon wear deposits at sites where the closing disk contacted the strut.
   Designs of modern heart valves achieve low peak stresses throughout the cardiac cycle to minimize the potential for creep deformation or fatigue.
6. In the early 1970s, what biomaterial problems were revealed by implant retrieval analysis that helped to prompt the need for FDA regulation of medical devices, as authorized through the Medical Device Amendments of 1976?
   Answer: Explant analysis of the Dalkon Shield intrauterine device (IUD) revealed the multifilament tail string served as a wick for vaginal fluid and bacterial access inside the uterus. Deterioration of the outer nylon sheath, especially in regions of high stress adjacent to the knotted attachment side, provided a route for bacteria to exit the sheath into the sterile uterine cavity and contributed to string breakage during attempted removal. The absence of heat-sealed ends on the multifilament tail strings and deterioration of the outer nylon sheath were identified as contributing factors in the high infection rates and the FDA identified the multifilament tail string as a hazard for its role in the infections.

3.1.10

Legal Concepts for Biomaterials Engineers

MILES GRODY[1], STEPHEN F. BADYLAK[2]

[1]Miles Grody Law, Potomac, MD, United States

[2]University of Pittsburgh, Pittsburgh, PA, United States

Introduction

It can be expected that the intricacies of the law are just as unfamiliar to biomaterials engineers as the intricacies of engineering are to lawyers. Nonetheless, throughout the course of a career biomedical engineers and other professionals in the medical device industry will routinely encounter a range of issues that require legal consideration or can have legal ramifications. Consequently, it is important for such professionals to develop a general awareness and familiarity with the types of situations in which legal issues will arise. Even if one is not comfortable with handling the situation alone, the appropriate legal resources can be martialed to assist in managing the issues in a manner that supports, and perhaps even reinforces, the mission of the individual and their employer or organization.

Areas of legal concern that medical device professionals can expect to routinely encounter include the following general categories:

1. Employment agreements
2. Confidentiality and materials use agreements
3. Intellectual property: Patents, trade secrets, and freedom to operate
4. Contract negotiation, performance, and compliance
5. Sponsored research agreements
6. License agreements

Fortunately, from a biomaterials engineer's perspective the legal issues associated with these six areas at least partially overlap. Consequently, becoming acquainted with legal issues involved in even a single category should assist in understanding, and even anticipating, issues associated with other categories. Herein, a description of the legal issues typically involved with each of these categories is provided, along with a discussion of why these issues can make a difference both personally and professionally not only for the individual, but also for the broader organization within which their work is performed.

While medical device professionals in industry may approach specific legal issues from a different perspective than their academic counterparts, an awareness and sensitivity to these issues remains valuable regardless. The importance of various factors influencing such issues may vary, but the issues themselves tend to recur for both industry and academic professionals. The bias herein toward factors influencing industry professionals should be informative to those in academia as they interact with companies or consider moving to the private sector.

Employment Agreements

Perhaps the first legal document that any medical device professional will encounter in a post-university career involves an employment agreement. Understandably, when selecting an employer, the medical device professional will be focused primarily on matters such as job title, compensation, benefits, vacation time, and opportunities for advancement. These topics typically are covered in an offer letter, which may also include a provision stating that the medical device professional is an "employee at will." It is unlikely that an established employer will allow any newly minted employee to negotiate away this provision. The import of the provision is that the employer has reserved the right to terminate the employment at any time, with or without cause, and the medical device professional may have limited recourse in the event of what they may regard as an unwarranted employment termination.

The employment documents the medical device professional is required to sign will also include a formal legal contract addressing matters such as the treatment of confidential information, assignment of inventions, protection of trade secrets, non-competition, and non-solicitation. While these matters may not seem particularly remarkable or relevant at the time of signing, it should be realized

that these provisions can have important consequences for future job opportunities. Each of these provisions imposes legal obligations that can persist for several years after their employment with a particular company has ended. These provisions may impact not only which companies the medical device professional can join, but also the types of assignments that can be accepted with any future employer.

The employment agreement confidentiality provision should be similar to those found in non-disclosure agreements, which are discussed in detail below. This provision establishes that the employee is personally bound to protect the secrecy of any confidential information to which they are exposed during their employment, whether this confidential information belongs to their employer or to any third party with which the employer has entered a non-disclosure agreement. Less prominent, but potentially just as important, may be a provision stating that the new employee may not bring into the premises of the employer or use or rely on in the course of their work any unauthorized confidential information to which they may have access, such as confidential information from a prior employer. The ubiquity of such provisions in employment agreements should highlight for the medical device professional that companies take the protection of confidential information very seriously. Confidential information belongs to the company and not the individual, and any failure, whether intentional or accidental, to respect the agreed confidentiality terms can have severe consequences for the employee, including termination and potential damage to their professional reputation.

Assignment of inventions provisions establish that the employer, not the employee, is the owner of any inventions that the employee may create in the course of their work for the company. As discussed in the intellectual property section below, companies frequently file patent applications on inventions that may be valuable to their business. The drafting and prosecution of patent applications inevitably requires involvement from the individuals who participated in the invention's creation. The assignment of inventions provision imposes a legal obligation on the biomaterials engineer to cooperate with the company in the patent prosecution process, including executing any documents related to the patent application as may be reasonably requested by the company.

Protecting trade secrets constitutes one of the most important confidentiality obligations that any company places on its employees. The Defend Trade Secrets Act of 2016 (DTSA) illustrates the seriousness of protecting trade secrets (Defend Trade Secrets Act). This Act established for the first time the right of a trade secret owner to sue in federal court anyone who breaches the provisions of the Act, including the unauthorized disclosure or use of trade secrets by current or former employees. The DTSA allows companies to seek punitive damages, and reimbursement of attorney's fees, against former employees, meaning judgments against a former employee could be in the several thousands to millions of dollars. Trade secrets are discussed in more detail below because of the likelihood that most medical device professionals will be exposed to these throughout their career. The importance of protecting trade secrets, and not breaching trade secret protection obligations, whether by an employment agreement, preexisting state law, or the DTSA, cannot be overemphasized.

Non-competition provisions present perhaps the most obvious restrictions on future employment opportunities a medical device professional may pursue. Such provisions typically prevent the departing employee from accepting employment from, or performing consulting work for, any competitor of the former employer for post employment periods ranging from approximately 1 to 2 years. Naturally, the provisions also prohibit the employee from working for any competitor of their employer during the period of the employee's employment. When evaluating various employment opportunities, thought should be given to how non-competition restrictions might impact career advancement opportunities. Medical device professionals should ensure that their skill sets are appropriately diversified so that after they leave an employer, for whatever reason, they will have the ability to find another job that will not place them in breach of their non-competition obligations.

Non-solicitation provisions are similar to, but distinct from, non-competition provisions. Typically, non-solicitation provisions in employment agreements prevent former employees from trying to entice away colleagues from their former employer. Non-solicitation provisions will also place restrictions on the former employee's freedom to enter into business arrangements with customers or contractors with whom they interacted during their former employment. Like non-competition provisions, non-solicitation restrictions may last for approximately 1 to 2 years post employment. Medical device professionals should be cognizant of the potential for non-solicitation provisions to impact the range and types of professional and business relationships in which they might engage once they seek new employment.

Confidentiality and Materials Use Agreements

Perhaps the most frequent issue a biomaterials engineer will encounter that involves legal considerations is a confidentiality agreement, also known as a non-disclosure agreement or NDA. Most companies and other organizations have adopted protocols requiring an NDA before confidential information is shared with a third party, such as another company or institution with which it is considering entering into a business arrangement. It is frequently desirable or necessary for some component of one party's confidential information to be shared with the other party so that a potential collaboration or contractual agreement can be fully considered. Consequently, an NDA is often signed before any substantive discussions occur, and it is not uncommon for a business relationship to fail to materialize even after the NDA has been executed. If a formal relationship does develop, the confidentiality terms captured in the

original NDA will persist, and may even be enhanced in the agreements that define the scope of the ongoing and forward-looking business relationship.

Each NDA is focused on one of the most important and valuable assets any organization possesses: its confidential information. While there are many categories of information that are generally considered confidential, there is no single standard definition that is common across all organizations and addresses every possible piece of confidential information an organization may possess. Consequently, one of the first things that any reader encounters in an NDA is a definition of what constitutes confidential information for the purposes of that NDA. A typical provision in a mutual NDA, protecting information shared by each party, might state the following:

> *Confidential Information shall mean any and all technical business and other information including, without limitation, patent, copyright, trade secret and proprietary information, techniques, sketches, drawings, models, inventions, know-how, processes, formulae, apparatus, equipment and biological materials related to the current, future and proposed products and services of each of the parties, and includes, without limitation, their respective information concerning research, experimental work, development, design details and specifications, engineering, financial information, procurement requirements, purchasing, manufacturing, customer lists, business forecasts and sales, and marketing plans.*

This provision includes language that clearly could not and would not have been drafted by anyone except a lawyer, and attempts to include everything, except the often referred to "kitchen sink." The problem, as referenced at the beginning of this chapter, is that the lawyer who drafts such language almost certainly is not also a biomaterials engineer. As a general matter, it can be anticipated that the lawyer drafting an NDA, or for that matter attempting to represent or protect any other issues that are central to the activities of a medical device professional, will never understand the individual's business and concerns as well as the individual himself. It is therefore possible that the standard description of confidential information appearing in an NDA provided by legal counsel might not include the specific category of information that is anticipated to be shared with the third party. Definitions provided in contracts are very important. Medical device professionals should pay particular attention to such definitions, and if it is believed that something important may be missing, this issue should be raised and pursued until it is addressed to their satisfaction.

The following steps, at a minimum, should be taken to maximize assurance that the party receiving confidential information will abide by the terms of the NDA, and therefore minimize the possibility that confidential information is misused by a third party, especially a potential or actual competitor: (1) ensure that an NDA has been executed with the receiving party before any confidential information is shared; (2) ensure that any confidential information provided to the other party is clearly marked as belonging to the biomaterials engineer's organization; and (3) carefully consider whether information that any member of the biomaterials engineer's organization discloses verbally to a third party should be treated as confidential under the terms of the NDA.

The medical device professional should request to see an executed copy of the NDA before any confidential information is shared so that they know what is covered within the defined scope of confidential information, the period of time the receiving party will be obligated to protect the confidentiality of the information (often there are expiration dates ranging from 1 to 5 years), and the limitations for which the confidential information may be used by the receiving party. The medical device professional should ensure that the NDA has been written to protect their organization's confidential information, and not just the confidential information of the other party. Typically, organizations sign either a mutual NDA or a one-way NDA. While a mutual NDA protects both parties' confidential information, a one-way NDA protects only one designated party's information. It is often preferable to execute a one-way NDA provided it is your organization's confidential information that is designated for protection.

NDAs often include a provision requiring the party seeking protection to clearly mark all shared information as confidential, and the medical device professional should assume responsibility for doing this to the extent they are sharing confidential information. However, it may not be sufficient to simply mark a document as "Confidential." Even though two parties may not dispute that information in a document is confidential, they still may argue over which party actually produced the document and therefore has the right to claim ownership. The simplest remedy is to include the organization's name in the label that identifies a document as confidential, and to insert this label as a header or footer on every page of the confidential document. Such labeling is a simple and prudent practice for all documents that include confidential information, regardless of whether it is anticipated that these documents may be shared at some future point with a third party.

Beyond simply marking documents as confidential, the medical device professional should give additional and careful consideration to whether anything any member of their organization disclosed verbally to a third party contains information that should be considered confidential. Many NDAs state that information conveyed verbally will not be treated as confidential unless it is identified as confidential at the time it is first discussed. The NDA may also require the disclosing party to send a written document to the receiving party within a defined period of time after the discussion occurred, usually no more than 30 days, stating that confidential information was shared and specifically describing that confidential information. As might be imagined, this exercise is a burdensome process, so the disciplined individual should not share confidential information with third

parties unless there is an advance plan as to how the ownership of that confidential information can be clearly mapped back to their organization.

NDAs invariably include limitations on the categories of information that may be protected. For example, excluded information will include information the receiving party already possessed, or information that has entered the public domain through no fault of the receiving party. Also excluded is information that the receiving party independently develops, without reference to the disclosing party's information. Proving such independent development can be fraught with uncertainty, however, and should not be relied upon in the absence of careful and disciplined planning and procedures, including the advice and guidance of an attorney experienced in protecting confidential information. Diligent record keeping in a laboratory notebook, which is discussed in more detail below, may be essential for demonstrating independent development.

When working with a third party, a biomaterials engineer often may want not only to verbally share information considered to be confidential, but also sample materials that are based on or incorporate that confidential information. It is common practice in such instances to execute, in addition to an NDA, a materials use agreement or a materials transfer agreement, often referenced by the acronym "MUA." As a general matter, the biomaterials engineer can regard an MUA as a strategy for extending limitation on use provisions comparable to those in an NDA to any proprietary materials that are shared with the receiving party. In the context of intellectual property law, as discussed in more detail below, the term proprietary refers to materials that are based on technology that a party may own, even if the technology itself is not confidential. For example, patents constitute detailed public descriptions of materials that are proprietary to the patent owner, but, by virtue of the published patent, are not confidential.

A medical device professional considering execution of an MUA should be particularly concerned with three issues, specifically: (1) how the shared material can be used by the receiving party; (2) the obligations of the receiving party to report to the disclosing party the results of its activities with the shared material; and (3) the implications of any ownership and use rights stemming from possible inventions resulting from the receiving party's work with the shared material.

As a general matter, proprietary materials shared with a receiving party are valuable, whether this value reflects the cost involved in the production of the specific items that are shared, or the research and development costs involved in the original conception and reduction to practice of the shared material. Under certain circumstances, a biomaterials engineer's organization might perceive potential value in sharing its proprietary material with a third party because that third party may possess its own proprietary knowledge or techniques that could enhance the overall value and usefulness of the shared material. Consequently, when a biomaterials engineer or other medical device professional considers sharing proprietary material with a third party, a limited and specific purpose for which the material can be used by the third party should be clearly defined to ensure that the third party does not have unlimited rights to do whatever they want with the material.

If the biomaterials engineer's organization executes an MUA with a third party that includes a clearly defined purpose, then it is reasonable to expect the receiving party to actually work with the material in a manner that produces results. The sharing party's right to review such results should be clearly defined. In most circumstances it can be assumed that the sharing party would not have provided its proprietary composition to the receiving party without the expectation that it would receive a reasonably detailed report on the results of the receiving party's activities with the composition. Rather than leaving the receiving party with discretion over whether to provide the results, the biomaterials engineer should ensure that the MUA includes a specific provision requiring production of a detailed written report. Such information may be essential for the biomaterials engineer's organization to develop an informed opinion regarding whether to invest additional time and resources into the material itself or furthering a working relationship with the receiving party.

Before sharing proprietary materials, a biomaterials engineer should give careful thought to whether the activity of the third party might result in a new patentable invention. If it is possible that a patentable invention might result, the biomaterials engineer should proceed with great caution, and should ensure that others within senior management are aware of this possibility. Ownership of a patent is based on inventorship, and as discussed in the employment agreement section above, patents belong to the inventor's company or organization through assignment. Sharing proprietary material with a receiving party does not necessarily make the sharing party an inventor of the work conducted by the receiving party, particularly if the receiving party conducts its work with the material independently of any involvement by the sharing party, and using methodologies or additional compositions that are proprietary to the receiving party. Consequently, a potentially serious risk arises that the receiving party may gain patent rights involving or incorporating the sharing party's proprietary material, and that these rights might be separate and distinct from any patent rights of the sharing party. Possible ramifications of this risk are discussed in more detail in the patent section below. One of the best and easiest methods for a sharing party to avoid such a risk is to ensure that the purpose for which a proprietary material is shared under an MUA is unlikely to result in the development of a new invention, and to ensure that this purpose and the associated methodologies are clearly defined in the MUA. Failure by the receiving party to follow the purpose or abide by the methodologies would constitute a contractual breach entitling the sharing party to legal remedies.

Intellectual Property: Patents, Trade Secrets, and Freedom to Operate

Intellectual property, commonly known as IP, refers to creations of the mind, such as inventions, trade secrets, trademarks, literary and artistic works, and designs. Important legal rights and considerations are associated with various forms of IP. Two of the most important forms of IP that regularly impact the activities of a medical device professional are patents and trade secrets. Patents and trade secrets involve doctrines that define specific legal rights relating to an organization's ability to claim exclusive proprietary ownership of its inventions or the methodologies it has innovated to produce its products and inventions and to conduct its business. Any biomaterials engineer working in a research and development environment or a production environment is likely to regularly be working with, and perhaps even developing, their organization's patents and trade secrets.

Patents and trade secrets can be thought of as opposite sides of the same coin. Patents are granted for inventions that are novel and non-obvious, and are obtained through patent applications submitted to the governmental patent office of the nation in which the applicant is seeking patent protection. If granted, patent applications provide the patent owner with exclusive rights to practice the invention for a period of 20 years from the date the patent application was first filed. A patent, which is a publicly accessible written document describing an invention, can be thought of as a legal monopoly on the use of an invention until the date the patent expires.

Unlike patents, trade secrets are not filed with any governmental entity, and do not have expiration dates similar to patents. The types of trade secrets a biomaterials engineer may encounter most frequently involve the specific steps and methodologies an organization develops to conduct research or manufacturing activities that it considers proprietary and valuable. Qualification of such steps and methodologies as trade secrets depends upon the measures that the organization takes to ensure that these are kept confidential. The classic example of a trade secret involves the specific recipe for Coca-Cola, which continues to qualify as a trade secret decades after it was developed because its confidentiality has been maintained. As a general matter, an organization can lose its exclusive rights to its trade secrets when such information is disclosed to the public. Consequently, in contrast to patents, organizations typically take great care to ensure their trade secrets are not disclosed publicly. There is no pre-set expiration date on the proprietary rights associated with trade secrets, but these rights can automatically expire when the steps or methodologies involved in the trade secret become publicly disclosed.

Patents and trade secrets are potential alternatives for the work performed by a biomaterials engineer stationed in a research and development department. Despite sometimes mundane laboratory routines, it is important to be consistently conscious of the potential development of patents and trade secrets. As a best practice for identifying and supporting patent or trade secret rights, the biomaterials engineer should always keep an accurate and detailed laboratory notebook recording their work, sometimes referred to as an inventor's notebook. The pages of the notebook should reflect the date on which the work or experiments were performed, should be signed by the person who wrote the notes, and should be contemporaneously witnessed by the signature of a second person. The information recorded in an inventor's laboratory notebook can be extremely helpful for drafting a patent application, and can be critical for determining inventorship. Similarly, this information also can be dispositive if it becomes necessary for an organization to demonstrate that it is entitled to trade secret protection for any of its proprietary methodologies.

At some point during the course of performing their work a biomaterials engineer may recognize the possibility that they have created an invention. When this realization occurs, another best practice is to prepare an invention disclosure document. The biomaterials engineer's organization may already have a preferred invention disclosure template, or if not, templates can be found on the web. Invention disclosure forms typically should include a summary description of the invention, the name(s) of the inventor(s), the date the inventors believed they completed the invention, and a detailed discussion of the steps involved and work performed in creating the invention. Additionally, the invention disclosure can include a summary explanation of why the inventors believe their creation is different from any existing or previous materials or techniques known to or practiced by others. Such preexisting materials and techniques are referred to as "prior art." As discussed in more detail below, a fundamental principle for an invention to be recognized as novel and patentable is that it must be distinct from any prior art—in precise terms, it must be novel and non-obvious.

Incorporating a new, proprietary invention into an organization's business practices should entail following a well-considered, disciplined protocol, including the involvement of at least one attorney who specializes in intellectual property law. The most efficient way for the biomaterials engineer to engage an IP attorney in the assessment of a potential invention is to provide that attorney with a detailed, carefully written invention disclosure. No matter how well written the invention disclosure may be, it is inevitable that the IP attorney will have multiple questions for the inventors. The more detailed these questions are, the better. Inventors must educate their IP attorney regarding the specifics of their invention. There is a direct correlation between any IP attorney's understanding of these specifics and that attorney's ability to recommend optimal strategies for protecting the various IP rights that the biomaterials engineer may have created. Ideally, a well-written invention disclosure should allow an experienced IP attorney to advise the biomaterials engineer's organization on at least two issues: (1) the likelihood that the described invention may be patentable, and (2) the likelihood that practicing the described invention

might infringe on the existing patent rights of any third party. A well-written invention disclosure may also enhance the IP attorney's ability to advise the biomaterials engineer and their organization on the relative risks and benefits of pursuing a patent as opposed to maintaining the invention as a confidential trade secret.

Medical device professionals should recognize the potential urgency of filing a patent application if their research has produced a possibly novel and non-obvious invention. On September 16, 2011, the America Invents Act (AIA) became law (Leahy-Smith America Invents Act). An important feature of the AIA is that, regardless of who may have created an invention first, ownership of the invention is determined by the first party that files a patent application. Particularly if a biomaterials engineer is experimenting in a field that has stimulated multiple diverse research initiatives, filing a patent application quickly could make the difference between having the ability to follow through with research to its completion, or abandoning it because a third party filed first. To optimize the likelihood of being the first to file, patent seekers often move quickly to file what is known as a provisional patent application. The provisional application customarily includes as detailed a summary of the invention as possible at the time it is filed. Most importantly, filing the provisional application establishes what is known as the claimed invention's priority date. Within 12 months after filing a provisional patent application, the applicant can revise and enhance the application with new information learned since the priority date was established, and then convert the application into a non-provisional application so that examiners within the patent office can then begin their review to determine patentability. Nonetheless, for purposes of the AIA and various international patent offices, the first to file date will be the priority date.

Regardless of whether a provisional patent application has been filed, the decision makers within the biomaterials engineer's organization may deliberate over whether it is worth investing further resources and effort into developing the invention. Part of these deliberations will involve whether to incur the expense associated with authorizing the IP attorney to conduct a freedom to operate analysis. A freedom to operate analysis involves a combination of automated and non-automated research techniques to review patents, patent applications, and other documents in the public domain relating to prior art that may be similar to the art described in the invention disclosure. Upon completing the freedom to operate analysis, the IP attorney should be able to offer informed opinions on two distinct questions: (1) whether the described invention may be patentable; and (2) whether practicing the described invention may infringe any third party's patent. As a result of this analysis the IP attorney may also be able to recommend ways to refine the invention to enhance the likelihood of patentability or reduce the possibility of infringing any third party patent.

If the IP attorney opines that a reasonable possibility exists that a proposed invention would infringe a third party patent, and no reasonable strategy can be identified for avoiding such potential infringement, the biomaterials engineer's organization may decide to abandon any plans for putting the proposed invention into practice. While abandoning the proposed invention inevitably will be disappointing, the insights gained from the IP attorney's analysis will still be valuable. There can be serious and expensive financial consequences and penalties associated with practicing the art described in a third party patent when patent infringement litigation is threatened or engaged. Based on the biomaterials engineer's careful description of their proposed invention, and the resulting analysis from the IP attorney, the biomaterials engineer's organization will hopefully have avoided the potentially crippling expenses associated with patent infringement litigation and any resulting judgment, or at least gained a clear picture of the risks before proceeding (Keeley, 1999).

If the IP attorney opines that the proposed invention is unlikely to infringe any patented prior art, it then becomes important to assess whether it may be more valuable to patent it or practice it as a trade secret. A broad array of business, legal, financial, and practical factors may influence how such questions are resolved (Durham, 1999a). One of the primary factors in such a decision, however, involves the fact that pursuing a patent application necessitates describing the proposed invention in a sufficiently detailed manner such that another person in the biomaterials engineer's field (generally referred to as a "person skilled in the art") can replicate the invention based on the description provided in the patent application. Unless they are abandoned, patent applications typically are published approximately 18 months after the provisional application is filed, regardless of whether a patent is ultimately granted. The review process conducted by U.S. and international patent offices often takes more than 18 months, meaning that there is a reasonable likelihood that the detailed description of a claimed invention contained in a patent application may be published before any determination is reached whether that claimed invention is patentable.

While the exclusive legal rights associated with the grant of a patent are significant, these must be weighed against the risk that the patent may not be granted. In this regard, the biomaterials engineer should be particularly sensitive to, and focused on, two distinct components of any patent application. These components are referred to as the specification and the claims. The specification involves a detailed description of all aspects of the claimed invention, including in particular those features that distinguish the claimed invention from any prior art. The specification must be sufficiently detailed so that anyone skilled in the art who reads it could replicate the described invention, and must include the best way the inventors know to practice it (Durham, 1999b). In other words, in its specification every patent application contains a complete disclosure of the invention that, if published, will become publicly available so that anyone can reproduce the work unless a patent is granted.

The claims section of the patent application, which is typically far shorter than the specification, precisely describes

the features of the invention that make it novel and non-obvious, and therefore are entitled to 20 years of patent protection. Exclusive rights associated with granted patents are based on what is specifically described in the claims, as opposed to what is more broadly disclosed in the specification. For claims to be granted, valid and legally enforceable, everything described in the claims must be supported by the teachings and descriptions included in the specification.

The factors that determine whether patent claims may be granted, and even if granted whether they have any commercial or competitive value, can be complicated. No matter how skilled the IP attorney, it is inevitable that the inventors named on the patent application will have insights that the IP attorney will not possess except to the extent the inventors specifically teach these to the IP attorney so that they can be incorporated into the patent application. Stated differently, a medical device professional seeking patent protection must expect to devote considerable time, and very detailed attention, to the preparation of a patent application and to any governmental patent office's review of that application. The pursuit of an actual patent grant involves a process referred to as patent prosecution and requires continued focused engagement of the inventors in coordination with their IP attorney. By the time a patent office makes a final decision on the patentability of any claims in a patent application, it can be expected the inventors and the IP attorney will have had multiple extensive and detailed conversations and reviews of the documents submitted by the biomaterials engineers' organization to the various international patent offices where patent protection is being sought.

The 20-year exclusivity rights associated with a granted patent may be more valuable to a medical device professional's organization than the relatively weaker, but potentially longer term, rights associated with trade secrets. Consequently, based on the information contained in the invention disclosure, the biomaterials engineer's organization should make an informed and deliberate decision whether to pursue a patent or rely on trade secret protection regarding any particular novel and non-obvious concept. The prosecution of a patent application and maintenance of the patent once granted can be expensive; therefore, the decision may be based not just on the likelihood of a patent being granted, but also the cost and value of the patent. An IP attorney who is experienced in the technical field of the biomaterials engineer's organization can help advise on the relative benefits of pursuing a patent versus relying on trade secret protection laws.

Contract Negotiation, Performance, and Compliance

The standard protocol followed when two or more organizations choose to jointly invest their resources in a common project or activity entails the execution of a written contract. A contract includes written terms and conditions establishing the rights and obligations of each party as these relate both to the purpose of the contract and also to any matters or legal rights that may be impacted by the contract. Contracts can be very detailed, and may rival patent applications regarding the precision and discipline with which they are drafted. Careful drafting is important, because any lack of clarity can result in misunderstandings between the parties as to their respective contractual rights and obligations. Such misunderstandings can not only undermine the spirit of cooperation and goodwill between the parties but, if serious enough, can undermine the entire relationship between the parties, even resulting in breach of contract litigation. When a contractual relationship between parties begins to deteriorate, it is not uncommon for an organization's management to examine not only the terms of the contract, but also the expectations and promises of the individuals who originally advocated for the contract, in an effort to determine why it is failing to meet the organization's objectives.

Biomaterials engineers need to be attentive to reviewing and understanding contracts if for no other reason than the various functions they will be responsible for performing will be subject to specific obligations established in the contract. Further, contracts executed by a biomaterials engineer's organization may impose certain personal obligations on them, particularly with respect to the protection of confidential information.

Clearly, to the ordinary individual, the review of a contract can be boring and intellectually taxing. The objective of many provisions in the contract may not be readily apparent, and it may not be clear which provisions may be subject to negotiation versus those that may trigger unexpected negative responses from the other party if opposed. Despite these inconveniences and uncertainties, a medical device professional proceeds at their own peril if they fail to focus carefully on the provisions of contracts that relate specifically to their areas of responsibility and their job performance.

It is axiomatic that in today's world no one can become a biomaterials engineer without having developed rigorous and disciplined intellectual capabilities and work habits. These same qualities should be applied to the negotiation and review of contracts. The provisions of any contract can be divided into two general categories: the business terms (i.e., the scope of work and associated payment schedule), and the legal terms that are often referred to as "legalese." The biomaterials engineer should be prepared to play a leading role with respect to the business terms, including the scope of work, that are incorporated into any contract that they, or any team they lead, are expected to execute. At the risk of oversimplifying, the business terms may be characterized generally as Party A agreeing to perform Task X for Party B by a certain date and according to certain specified standards, and in exchange Party B will pay Party A a predetermined amount of money based on a contractually documented payment schedule. Such business terms may be very detailed, and may contemplate a range of different possibilities, but as a general matter they should be written in plain English, not legalese. Because these terms should

be in plain English, any biomaterials engineer involved in the contract negotiation process should ensure that they understand these terms, and can deliver on them, before their organization commits by executing the contract. Similarly, if these terms are not in plain English, the biomaterials engineer should be prepared to challenge them and to explore whether there are options to resolve any ambiguities or problems, including writing these terms more clearly. It is difficult to deliver on contractual obligations if the obligations are unclear.

The biomaterials engineer's responsibilities are not satisfied just by resolving issues with the business terms of a contract. A disciplined biomaterials engineer should also pay at least some attention to those contract provisions that may be classified as legalese. Legalese provisions typically can be categorized into two distinct, but somewhat overlapping, categories: (1) those that impact how disputes and litigation of any alleged contract breach might be handled; and (2) those that generally define the business relationship between the two parties. If a biomaterials engineer is expected to approve, either explicitly or implicitly, the terms of any contract on which they must execute, it is not unreasonable for the biomaterials engineer to insist on understanding not only the business terms of the contract, but also these two categories of legalese provisions.

The first category of legalese provisions, concerning how disputes or litigation may be conducted, involves issues and considerations that typically are decided by attorneys, or business professionals with significant legal expertise and experience. Because of this dependence on legal experience for ensuring that such provisions are optimized for the medical device professional's organization, it can be anticipated that medical device professionals may be free from blame if these provisions ultimately work against their organization's best interests. In other words, these are primarily legal issues, and contract lawyers should have taken care of them, not the engineers and scientists. This being said, the issues involved in this category of legalese provisions are not so complicated that medical device professionals cannot make constructive contributions. Individuals should not be reluctant to ask their attorney to clarify the intent of specific provisions addressing disputes, the possible alternatives, and the reason that the terms chosen for the contract might be more advantageous than possible alternatives.

The second category of legalese provisions, involving business terms, should be more easily understandable to medical device professionals than the first category. These provisions involve topics such as ownership of work produced pursuant to the contract, project management and updates between the parties, reasons that the contract may be terminated, confidentiality, and non-competition, to name a few. While these provisions may generally be regarded as standard from one contract to the next, there may be certain business arrangements where a so-called standard provision could work against the medical device professional's best interests, and a customized provision might be appropriate. For example, the medical device professional's organization should reject a non-competition provision if the consequence of such a restriction would severely limit the organization's opportunities for growth. Medical device professionals should seek to develop a collegial relationship with their attorney so that together they can jointly evaluate those situations where customized contract provisions should be substituted for standard provisions.

Once a contract has been signed, the biomaterials engineer should take careful note of those provisions that bear specifically on their department's performance responsibilities. If the biomaterials engineer is leading a team that is delivering on the contractual commitments, then the extent to which it could be valuable, if not essential, that all team members also become aware of these commitments should be considered. Contract negotiation can be a prolonged, and sometimes painful, process. It is not uncommon, once the contract has been executed, for the parties to say they hope everything will proceed so smoothly that they can put the contract in a drawer and not look at it again. One should not be fooled by such hyperbole. Hopefully they will never have to look again at the first category of legalese provisions in the contract, addressing disputes and litigation. The biomaterials engineer, however, certainly will need to be familiar with the scope of work described in the contract, and may find it valuable to refer back to this from time to time to ensure not only that their organization, but also the other party, are meeting contractual obligations in a satisfactory and timely manner.

Sponsored Research Agreements

Sponsored research agreements and license agreements are two of the most important categories of contracts where medical device professionals may be the most prominent advocates within their organization for the contemplated business relationship. Biomaterials engineers are likely to play the leading role not only of recommending the relationships that lead to these agreements, but also of delivering on the responsibilities specified therein. Consequently, biomaterials engineers can expect to engage proactively in negotiation of the business terms of these agreements. While individuals from other departments, including the legal department, may provide important and constructive advice regarding the structure of the agreements, the medical device professional should not casually acquiesce to entering any sponsored research agreement or license agreement if they do not clearly understand the respective business commitments of the parties or if they believe an agreement might place their organization in an inappropriately disadvantageous or compromised position. The attorney who advises the medical device professional's organization regarding the agreement should be able to identify and assist with avoiding many potential contractual pitfalls. However, the biomaterials engineer almost inevitably will understand the specific scientific and engineering fields involved better than the attorney. Therefore, the

attorney's effectiveness will be directly impacted by how effectively the biomaterials engineer engages in the contract drafting and negotiation processes.

Sponsored research agreements, or SRAs, typically involve situations where a university agrees to conduct a clearly defined research project for an industrial entity in exchange for a fixed cost. All of the issues discussed above relating to contract negotiation, performance, and compliance apply specifically to SRAs. As the biomaterials engineer may be the company's lead advocate for any particular SRA, this individual should play a leading role in developing the business terms for the SRA. In the context of the SRA, one component of the business terms includes the specific tasks or experiments that the university is agreeing to perform. These tasks are accompanied by the associated deliverables, such as the written reports describing the results of these tasks or experiments, and a schedule for when these reports will be provided. This component of the business terms is often written by the biomaterials engineer, in coordination with a university counterpart, and is attached to the terms and conditions of the SRA as a separate but integrated addendum. The attorney advising the company will likely review the contents of this attachment, and may have questions or suggestions for the biomaterials engineer regarding its content, but the biomaterials engineer should recognize that the attorney's ability to make specific recommendations regarding the attachment's contents may be limited because the attorney is unlikely to possess the same level of insight into its subject matter as the biomaterials engineer.

Other important components of the business terms specific to the scope of work may appear either in the main body of the SRA or the attachment describing the specific project. Examples of these components include the payment terms, and the identity of the principal investigator. Biomaterials engineers should expect that representatives from the finance department will want to review and approve the cost of any SRA before it is executed. The finance department representative and the company attorney may make helpful suggestions regarding how payments should be structured, such as an upfront amount, installment payments on certain calendar dates or when certain milestones are achieved, and a final payment after the university has fully delivered on its commitments.

When medical device professionals within industry are advocating for a research project with a specific university, it is likely because of the general expertise and resources within the relevant university department and a confidence and comfort level with the researcher who will be designated as the principal investigator. While SRAs typically identify the principal investigator by name, the SRA's general terms and conditions also should discuss the rights of the parties if the named principal investigator becomes unavailable to complete the project. Universities typically lead with the position that they can unilaterally name a replacement principal investigator, or they can terminate the project if a suitable replacement cannot be found. Such a result can have important, and potentially adverse, consequences for the project and the company. This outcome is especially the case if the SRA allows the university a unilateral right to cancel the project, as SRAs typically establish that money paid by the company and used for the project is nonrefundable. Such lost funds, however, may not be the worst consequence for the company. For example, if a sponsored research project is one critical component of a comprehensive strategic product development plan, the disruption to the development schedule caused by the SRA cancellation could result in adverse, and potentially high-profile, impacts and delays across multiple departments. In light of these possibly serious consequences, the industry biomaterials engineer should coordinate closely with their attorney regarding the SRA terms addressing replacement of a principal investigator. At a minimum, the biomaterials engineer may want to ensure that the SRA obligates the university to exert best efforts to find a reasonably acceptable replacement, and provides the company with the right to approve such replacement principal investigator.

When entering an SRA, the biomaterials engineer, along with the advising attorney, should give careful consideration to any IP rights that may result. Business executives within the biomaterials engineer's company might expect that, because the company has defined the scope and is funding the project, the company should own all intellectual property rights that may result. As a general matter, universities will not agree to this. Central to the university's mission is the advancement of knowledge that can serve the public good, including openly sharing new discoveries or inventions. Provisions in research agreements that might impose blanket restrictions are anathema to this mission. As a result, in SRAs universities claim both rights to publish the results of their research, and ownership of any associated inventions, including the right to file patent applications (National Research Council, 1993). Based on this, from the medical device professional's perspective, similar and even more careful planning regarding ownership of IP rights should be applied to SRAs as compared with MUAs.

Prior to entering an SRA the biomaterials engineer should assess the likelihood that the project, as defined in the SRA's scope of work, will or could result in a patentable invention. If the project could result in an invention, the biomaterials engineer should alert other key company decision makers so that serious and collective consideration can be given to whether the research project should be conducted in-house, ensuring that ownership of any resulting invention will belong exclusively to the company, rather than outsourced to the university. If the decision is made to proceed with the SRA, careful attention should be paid to the terms of the SRA that describe the company's rights to any resulting invention. At a minimum, the SRA should provide the company with a first right to negotiate an exclusive license for any patentable invention that may result from the sponsored research. In coordination with the company attorney, the biomaterials engineer should review this provision to ensure that it affords the company the necessary opportunity to develop and commercialize the invention.

Another standard provision of SRAs that should receive careful attention from the biomaterials engineer involves publication rights. Typically, universities include a provision which reserves the right for the university to publish the results of the research, regardless of whether these results might have been favorable or unfavorable to the sponsoring company. If publication of unfavorable results might be damaging to the company's business, this should be considered before the company signs the SRA, and consideration should be given to whether the potential damaging component of the research could be conducted in-house, or in some manner that would provide the company with complete discretion regarding the publication, or non-publication, of the results.

If the sponsored research produces positive results, the biomaterials engineer's team and company may be pleased with the possibility of publication by the university, as this might be perceived by the scientific community as objective validation of the company's technology, despite the necessary acknowledgment of company funding. Such publication, however, may have implications for any patents rights that could result from the research. Consequently, the content and timing of what is being published should be carefully managed and monitored. In the U.S., as well as many non-U.S. jurisdictions, potential patent rights can be lost because of public disclosures. For example, if university researchers present the results and details of a new invention at a scientific conference or in a scientific journal more than a year before a U.S. patent application has been filed, that disclosure alone can disqualify the invention from any patentability in the U.S. This 1 year disclosure grace period is only available to inventors, so if the disclosure is made by a non-inventor before a patent application has been filed, suddenly the invention may no longer be patentable. Many non-U.S. jurisdictions do not recognize such a 1-year inventor grace period, so international patent opportunities may be lost as soon as the public disclosure occurs (KU Center for Technology Commercialization). Regardless of whether the presentation is given by the inventor, the publication of the research might inspire independent research groups investigating in the same field to file patent applications so that they can become the first to file, as discussed in the intellectual property section above.

In consideration of the above guidelines, one of the most important responsibilities of the biomaterials engineer when managing and monitoring sponsored research involves ensuring that no research results are inadvertently made public. Further, if patentable, the sponsoring company ideally should have already made a decision as to whether it will support the costs and efforts associated with prosecuting the patent application. As discussed in more detail in the next section, the sponsoring company may have already entered into a license agreement with the university regarding the patent rights, or at a minimum executed a term sheet with the university regarding the key business terms that will be incorporated into a license agreement that the university and sponsoring company anticipate executing promptly.

License Agreements

As a general matter, ownership and management of technologies invented or developed by university researchers, scientists, and engineers are delegated by universities to a technology transfer office. The technology transfer office typically is organized as an independent corporate entity that is wholly owned and controlled by the university. The technology transfer office is dedicated to the best interests of the university, but operates much more like a business than other departments or offices within the university (Alper, 2016). Awareness of this somewhat unique status within a university can be helpful to medical device professionals, because it may shed light on why interacting with a technology transfer office may differ from dealing with any other university department.

The orientation of a technology transfer office might be most easily understood by considering the differences between entering into a sponsored research agreement and entering into a patent license agreement. When negotiating a sponsored research agreement, the lead biomaterials engineer from the sponsoring company will be interacting directly with a university researcher possessing specific subject matter expertise, who most likely will also be the principal investigator. The principal investigator and the sponsoring company's lead biomaterials engineer will define the scope of the project and agree on a total cost, at which point the principal investigator may provide the sponsoring company with the university's standard sponsored research agreement template. Typically, any revisions to this template will be negotiated between and drafted by an attorney from the university's general counsel's office and the company's attorney, and then the SRA will be executed.

In contrast, the principal investigator typically will not play a significant role in the development or negotiation of a patent license agreement. These negotiations are managed by an IP specialist within the university's technology transfer office who acts independently of the principal investigator and exercises broad discretion regarding whether to involve the principal investigator in the technology transfer office's license negotiations with the company. From a practical perspective, medical device professionals within a sponsoring company should recognize that they may be dealing with a completely distinct entity when negotiating a patent license agreement from the entity that negotiated the SRA. It may be just as important to develop relationships and a rapport with the technology transfer office as it was with the department that conducted the research.

Typically, an attorney or patent license specialist from a sponsoring company will take the lead for the company in negotiating the terms of a patent license agreement, but the company's lead biomaterials engineer for the research should expect to play an integral and indispensable role. Generically, a license can be thought of as a permission to do a particular activity, or to use a particular composition. As discussed above, patents provide the patent owner with exclusive 20-year rights to practice the invention claimed in

the patent. A patent license agreement, therefore, establishes the terms and conditions under which a patent owner provides a third party, referred to as the licensee, with the legal right to practice the art covered and protected by the patent during the patent term.

Many companies and university technology transfer offices follow a two-step practice to negotiating and finalizing patent license agreements. The first step involves negotiating a non-binding term sheet, and the second involves incorporating the provisions of the term sheet into a comprehensive and binding license agreement. The term sheet summarizes the key business terms related to the proposed patent license. From a sponsoring company's perspective, even though the lead biomaterials engineer or the attorney may play an important role in developing and negotiating the term sheet, input from and participation by the company's financial experts, regulatory experts, and business line executives can be critical. A patent license agreement can commit a company to multi-layer resource and financial obligations, including financial penalties for failures to meet contractual commitments. Consequently, medical device professionals should be cautious about presenting their company as being prepared to enter into a patent license agreement unless they know that all of the impacted company departments have affirmed and support the commitments that will be associated with the license agreement.

The fact that any particular invention may be patentable, or even patented, does not mean that the invention is ready to be commercialized. In the United States, for example, even though the Patent and Trademark Office may have granted a patent, if the Food and Drug Administration (FDA) has not cleared or approved the invention for commercial use, the patent owner or licensee cannot market or sell the new product for any purpose that requires FDA clearance or approval. Simply put, the product may be commercially worthless if it cannot meet FDA standards. Because universities, and their associated technology transfer offices, are particularly interested in seeing the results of university research being used to promote the public good, term sheets that serve as the predicate to patent license agreements typically address the steps that must be accomplished so that the technology can be properly commercialized. These steps are generally referred to as milestones. A typical example of successive milestones that might be listed in a patent license agreement include (1) completion of a preclinical research project, (2) commencement of a clinical trial, (3) completion of that clinical trial, (4) regulatory approval, and (5) first commercial sale. In practical terms for medical device professionals, this means that a license agreement will include clearly defined tasks, with a clearly defined schedule, on which they may be responsible for delivering over a several year period. The failure to achieve milestones may provide the university with the right to terminate the patent license agreement, constituting a drastic result that would foreclose the company from commercializing patented technology it likely invested millions of dollars licensing and funding.

From a financial perspective, in addition to the costs associated with performing milestones, the most important provisions of the term sheet will likely be those specifying the milestone payments and license and royalty fees that the company will incur. Typically, milestone payments to the university are incurred as contractually specified milestones are reached, and are additional to the costs the licensee incurs to perform the milestones. Separately, the license fee represents any initial and/or minimum annual fee that the company must pay to the technology transfer office so that the patent license does not expire. The royalty fee, which may be partially integrated with the license fee, will typically be calculated as a percentage of the net revenues the company receives from sales of products that constitute or are based on the licensed technology.

Litigation

No introduction to legal issues encountered in business or academic settings would be complete without some discussion of litigation. We live in a litigious society, and it would be surprising for anyone to pursue a lengthy career without facing, at least once, the threat or reality of a lawsuit. Litigation can concern any of the topics addressed in this chapter: for instance, contract performance issues, confidentiality and non-competition breaches, IP inventorship, ownership or infringement claims, etc. Additionally, certain medical devices have gained notoriety through their involvement in product liability suits.

Litigation typically begins with the filing of a formal complaint, which often, but not necessarily, may be preceded by a demand letter warning that a complaint will be forthcoming. Receiving a complaint can be unsettling, and even alarming, particularly for non-lawyers, because it immediately places the recipient in a stressful and uncertain situation. Companies and universities typically hire outside lawyers who specialize in litigation to represent them in lawsuits. Litigators can be expensive, but retaining the right one, with the appropriate litigation and subject matter expertise, can be critical. Such an individual should be able to provide perspective on the risks posed by the litigation, detail a range of strategies that should be considered, and outline possible outcomes based on such strategies. Virtually no experienced litigator will guarantee any specific result, because litigation is inherently uncertain, but a qualified litigator should be able to present options that will allow the client to make an informed choice regarding optimal strategies to pursue.

The medical device professional should recognize that hiring a litigator does not absolve him from further involvement in the dispute. Litigation is very fact specific, so if the litigation concerns activities in which the medical device professional was involved, he will need to engage in detail with the litigation team to ensure the litigators know and understand all the relevant facts. The medical device professional should expect to spend a significant amount of time interacting with his own in-house counsel, or directly with the outside litigation team, in an effort to appropriately educate them.

Most lawsuits will not place the medical device professional at risk for personal liability, particularly if he was acting within the scope of his employment authority, and did not engage in clearly negligent or willfully malicious conduct. Typically, even if the party initiating the lawsuit, referred to as the plaintiff, specifically names the medical device professional in the complaint as a defendant, so long as he was acting within the scope of his employment, his employer will likely retain counsel for him, including paying the attorneys' fees. In the atypical situation where a medical device professional must personally hire an attorney, he should consider asking his attorney to investigate his employer's obligations to advance coverage of legal expenses, or at least indemnify him for any expenses he incurs. Such knowledge may influence the type of fee structure the medical device professional enters into with his litigator, and the ways in which he interacts with his litigator.

Conclusion

On first impression the broad array of legal issues that medical device professionals likely will encounter can be daunting. However, this does not have to be the case. Playing an active role in understanding and structuring the legal opportunities and constraints impacting a medical device professional's career and activities can be intellectually stimulating and professionally rewarding. The introductory roadmap provided above should eliminate at least some of the mystery that might discourage the necessary effort to unwind legal puzzles. This roadmap provides guidance for medical device professionals' coordination and cooperation with attorneys to convert situations involving legal issues into professional benefits and opportunities for themselves, and strategic and business advantages for their employer.

Introduction

Engineering ethics often takes the classical approach of preventive ethics. That is, engineering ethics most commonly focuses upon safety and regulation in an attempt to prevent the failure of future products. Such approaches generally rely on sets of standards and guidelines in an attempt to normalize development and ensure safety. While medicine certainly has standards and guidelines that govern and normalize its practice, as well as holding safety in the highest regard, the manner in which ethical issues are addressed by medical professionals often differs from the strategies used by engineers and scientists. As medical issues are complex, and focus primarily upon the treatment of individuals rather than the development of products or interpretation of research results, medical ethics has a strong emphasis on core values in decision making as well as on respect for the autonomy and wellbeing of the patient.

Engineering ethics and medical ethics have, of course, been the subject of countless textbooks, manuscripts, and lectures. However, the subjects of engineering ethics and medical ethics are generally treated as separate. The development of novel medical products requires those involved, whether they are scientifically or medically oriented, to be able to consider the ethical issues arising from both the engineering and medical aspects of the proposed product. Furthermore, as novel medical products continue to develop to include living components or utilize controversial methods such as gene editing, the need for discussions and consideration of previously unrecognized ethical issues will only increase. Thus scientists, engineers, medical professionals, and others working on novel medical products will need to be well versed in the myriad ethical issues that may arise.

The purpose of this chapter is to briefly review ethical issues in the development of medical products. These issues are relevant in multiple contexts, including drugs, medical devices, and other types of therapy. However, the broad ethical issues that arise in the development of each of these types of medical products are similar. These issues include not only the classical aspects of safety, regulatory compliance, and animal and human testing, but also emerging issues such as the use and inclusion of stem cells in medical products and gene editing, among others. While the topics presented herein are representative of the types of issues that may arise, they should not be considered comprehensive and this chapter should be used as a starting point for the study and discussion of the ethical issues associated with the development of medical products.

Selected Approaches to Ethical Reasoning

When discussing ethical decision making, whether based upon concepts from engineering or from medicine, it is useful to define a set of terminologies or methodologies by which one can assess and discuss issues that arise. As this chapter will discuss multiple ethical issues, and relies on the use of multiple terms and methods of ethical decision making, a short description of select approaches is provided below. A more in depth review of these concepts can be found in Harris et al. (2008). It is important to note that moral and ethical issues arise when there is divergence between these approaches to decision making and that ethical decision making becomes simplified when these approaches converge.

The Utilitarian Approach

In the simplest terms, a utilitarian approach is one that favors a decision that does the most good or prevents the most harm. Such approaches are widely used in engineering and business. This often includes a cost–benefit analysis or risk–benefit analysis. While this idea is simple in theory, in practice it can be much more complex. It is often difficult to define what represents a good outcome and for whom, particularly when the outcomes deal with profiting from human health. For example, one might ask the question: "Is a good outcome one that provides the best treatment for patients, or one that maximizes profit for the company selling the device?" Additionally, the use of a utilitarian approach might favor the good of the majority at the expense of an individual or group of individuals. Such issues will be discussed in more detail in the section on human clinical trials.

The Rights Approach

By contrast, the rights approach favors decisions that protect and respect the moral rights and autonomy of individuals. That is, human beings have inherent worth and dignity, and individuals should not be used as a means to an end. The rights approach is the basis for many of the rules that govern clinical trials, patient selection, informed consent, and medical autonomy. However, it should be noted that at times these rights come into conflict with the rights of the provider or other stakeholder, creating conflict. For example, whether or not one has a right to die by assisted suicide, and whether or not a provider should have the right to refuse such a request, is an ongoing debate. Additionally, the rights approach may come into conflict with the utilitarian approach when a patient cannot afford treatment, or when considering the allocation of scarce medical resources such as organ transplants.

The Justice Approach

The justice approach favors decisions that lead to the equitable distribution of access and benefits as well as the potential burden of care across society. The justice approach requires avoiding discrimination in the selection of clinical trial subjects without a scientific justification, and seeks to protect those with diminished autonomy. The fairness or justice approach also requires equal access to, or at least fair distribution of, scarce medical resources. For example, the United Network for Organ Sharing (UNOS) is the organization tasked with distribution of transplant organs in the United States. The process that UNOS has developed for allocation of liver transplants, called the Model for End-Stage Liver Disease score, allocates organs largely based upon urgency (i.e., the sickest patients first) and geographical location. The intent of this process is to maximize the supply of donor organs while improving access to this scarce resource. However, whether the system is truly equitable and works well for all stakeholders is not clear.

The Virtue Approach

Ethicist William F. May states "[The Professional] had better be virtuous. Few may be in a position to discredit him" (May, 1988). Such expectations derive largely from the trust that the public places in scientists and medical professionals. The virtue approach favors actions that are in line with certain ideals or virtues. For example, honesty, integrity, and compassion are examples of virtues that might be expected of scientists and medical professionals engaged in the development of medical products. The virtue approach commonly comes into discussions of professional responsibility, scientific integrity, and disclosure of conflicting interests, each of which is discussed in this chapter.

Safety

The safety of the public and the wellbeing of patients are held paramount in both engineering and medical ethics. Indeed, safety and wellbeing are among the first concerns covered in professional codes of ethics across scientific, engineering, and medical professional societies. Practically speaking, however, the safety of novel medical products is evaluated using guidelines that have been established by the United States Food and Drug Administration (FDA) or other national regulatory bodies. Such regulations are discussed in depth in Chapter 3.1.7 Regulatory Constraints for Medical Products Using Biomaterials.

The guidelines established by the FDA are in place to provide a set of testing, which, if successfully completed, can provide reasonable expectation of safety when used in human beings. That is, from a utilitarian perspective, the technology has shown a risk–benefit profile that is clearly associated more with benefit than with risk. The specific testing that is performed for a given medical product will depend upon its design, components, intended use, and predicate products already in the market. Individual tests are specified by test standards, including those from the ASTM International (formerly American Society for Testing and Materials) and the International Organization for Standardization, the purpose of which is to ensure reproducibility of testing between laboratories. Additionally, it is expected that testing will adhere to good laboratory practice and that manufacturing of the products to be tested will be carried out under good manufacturing practice. These practices govern the processes and conditions under which manufacturing and testing are carried out, and the standards of documentation needed to ensure the quality of these activities. The specifics and scope of technical standards are reviewed in Chapter 3.1.8 Role of Standards for Testing and Performance Requirements of Biomaterials.

While it is important to understand that these guidelines do exist, and that they are in place for the protection of the patient, these represent regulatory issues and do not, in and of themselves, necessarily present ethical issues. That is, the public expects that approved medical products will have undergone rigorous testing to ensure their safety. It is the

moral and ethical responsibility of those designing, testing, and selling the medical products to ensure that they are safe and function as intended. While the standards and expectations for safety may not raise ethical issues themselves, many ethical issues do arise during the course of testing, particularly testing performed in animals and humans, as well as in the interpretation of the data that result from such testing. These issues are discussed in more depth later. Ethical and legal issues may also arise after regulatory approval should patients experience side effects and/or failure of medical products; such issues are covered in Chapters 3.1.9 Medical Device Failure—Implant Retrieval, Evaluation and Failure Analysis and 3.1.10 Legal Concepts for Biomaterials Engineers, and are therefore not discussed here.

Animal Testing

For those involved in the design and testing of medical products, there are many techniques and strategies that can be employed to comprehensively characterize and test a novel device; however, it is difficult to foresee how a material or device may interact with the varied and complex cellular, tissue, and organ systems found within a human being. Therefore animal models are critical tools that help to assess the toxicity, biocompatibility, safety, and potential effectiveness of a device before testing the device in a human subject.

General opinion leans toward accepting animal research as morally allowable (von Roten, 2013); however, as evidenced by the surge of animal research protests in recent years, there are those who still question the necessity and appropriateness of animal research. This, in part, stems from the belief by some that animals have the same value and moral standing as a human being, and therefore should not be subjected to anything that would not also be done to a human for research purposes. With such an extreme view, arguably much of the preclinical research that is done to ensure safe, effective products for human use would be prohibited. Others take a more utilitarian stance against animal research, suggesting that animals possess distinct physiology from human beings and that these differences yield results that are not applicable or appropriate to extend to predictions about humans (Hajar, 2011).

A more tempered view recognizes that animal experimentation is necessary to ensure the safety of medical products to be used in humans, but, while animals are under our care and participating in our studies, they should be treated as ethically and humanely as possible. This includes giving access to adequate room, nutrition, and enrichment, while alleviating—to the extent possible—stressful situations, pain, and suffering, while also allowing them a space that provides for behaviors exhibited naturally when not in captivity (Whiting, 2011; Fenwick et al., 2009).

In the design of animal studies, it is important to minimize animal usage and distress if possible, and, unsurprisingly, throughout history individuals and organizations have put forth guidelines and suggestions to help us achieve these goals (Franco, 2013). In 1959, R.L. Burch and W.M.S. Russell published the book *The Principles of Humane Experimental Technique* (Russell and Burch, 1959). This book sought to give guidance about ways in which welfare could be maximized while only using as many animals as absolutely necessary. It was in this text that the concept of "The Three Rs" was introduced: Replacement, Reduction, and Refinement. The "Three Rs" provides a practical framework for minimizing animal usage and ensuring adequate care.

Replacement refers to using an alternative strategy for an experiment that would otherwise use animals for research. For example, in some studies it may be feasible to use a computer simulation or in vitro cell culture experiment as opposed to animals. However, Replacement can also refer to replacing a higher-order more sentient animal species with an animal species shown to have a lower perception for pain (e.g., replacement of a vertebrate animal with an invertebrate). Reduction refers to a strategy that optimizes the amount of information obtained per animal while minimizing the total amount of animals needed to fulfill objectives of the research question. For example, a study in which a longitudinal cohort of animals is used to generate many data points per animal will result in fewer animals being used when compared to a study in which a unique animal must be used for every time point. Finally, Refinement refers to strategies that aim to decrease the potential pain or distress an animal may encounter during its time in a research experiment. This could include using a newer surgical technique that is known to be less invasive with a shorter recovery time, or could include modifications of a pain management dosing schedule known to better control breakthrough pain after a procedure.

In addition to "The Three Rs," there are additional resources available to help guide and direct appropriate and ethical research with animals. In 1966, Congress passed the Laboratory Animal Welfare Act (AWA), which was the first law that specifically dictated policies concerning husbandry practices and treatment of animals for research purposes. The Animal and Plant Health Inspection Service under the United States Department of Agriculture helps to enforce and maintain tenets set forth in the AWA. While requirements can be extrapolated to provide guidance for most animal research, the species of animals specifically protected under this Act are limited to certain warm-blooded species, including nonhuman primates, dogs, cats, rabbits, guinea pigs, and hamsters. A 1985 amendment to the AWA helped to make research institutions and facilities more accountable through the mandate that they establish Institutional Animal Care and Use Committees (IACUCs) to review and approve proposed research using live animals protected under the Act. Although many frequently used species are left out of the Act, federally funded facilities are also required to have oversight of uncovered animals (e.g., rodents and birds), as these species are protected under the Public Health Service Policy on Humane Care and Use of Laboratory Animals. Under this policy, research must adhere to recommendations set forth in the *Guide for the Care and Use of Laboratory Animals*, which is produced by

the National Research Council and the Institute for Laboratory Animal Research.

Before initiating any type of animal work, researchers should thoughtfully consider the types of regulations and guidelines that must be adhered to based on the type of species and research that will be conducted. In addition, each aforementioned principle of "The Three Rs" must be comprehensively considered to design a study that fulfills each requirement. If it is determined that nonanimal work is indeed not a suitable alternative, oftentimes preliminary in vitro data or limited animal pilot studies will help inform calculations and decisions about the lowest number of animals necessary for a study. After a protocol is proposed to and approved by an individual's respective IACUC, care should be taken to follow any additional guidelines, laws, and regulations as dictated by local or state laws.

Human Testing

While animal testing is used for both exploratory and safety testing, human clinical trials are the final stage for testing the safety and efficacy of novel medical products that have shown sufficient results in preclinical in vitro benchtop and in vivo animal models but still require human clinical testing. It is important to note, however, that not all medical products require human clinical testing, and this topic is reviewed in Chapter 3.1.7 Regulatory Constraints for Medical Products Using Biomaterials. Historically, guidance for conducting human subject research was often derived in response to unethical clinical studies performed on disadvantaged, nonconsenting ethnic or racial minorities. The first of these reactionary ethical codes was the Nuremberg Code, a set of principles defining the rights of human research subjects, which was used to try Nazi physicians accused of unethical human experimentation in the Nuremberg trials. The Nuremberg Code contains 10 principles outlining the qualifications for ethically sound medical research, with a focus on informed patient consent in the absence of any coercive influence, scientifically sound study design with prior validation of safety and efficacy in the appropriate benchtop or animal models, and beneficence toward study participants, including study termination when faced with unanticipated deleterious consequences. While the Nuremberg Code eventually became one of the most important sets of ethical guidelines for human research, it was not widely accepted in Western medicine until several decades after its creation (Nardini, 2014).

During this period, another human subjects study was taking place in Tuskegee, Alabama—the "Tuskegee Study of Untreated Syphilis in the Negro Male"—a study intended to record the occurrence of syphilis in the black community to justify treatment programs. Initially intended to last only 6 months and provide free checkups and medical care to the study participants, the Tuskegee Study lasted 40 years, over which time study participants were never fully informed of the risks associated with the study, never informed of the purpose of the study, and never offered study exit or penicillin treatment for their syphilis when penicillin became available as a syphilis treatment in 1947. After public discovery of the ongoing Tuskegee Study in 1972 and subsequent public outcry over the perceived inhumane treatment of the research participants, the National Commission for the Protection of Human Subjects of Biomedical and Behavior Research was assembled to set defined ethical guidelines for human subjects research as well as to review the Tuskegee Study to determine if these ethical guidelines had been violated by the study. The committee determined that while the study subjects were willing participants, the study was not ethically justified since the study participants were never told the true purpose of the study or warned about the potential risks associated with enrollment, resulting in an inability to provide proper informed consent for study enrollment.

In 1979, the National Commission published the *Belmont Report*, a set of three fundamental principles underlying ethically sound biomedical human subjects research. The first principle of the *Belmont Report* concerns respecting and protecting the mental and physical autonomy of subjects participating in clinical research by providing a truthful and comprehensive view of the study design as well as a thorough review of all risks associated with the treatment or any procedures associated with the treatment. Presenting this information to prospective patients in a holistic, nondeceitful manner without the influence of coercion forms the basis of informed consent, an essential feature for patient inclusion in clinical trials today. In addition to Respect for Persons, the *Belmont Report* also identifies Beneficence and Justice as two additional features essential for ethical human subjects research. The principle of Beneficence is philosophically similar to many ideas outlined in the Hippocratic Oath, particularly the idea that healthcare providers and members of the research team should strive to "do no harm" while maximizing the quality of care available to patients. The principle of Beneficence also dictates cessation of clinical trials that induce undue stress or unanticipated negative health consequences in study participants. The study must also be conducted in a just manner, particularly with regard to equal recruitment across population groups without exploitation of disadvantaged populations. Additionally, any compensation provided for study participants should be sufficient to compensate for one's time, equally distributed across study participants, and proportional to the risks associated with the study research procedures or therapeutics. These three guiding principles outlined in the *Belmont Report* serve as the formative basis for human clinical trial bioethical guidelines and legislation in the United States (Department of Health E Welfare and National Commission for the Protection of Human Subjects of B Behavioral R. The Belmont Report, 2014).

As the field of bioethics developed over time, additional guidelines and principles have been developed to further refine and guide ethical clinical trials and human subjects research. The Declaration of Helsinki first published in 1964 and since refined by the World Medical Association outlines the basic principles underlying ethical human subjects

research, including guidelines on what is considered human subjects research, the purpose of human clinical research, the scientific basis necessary for transition from preclinical models to human subjects research, guidelines on patient recruitment and just compensation for the participants, proper modalities for managing and communicating study risks to research subjects, guidelines for protecting patient privacy, methods and considerations for obtaining informed consent, guidelines for which patients can and cannot give informed consent, as well as guidelines for the publication of study results and experimental data dissemination (World Medical, 2013). Additionally, the Declaration of Helsinki outlines the importance of independent review of all proposed human research studies by research ethics committees to ensure studies have sufficient scientific basis in preclinical models to transition to clinical trials and to review the proposed research protocols to ensure the study will not violate any of the previously outlined bioethical principles. Practically speaking, in the United States, any human research studies supported directly or indirectly by federal funding are required to be submitted to an Institution Review Board (IRB) for review. Each organization conducting federally funded human subjects research is required to organize an IRB, which meets the federal minimum requirements of having at least five members with at least one member who is a scientist, one nonscientist member, and one member of the community with no personal or familial affiliation with the institution. It is important to ensure that all members of an IRB have no financial or personal conflicts of interest associated with the research proposals being reviewed by the board. Proposals submitted to an IRB for review will be analyzed for sound scientific validity with sufficient data supporting efficacy from preclinical testing, planned mechanisms for patient enrollment, mechanisms of patient data collection, methods of protecting private patient medical information, and plans for unanticipated negative patient reactions to a given protocol or therapeutic. The IRB will also work to ensure that patient recruitment will be nondiscriminatory in nature and patients recruited are able to understand and give informed consent to study enrollment. Following approval of human subjects protocols, the IRB is responsible for monitoring the ongoing study for compliance with the submitted guidelines for the study as well as monitoring for any study complications and responding appropriately in cases where early study termination may be necessary to ensure patient safety. This review is to ensure that the study is sound from a utilitarian standpoint and provides for protection of the rights of individuals and justice, as previously defined.

Research Integrity

Research integrity is an individual researcher's obligation to honestly apply their knowledge, tools, and technical expertise to answer a given research question in a professional manner in accordance with all institutional rules, bioethical principles, and legal codes. Research integrity also dictates that researchers will interpret their results in a fair, nonbiased manner and disseminate those results to the scientific community and general public through objective publications of the study results following completion. Research integrity can also involve various aspects of professionalism that arise throughout the process of undertaking and publishing a study, such as properly attributing authorship credit when authoring manuscripts or development of proper systems for data management and storage during study data collection.

It is important for anyone involved in research studies to understand the obligations researchers are expected to uphold and maintain for several reasons. First, all scientific research is built upon prior work in the field, work that is often performed by other researchers or other institutions. Therefore it is essential that researchers undertaking a given experiment perform all aspects of experimental design, data collection, result depiction, and data dissemination in an honest, nonmisleading manner to allow for the results of the study to be applicable for future studies as well as repeatable and independently verifiable by other researchers working in that field of study. When all researchers adhere to this set of ethical principles, it helps build trust in the validity of the research others are undertaking and helps researchers in a given field have a sense of transparency about the current state of the field. Additionally, honest presentation and discussion of study results help guide subsequent development of reasonably informed future directions of study. From a non-scientific perspective, it is also important for those involved in research studies to conduct themselves with integrity to prevent the erosion of public trust in the scientific community. Since the technologies and therapeutics derived from research studies are ultimately to benefit members of the public, it is important that researchers conduct their studies with integrity and provide non-biased, non-sensationalized representations and discussions of their work in a manner that non-scientist public stakeholders can understand. Disseminating misleading or falsified data can not only erode public trust in the larger scientific community and stall research progress, but even more seriously it can introduce additional deleterious complications and loss of life in vulnerable patient populations who believed they stood to benefit from the technology.

Conflict of Interest

One significant aspect of research integrity involves conflict of interest. In the context of medical product development, a conflict of interest is defined as an interest that tends to make one's judgment less likely to benefit the patient than the patient is justified in expecting. Such conflicts frequently arise in both research and medicine. From an academic research perspective, such a conflict might include patent authorship, equity ownership, royalties, and research funding or contracts from a company involved in the development of a medical product. Such financial incentives might influence the obligation of a researcher to accurately report and interpret data from research studies according to

scientific and ethical norms. This creates the potential for poor quality research, which, if used to justify translation of research into products to be used in human patients, has the potential for harm. Similarly, conflicts of interest in medical professionals may influence their choice of treatments in patients, choice to use or recommend a particular medical product, or their reporting of clinical research studies.

There are clear benefits to academics and physicians working with industry partners. These include advancement of the development of new medical products, economic growth, and improvements in the quality of care for patients. This also includes increased research budgets, enhanced salaries, and other benefits such as access to equipment and materials that might otherwise be unavailable. However, these must be balanced against the potential impacts on research quality and reporting. For these reasons, most federal sponsors require that research institutions monitor, manage, and report conflicts of interest. Similarly, Congress passed the Physician Payments Sunshine Act, requiring medical product manufacturers to disclose payments to physicians and teaching hospitals as well as physician ownership or investment in companies. Disclosure of conflicts of interests in those who review regulatory submissions, FDA Advisory Committee Members, for example, have also come under scrutiny in recent years, and must be managed by regulatory bodies to protect human health.

Research institutions, regulatory bodies, and hospitals, however, are largely left to interpret and manage the ethical impacts of conflicts of interest. Questions that these institutions must answer relate to which financial interests must be disclosed and to whom, which interests pose a risk to research integrity, and how to manage the risks effectively. Scientific journals are also tasked with acting as gatekeepers of scientific publications, and most, if not all, scientific and medical journals require disclosure of conflicts of interest at the time of submission for publication. While some may suggest that having to disclose these relationships is unfair to the authors, and may influence the review of otherwise unbiased science, such guidelines are needed to protect research integrity and human health.

Emerging Ethical Issues in Medical Product Development

While the foregoing described ethical issues are well known and well discussed in the context of medical product development, new technological development comes with new ethical issues that have not previously been considered, and for which regulatory or standard guidelines may not exist. In the context of biomaterials, the materials themselves are not generally associated with significant ethical issues. However, as the field expands to include cells in biomaterial constructs such as is described in Section 2.6 Applications of Biomaterials in Functional Tissue Engineering, biologically active molecules or materials derived from human sources, or the delivery of genome modifying agents, new issues have emerged. A select group of these issues is discussed below.

Ethical Issues in Stem Cell Research

The enormous therapeutic potential and substantial progress in stem cell research over the years, especially in human embryonic stem (ES) cells and human-induced pluripotent stem (iPS) cells are contrasted by staunch opposition, most notably to ES cell research, by millions worldwide. Indeed, the ethical dilemma surrounding ES cells has been a subject of significant debate ever since the first report of successful isolation of human ES cells. Despite the long-running controversy, the ethical issues that arise in the discussion of the use of stem cells have yet to be resolved. Views on this subject are driven by many factors, including personal morality, cultural norms, and religious beliefs, among others. These views are also balanced by the belief that ES cells have tremendous therapeutic potential. The lack of consensus and agreement on the ethical issues surrounding ES cells are reflected in the range of legislative regulation in different parts of the world (Kastenberg and Odorico, 2008).

Though the ethical issues are various and complex, the major issues are related to the origin of the stem cell. Unsurprisingly, adult or cord blood stem cells are associated with fewer ethical objections. The ethical issues in ES cells derive from an inconsistent definition of human embryo and its corresponding moral and legal status. The problem with sourcing human ES cells is the inevitable destruction of embryos in the process of isolation. The challenge is to find the balance between respect for human life, if indeed an embryo can be considered a life, and the goal of alleviating suffering. It is ethically difficult to develop a policy that is acceptable to everyone given the moral belief shared by many that the destruction of a human embryo is morally equivalent to ending a human life, or, at the least, that the embryo has some inherent moral value. Another ethical debate concerns the use of surplus IVF embryos to source the ES cells and generally includes objections such as the principle of potentiality and proportionality, the slippery slope argument, and the subsidiarity principle (de Wert and Mummery, 2003).

Other sources of stem cells are also associated with ethical issues. The use of somatic cell nuclear transfer (i.e., cloning) to source stem cells has significant therapeutic potential. However, ethical issues with cells derived in this way include the underlying ethical objection and unclear moral status of cloned embryos (de Miguel-Beriain, 2015). Others, however, argue that the cloned embryos are not naturally created for reproduction and therefore should not be considered morally equivalent to natural embryos or even IVF embryos (de Miguel-Beriain, 2015). iPS cells are derived from somatic cells and thus bypass many of the ethical concerns related to the destruction of a human embryo. However, there is a unique set of ethical issues surrounding iPS cells as well, largely related to current scientific uncertainty and yet to be defined safety profile. Issues such as abnormal reprogramming during induction of pluripotency, potential tumorigenicity of therapeutically implanted iPS cells, potential use for cloning human beings, potential applications in producing human germ cells, potential to

make human embryos, and issues obtaining informed consent (Zheng, 2016) have yet to be addressed.

Regardless of the type of stem cell used to derive a particular treatment, there are ethical and safety issues pertaining to human donor tissues, including regulation of production, management and therapeutic use of donor tissue or organ samples, and following standardized guidelines and protocols (Chen and Liu, 2016). Acquiring commercial value, human tissue and cell samples have developed a market that creates the potential for conflict between donations inspired by altruistic considerations and profitability, leading to the potential for inadequate protection of the donor through informed consent (Riva et al., 2019). Another major area of ethical concern is ownership of genetic information versus use of that information for biomedical research with proper measures such as informed consent and strict confidentiality (Spinello, 2004).

Gene Editing

Broadly speaking, gene therapy refers to using genetic material to cure or treat a disease, with the ultimate goal of being a feasible and suitable replacement for more traditional treatments such as drugs or surgical intervention. Current gene therapy approaches include adding a new gene to cells, deactivating a gene that is not functioning properly, replacing a faulty or mutated gene with one that is functional, as well as other various strategies. If done correctly, for example, a longer-term solution to a disease or problem can be achieved through a source of functional protein that is being continually renewed (Ibraheem et al., 2014), or through the removal of a dysfunctional, inappropriate protein that was causing negative consequences.

In general, genetic material that is delivered to the cytoplasmic portion of a cell will have difficulty being translated to a protein. Vector carriers, therefore, are one way to deliver the genetic material to the nucleus where transcription can take place. Viruses are able to infiltrate and deliver their genetic material to host cells, making them an attractive option for vector carriers in gene therapy. Some viruses, such as retroviruses, deliver and incorporate their genetic material directly into a host's chromosomes, while others (e.g., adenoviruses) deliver material to the nucleus without host genome incorporation. Gene editing, a potential type of genetic therapy that may be even better described as "genetic engineering," is emerging as a way to more specifically alter a cell's genome. A recent approach, the clustered regularly interspaced short palindromic repeats and CRISPR-associated protein 9 system, makes use of scientific principles borrowed from bacterial defense mechanisms to target specific areas of chromosomes for alterations, removals, and additions of genetic material.

In general, gene therapy is a relatively young field. For many applications, researchers are still working to determine the safety of treatment strategies before efficacy testing can commence. There have been instances where experiments have ended with negative consequences, such as genetic mutations, illness, and even death (Cotrim and Baum, 2008; Jafarlou et al., 2016; Goswami et al., 2019). However, advances in safety and increased awareness of ethical issues are helping to continue to advance research and bring attention to these emerging technologies. With gene therapy comes thought-provoking considerations that many traditional therapies do not have. Gene therapy that modifies somatic cells, such as cells of the blood, is meant to treat the individual undergoing the procedure and will not result in the modification being genetically passed on to offspring; however, gene therapy targeting germline cells has the potential to affect subsequent generations. This, and a variety of other issues such as cost and potential to unfairly enhance certain genetic traits, constitute ethical concerns for gene therapy and gene editing.

Since these forms of gene therapy rely upon varying degrees of host genome editing, several distinct ethical considerations arise for each technology. Gene replacement therapeutics as well as editing technologies must follow the bioethical principles previously discussed, meaning that gene therapies should produce substantial benefit over currently available therapeutics, the risks associated with the technology should be manageable or negligible in comparison to the benefits provided through gene therapy, and the technology should be available to individuals in need without bias or socioeconomic prejudice (Wirth et al., 2013). Gene replacement therapeutics, which do not involve any host somatic or germline genome editing, need to ensure that the vector chosen for gene delivery to the cell nucleus is biocompatible and will not induce unwanted complications in patient populations receiving the therapy. Additionally, gene replacement therapeutics need to be appropriately applied in cases of serious pathophysiology where no significant alternative therapies are available. For therapeutics characterized by editing of the host genome, unique considerations arise based on whether the cell in which the genome edits are being made is a somatic or germline cell (Coller, 2019). Since somatic cell genome edits are nonheritable and any somatic edits made in an individual will not propagate throughout an individual's offspring, the ethical concerns surrounding this form of therapeutic are largely concerned with the safety of the editing technology being used, the risks associated with introducing genome edits in a given somatic cell type, and whether gene editing is the appropriate course of treatment given the alternatives available at the time of treatment. Gene therapies that involve germline genome edits are also both subject to the same ethical considerations as outlined for somatic gene editing as well as subject to another significant ethical dilemma—who is responsible for providing informed consent for therapies that affect both an individual and potentially an individual's yet to be born offspring? Considerable debate is ongoing surrounding the ethics of making this decision of consent for one's offspring (Coller, 2019; Wolf et al., 2019; Editors Sarah Chan and Sternberg, 2019). As germline gene editing technology is often intended to remove genes that are known to confer a lethal phenotype, one could argue that the principle of beneficence

dictates that clinicians and researchers apply the tools available to avoid undue suffering in cases where it is known that an individual will acquire a hereditable, potentially lethal pathology. However, there is still debate as to what pathophysiologies necessitate germline gene editing as opposed to other forms of gene therapy or conventional treatment options. Additionally, since many of the technologies proposed for performing these edits have been developed in the last several decades, data concerning the long-term, generational consequences of germline editing remain unknown. A final ethical consideration applicable to all gene therapy technologies is the consideration of whether this is an appropriate application of a given technology to ensure one is not crossing the boundary into nonessential gene therapeutics, where genes are delivered or edited in an individual devoid of any pathological medical condition for the purpose of individual ability enhancement or personal enrichment.

Cost and Access to Medical Products

Justice-based ethical reasoning would argue that all should have equal access to high-quality medical care. Furthermore, a rights of person approach would suggest that patients have the right to choose which medical treatments they should or should not receive. However, such approaches must be balanced against the costs and effectiveness of medical products. Achieving this balance creates moral and ethical issues in that it pits the interests of individuals and their right to be healthy against the reality of healthcare economics, limitations of insurance policies, and ever-increasing costs of care. That is, it requires us to place a limit on the value of the health of an individual or even on a human life.

In the United States, healthcare costs represent nearly 20% of GDP, and are increasing steadily (Callahan, 2008). It is estimated that 40%–50% of the increased costs per year comes from the introduction of new medical technologies and the increased usage of existing technologies (Callahan, 2008). These technologies can improve patient outcomes, enhance quality of life, and cure previously fatal diseases. However, some have argued that cost control is needed to maintain the stability of the healthcare system. These reductions include reduction in the use of expensive medical products, particularly those with minimal benefit over less expensive but similarly effective products. This requires, necessarily, that some patients will not have access to a level of care or choices that they have come to expect, and to which they feel they have a right.

Other issues that arise when considering the cost of novel medical products include access to expensive or scarce treatments. For example, sofosbuvir, a well-tolerated and highly effective cure for hepatitis C, was introduced in 2013. The cost of a course of sofosbuvir is more than $80,000 in the United States (Liao and Fischer, 2017). This equates to approximately $1000 per pill, despite a cost to produce of approximately $3. As hepatitis C rates are higher in lower socioeconomic populations, rates of hepatitis C in Medicaid-covered individuals is estimated at 7.5 times that of commercially insured individuals (Liao and Fischer, 2017). In 2014, following approval of the drug, some states experienced high rates of prescriptions, leading to the need to enact new coverage criteria. New York state, for example, spent 6% of its total prescription budget on sofosbuvir in the first half of 2014, before enacting new coverage criteria that limited access to prescriptions (Liao and Fischer, 2017). These criteria included drug and alcohol abstinence, psychosocial readiness of the patient for treatment, and disease severity, among others. Clearly, from a utilitarian standpoint, restrictions were needed to sustain Medicaid programs and allow for the cost of treatment of patients with other diseases. Conversely, the use of such criteria runs contrary to the belief that all patients should be able to receive treatments that sustain or restore their health regardless of socioeconomic class or personal choices. These issues often raise the question of whether drug and device companies should be able to charge high prices for life-saving treatments. Such questions must be balanced against the utilitarian view that new medical technology development is both risky and costly, and the expectation that companies that undertake such risks have the right to profit from their success. Many argue that, without strong economic incentives, companies would not be willing to take such risks.

Conclusions

This chapter sought to identify and discuss some of the moral and ethical issues that may arise during the development of medical products. The primary, and perhaps the most important, moral and ethical issues surrounding medical products have to do with protecting the safety and improving the wellbeing of the patient. However, the manner in which this is achieved may involve moral and ethical issues related to the use of animals and human subjects during testing of the product. It is expected that researchers, both academic and corporate, will perform their work in a manner that is free of conflict and honest, reflecting the trust placed in scientists, engineers, and medical professionals by the public. These classical concepts are applicable to all medical products. However, with increasingly novel designs, high-powered treatments, and even cures for life-threatening diseases, the type and number of ethical issues have increased. Biologically active components, such as stem cells and methods that have the potential to permanently alter the human genome are now a reality and the associated ethical issues must be considered. Lastly, the potential for moral and ethical challenges does not end once the product has been developed. Cost and access to medical products also raise significant issues, many of which are not often considered by those involved in research and development. This chapter is not comprehensive, and it should be understood that continued scientific progress will certainly lead to new and unexpected issues. For this reason, those involved in the development of medical products should be familiar with the pertinent ethical issues involved with their projects as well as stay informed of developing issues in their field. Doing so can only increase the safety and effectiveness of medical products.

Appendix A

Properties of Biological Fluids

STEVEN M. SLACK*

This appendix represents a compilation of information relevant to biomaterials scientists regarding the properties and compositions of several body fluids, i.e., blood, plasma (serum), cerebrospinal fluid, synovial fluid, saliva, tear fluid, and lymph. Where possible, ranges of values are provided, but the reader should recognize that significant variations are possible, particularly in states of disease. Further, the data reported here reflect adult measurements and may be substantially different in a pediatric population. Values for cerebrospinal fluid refer to the lumbar region, those for synovial fluid refer to the knee joint, and those for lymph refer to the thoracic duct, unless otherwise specified. Table A1 lists the physicochemical properties of these fluids. Table A2 provides the typical cellular composition of human blood. Table A3 shows the normal volumes of these fluids in males and females, and presents equations whereby such volumes can be estimated from the mass of the individual. Next, Table A4 lists the approximate concentrations of the major proteins present in various biological fluids. Tables A5 and A6 present the concentrations of inorganic and organic species, respectively, in these fluids. Table A7 provides data on the major plasma proteins, i.e., concentration, molecular weight, isoelectric point (pI), sedimentation coefficient (S), diffusion coefficient (D), extinction coefficient (E_{280}), partial specific volume (V_{20}), carbohydrate content (C),

*__Dr. Steven M. Slack__ died on April 29, 2010. He was Professor in the Department of Biomedical Engineering and Associate Dean of Graduate Studies in the Herff College of Engineering, at the University of Memphis in Tennessee. He is sorely missed by the current and founding editors of this textbook, by his colleagues around the world, and especially by his many students at the University of Memphis.

TABLE A1 Physicochemical Properties of Several Biological Fluids

Property	Whole Blood	Plasma (Serum)	Cerebrospinal Fluid	Synovial Fluid	Saliva	Tear Fluid
Freezing-point depression[a]	0.557–0.577	0.512–0.568	0.540–0.603	—	0.07–0.34	0.572–0.642
Osmolality[b]	—	275–295	290–324	292–300	—	309–347
pH[c]	7.35–7.45	7.35–7.43	7.35–7.70	7.29–7.45	5.0–7.1	7.3–7.7
Refractive index[d]	16.2–18.5	1.3485–1.3513	1.3349–1.3351	—	—	1.3361–1.3379
Relative viscosity[e]	2.18–3.59	1.18–1.59	1.020–1.027	>300	—	1.26–1.32
Specific conductivity[f]	—	0.0117–0.0123	0.0119	—	—	—
Specific gravity[g]	1.052–1.061	1.024–1.027	1.006–1.008	1.008–1.015	1.002–1.012	1.004–1.005
Specific heat[h]	0.87	0.94	—	—	—	—
Surface tension[i]	55.5–61.2	56.2	60.0–63.0	—	15.2–26.0	40–50

[a]Units are °C.
[b]Units are mosm/kg H_2O. Calculated from freezing-point depression.
[c]pH measured from arterial blood and plasma, and from cisternal portion of CSF.
[d]Measured at 20°C.
[e]Measured in vitro at 37°C for whole blood, plasma, and synovial fluid, and at 38°C for cerebrospinal fluid. The viscosity of serum is slightly less than plasma due to the absence of fibrinogen.
[f]Units are S/cm. Measured at 25°C for plasma, 18°C for CSF.
[g]Relative to water at 20°C.
[h]Units are cal/g °C.
[i]Units are dyn/cm. Measured at 20°C.

and half-life. Finally, Tables A8 and A9 present information on the proteins involved in the complement pathway and blood coagulation pathway, respectively. Some of the information contained in this appendix have been previously published in Black, J., & Hastings, G. (eds.) (1998). *Handbook of Biomaterial Properties*. Chapman & Hall: New York, NY, pp. 114–124.

TABLE A2 Cellular Composition of Blood

Cell Type	Cells/μL	Half-Life in Circulation
Erythrocytes	$4.6–6.2 \times 10^6$ (M) $4.2–5.2 \times 10^6$ (F)	25 ± 2 days
Leukocytes		
Neutrophils	3000–5800	6–8 hours
Eosinophils	50–250	8–12 hours
Basophils	15–50	?
Monocytes	300–500	1–3 days
Lymphocytes	1500–3000	Variable
Platelets	$1.5–3.5 \times 10^5$	3.2–5.2 days
Reticulocytes	$2.3–9.3 \times 10^4$	—

TABLE A3 Volumes of Various Biological Fluids[a]

Parameter	Whole Blood	Erythrocytes	Plasma	CS Fluid	Tear Fluid
Volume (mL)	4490 (M)	2030 (M)	2460 (M)	100–160	4.0–13
	3600 (F)	1470 (F)	2130 (F)		

[a]The following equations can be used to estimate blood volume (BV), erythrocyte volume (EV), and plasma volume (PV) from the known body mass (b, kg) with a coefficient of variation of approximately 10%:

Males (M)	Females (F)
$BV = 41.0 \times b + 1530$	$BV = 47.16 \times b + 864$
$PV = 19.6 \times b + 1050$	$PV = 28.89 \times b + 455$
$EV = 21.4 \times b + 490$	$EV = 18.26 \times b + 409$

TABLE A4 Protein Concentrations (mg/dL) in Various Biological Fluids

Protein	Plasma (Serum)	Cerebrospinal Fluid	Synovial Fluid	Saliva	Tear Fluid	Lymph
Total	6000–8000	20–40	500–1800	140–640	430–1220	2910–7330
Albumin	4000–5500	11.5–19.5	400–1000	0.2–1.2	400	1500–2670
α_1-Acid glycoprotein	50–115	0.1–0.25	—	—	—	260
α-Amylase	—	—	—	6–70	—	—
α_1-Antitrypsin	85–185	0.4–1.0	45–110	—	1.5	—
Ceruloplasmin	15–60	0.07–1.0	1–7.5	—	4	—
Fibrinogen	200–400	0.065	—	—	—	—
Fibronectin (μg/mL)	150–300	1–3	150	<1	3–9	—
Haptoglobin	70–140	0.075–0.4	—	9	—	—
Hemopexin	50–120	—	—	—	—	—
IgA	100–400	0.1–0.3	60–115	2.2–15	4–80	—
IgG	650–1600	0.7–2.0	150–46	0.3–1.8	4–60	780
IgM	30–120	—	9–20	0.1–1.2	trace	—
Lysozyme	0.3–0.8	—	—	13–66	100–280	—
α_2-Macroglobulin	150–450	0.3–0.65	10–50	—	—	—
Transferrin	200–320	0.5–1.2	—	—	10	—

TABLE A5 Concentrations of Major Inorganic Substances (mmol/L) in Various Biological Fluids

Electrolyte	Whole Blood	Plasma (Serum)	Cerebrospinal Fluid	Synovial Fluid	Saliva	Tear Fluid	Lymph
Bicarbonate	19–23	21–30	21.3–25.9	—	2–13	20–40	—
Calcium	2.42	2.1–2.6	1.02–1.34	1.2–2.4	0.69–2.46	0.35–0.77	1.7–2.8
Chloride	77–86	98–109	122–132	87–138	6.5–42.9	110–135	87–103
Magnesium	1.48–1.85	0.80–1.05	0.55–1.23	>Serum	0.065–0.38	—	—
Total phosphorus	10.1–14.3	2.5–4.8	0.442–0.694	>Serum	3.9–9.3	0.11–10.3	2.0–3.6
Potassium	40–60	3.5–5.6	2.62–3.3	3.5–4.5	14–41	31–36	3.9–5.6
Sodium	79–91	125–145	137–153	133–139	5.2–24.4	126–166	118–132
Sulfate	0.1–0.2	0.31–0.58	—	Same as serum	—	—	—

TABLE A6 Concentrations of Organic Compounds (mg/dL) in Various Biological Fluids

Species	Whole Blood	Plasma (Serum)	Cerebrospinal Fluid	Synovial Fluid	Saliva	Tear Fluid	Lymph
Amino acids	4.8–7.4	3.6–7.0	1.0–1.5	—	—	5.0	—
Bilirubin	0.3–1.1	0.2–0.8	<0.01	—	—	—	0.8
Cholesterol	115–225	120–200	0.16–0.77	0.3–1.0	—	10.6–24.4	34–106
Creatine	2.9–4.9	0.13–0.77	0.46–1.9	—	—	—	—
Creatinine	1–2	0.6–1.2	0.65–1.05	—	0.5–2	—	0.8–8.9
Fatty acids	250–390	150–500	—	—	—	—	—
Glucose	80–100	85–110	50–80	—	10–30	10	140
Hyaluronic acid	—	—	—	250–365	—	—	—
Lipids, total	445–610	400–850	0.77–1.7	—	—	—	—
Phospholipid	225–285	150–300	0.2–0.8	13–15	—	—	—
Urea	20–40	20–30	13.8–36.4	—	14–75	20–30	—
Uric acid	0.6–4.9	2.0–6.0	0.5–2.6	7–8	0.5–2.9	—	1.7–10.8
Water (g)	81–86	93–95	94–96	97–99	99.4	98.2	81–86

TABLE A7 Properties of the Major Plasma Proteins

Protein	Plasma Concentration (mg/mL)	Molecular Weight (Da)	p*I*	S^a	D^b	E^c_{280}	V^d_{280}	C^e	Half-life (days)
Prealbumin	0.12–0.39	54,980	4.7	4.2	—	14.1	0.74	—	1.9
Albumin	40–55	66,500	4.9	4.6	6.1	5.8	0.733	0	17–23
α_1-Acid glycoprotein	0.5–1.15	44,000	2.7	3.1	5.3	8.9	0.675	41.4	5.2
α_1-Antitrypsin	0.85–1.85	54,000	4.0	3.5	5.2	5.3	0.646	12.2	3.9
C1q	0.05–0.1	459,000	—	11.1	—	6.82	—	8	—
C3	1.5–1.7	185,000	6.1–6.8	9.5	4.5	—	0.736	—	—
C4	0.3–0.6	200,000	—	10.0	—	—	—	—	—
Ceruloplasmin	0.15–0.60	160,000	4.4	7.08	3.76	14.9	0.713	8	4.3
Fibrinogen	2.0–4.0	340,000	5.5	7.6	1.97	13.6	0.723	2.5	3.1–3.4
Fibronectin	0.15–0.2	450,000	—	13–13.6	2.1–2.3	13.5	0.72	4–9	0.33
α_2-Haptoglobin									
Type 1.1	1.0–2.2	100,000	4.1	4.4	4.7	12.0	0.766	19.3	2–4
Type 2.1	1.6–3.0	200,000	4.1	4.3–6.5	—	12.2	—	—	
Type 2.2	1.2–2.6	400,000	—	7.5	—	—	—	—	
Hemopexin	0.5–1.2	57,000	5.8	4.8	—	19.7	0.702	23.0	9.5
IgA (monomer)	1.0–4.0	162,000	—	7.0	3.4	13.4	0.725	7.5	5–6.5
IgG	6.5–16.5	150,000	6.3–7.3	6.5–7.0	4.0	13.8	0.739	2.9	20–21
IgM	0.3–1.2	950,000	—	18–20	2.6	13.3	0.724	12	5.1
Lysozyme	0.003–0.008	14,400	10.5	—	—	—	—	—	—
α_2 – Macroglobulin	1.5–4.5	725,000	5.4	19.6	2.4	8.1	0.735	8.4	7.8
Transferrin	2.0–3.2	76,500	5.9	5.5	5.0	11.2	0.758	5.9	7–10

[a]Sedimentation constant in water at 20°C, expressed in Svedberg units.
[b]Diffusion coefficient in water at 20°C, expressed in 10^{-7} cm^2/s.
[c]Extinction coefficient for light of wavelength 280 nm traveling 1 cm through a 10 mg/mL protein solution.
[d]Partial specific volume of the protein at 20°C, expressed as $ml g^{-1}$.
[e]Carbohydrate content of the protein, expressed as the percentage by mass.

TABLE A8 **Properties of Proteins Involved in the Complement System**

Protein	Serum Concentration (mg/L)	Relative Molecular Weight M_r (Da)	Sedimentation Constant S_{20w} (10^{-13} sec)
C1q	50–100	459,000	11.1
C1r	35–40	83,000	7.5
C1s	32–40	83,000	4.5
C2	20–35	108,000	4.5
C3	1500–1700	185,000	9.5
C4	300–600	200,000	10.0
C5	120–180	185,000	8.7
C6	42–60	128,000	5.5
C7	4–60	121,000	6.0
C8	35–50	151,000	8.0
C9	45–70	71,000	4.5
Factor B	220–330	92,000	5–6
Factor D	Trace	24,000	3.0
Properdin	25–35	220,000	5.4
C1 inhibitor	145–170	100,000	—
Factor H	475–575	150,000	6.0
Factor I	30–45	88,000	5.5

TABLE A9 **Properties of Proteins Involved in Blood Coagulation**

Protein	Plasma Concentration (μg/mL)	Relative Molecular Weight M_r (Da)	Biological Half-Life $t_{1/2}$ (Hours)
Fibrinogen	2000–4000	340,000	72–120
Prothrombin	70–140	71,600	48–72
Factor III (tissue factor)	—	45,000	—
Factor V	4–14	330,000	12–15
Factor VII	Trace	50	2–5
Factor VIII	0.2	330,000	8–12
Factor IX	5.0	57,000	24
Factor X	12	58,800	24–40
Factor XI	2.0–7.0	160,000	48–84
Factor XII	15–47	80,000	50–60
Factor XIII	10	320,000	216–240
Protein C	4.0	62,000	10
Protein S	22	77,000	—
Protein Z	3.0	62,000	60
Prekallikrein	35–50	85,000	—
High-molecular-weight kininogen	70–90	120,000	—
Antithrombin III	210–250	58,000	67

Appendix B

Properties of Soft Materials

M. CRISTINA L. MARTINS*

INEB - Institute of Biomedical Engineering, University of Porto, Porto, Portugal

TABLE B1 **Some Mechanical and Physical Properties of the Most Common Polymers Used as Biomaterials and the Respective Application**

Polymer	Tensile Strength (MPa)	Tensile Modulus (GPa)	Elongation (%)	T_g (°C)	T_m (°C)	Water Absorption (%)	Water Contact Angle (°)	Biomedical Applications (Marchant & Wang, 1994; Pruitt, 2017; Lee et al., 2000; Maitz, 2015; Kroschwitz, 1990)
Polyethylene: Low-density polyethylene - LDPE (Marchant & Wang, 1994)	4–16	0.1–0.3	90–800	–20	95–115	<0.01	93–95	Tubing; shunts; catheters; medical packaging
High-density polyethylene - HDPE (Marchant & Wang, 1994)	21–38	0.4–1.2	20–1000	–125	135–138	<0.01	91	Plastic surgery implants; catheters; tendons
Ultra high molecular weight polyethylene - UHMWPE (Steven, 2004)	39–48	0.8–1.6	350–525	–160	125–138	–	–	Acetabulum in total hip prostheses; artificial knee prostheses
Polypropylene - PE (Marchant & Wang, 1994)	30–38	1.1–1.6	200–700	–12	125–167	<0.01	104	Heart valve structures; oxygenator and plasmapheresis membranes; nonabsorbable sutures; disposable syringes; finger joint prosthesis
Polyvinylchloride—PVC (rigid) (Marchant & Wang, 1994)	35–62	2.4–4.1	2–40	87–90	212	0.1–0.4	80	Catheters; blood bags; tubings[a]
(plasticized) (Marchant & Wang, 1994)	10–24	–	200–450					
Poly(tetrafluoroethylene) - PTFE or Teflon® (Marchant & Wang, 1994)	14–35	0.4	200–400	–10	327	0	110	Vascular graft; catheter coating; facial prosthesis; heart valve structures; stapes prosthesis (in tympanoplasty)
Poly(dimethylsiloxane) - PDMS or silicone (Marchant & Wang, 1994)	2–10	–	100–600	(–120)–(–123)	–	0.02	101–109	Oxygenator membrane; tubing; shunts; breast, joint, tracheal, bladder, and maxillofacial prostheses; heart pacemaker leads; heart valve structures; burn dressing
Poly(ethylene terephthalate) - PET or Dacron (Marchant & Wang, 1994)	59–72	2.8–4.1	50–300	69–82	265–270	0.1–0.2	73–78	Vascular grafts; heart valve structures; shunts; laryngeal, esophageal, and bladder prostheses; non-absorbable sutures; tendon reconstruction
Polyamides (nylons) (Marchant & Wang, 1994)	62–68	1.2–2.9	60–300	45–75	200–270	1.5	–	Hemodialysis membrane; nonabsorbable sutures

Poly(ether urethane) (e.g., Pellethane) (Lamba et al., 1998)	35–48	<0.01	350–600	(–43)–(–60)	188–204	–	62–107	Percutaneous leads; catheters; tubing; intraaortic balloons; wound dressing
Poly(ether urethane urea) (e.g., Biomer) (Lamba et al., 1998)	31–41	<0.01	600–800	(–53)–(–67)	120–150	0.02	63–69	Artificial heart components; heart valve; tubing; vascular graft prosthesis
Polystyrene - PS (Marchant & Wang, 1994)	35–83	2.8–4.1	1–3	116	137	0.10	45[b]	Tissue culture dish
Polycarbonate - PC (Marchant & Wang, 1994)	55–66	2.4	100–130	150	267	0.2	62[b]	Connectors; oxygenator housings; hemodialysis and plasmapheresis membranes (Lee et al., 2000)
Polysulfones (Marchant & Wang, 1994)	70.3	2.5	50–100	190–285	–	0.22	–	Artificial heart components; heart valve structures; oxygenator; hemodialysis and plasmapheresis membranes
Poly(aryl-ether-ether-ketone) - PEEK (OPTIMA LT1) (Kurtz & Devine, 2007)	93	4[c]	30–40	~143	~343	–	–	Orthopedic and spinal implants
Poly(methyl methacrylate) - PMMA (Marchant & Wang, 1994)	48–76	3.1	2–10	110	160	0.3–0.4	62	Dentures; bone cement; plasmapheresis and hemodialysis membranes; intraocular lens; middle ear prosthesis
Poly(2-hydroxyethylmethacrylate) - PHEMA (Marchant & Wang, 1994)	0.3	0.8	50	115 (dry)	–	>1	–	Catheter coating; drug delivery device; soft contact lens; vascular prosthesis coating; burn dressing
Poly(vinyl alcohol) (Kroschwitz, 1990)								
(98–99% hydrolyzed)	67–110		0–300	85	230	–	–	Drug delivery devices
(87–89% hydrolyzed)	24–79			58	180			
Poly(ε-caprolactone) (M_w: 44,000) (Engelberg & Kohn, 1991)	16	0.4	80	–62	57	<0.2	–	Drug delivery devices
Poly(glycolic acid) - PGA (Fambri, 2002)	57	6.5	–	35	225	–	–	Drug delivery devices; absorbable sutures; vascular stents
(fibers)	750	13.4		–	233			
Poly(lactic acid)—PLA (Engelberg & Kohn, 1991)								
L-PLA (M_w: 50,000–300,000)	28–48	1.2–3.0	6–2	54–59	170–178	–	–	Drug delivery devices; vascular stents
D,L-PLA (M_w: 107,000–550,000)	29–35	1.9–2.4	6–5	51–53	–			

TABLE B1 **Some Mechanical and Physical Properties of the Most Common Polymers Used as Biomaterials and the Respective Application**

Polymer	Tensile Strength (MPa)	Tensile Modulus (GPa)	Elongation (%)	T_g (°C)	T_m (°C)	Water Absorption (%)	Water Contact Angle (°)	Biomedical Applications (Marchant & Wang, 1994; Pruitt, 2017; Lee et al., 2000; Maitz, 2015; Kroschwitz, 1990)
Poly(ortho ester)[d] (M_w: 99,700)	20	0.82	220	55	–	0.2–1	–	Drug delivery devices
Poly(β-hydroxybutyrate) - PHB (Engelberg & Kohn, 1991) (M_w: 370,000)	36	2.5	2.5	1	171	–	–	Drug release devices; sutures; artificial skin; cardiovascular patches;
Poly(hydroxybutyrate-*co*-22 mol% hydroxyvalerate) (Engelberg & Kohn, 1991) (M_w: 227,000)	16	0.62	36	–5	137	–	–	orthopedic pins; nerve guides; wound dressings; bone marrow scaffolds (Chen & Wu, 2005)
Cellulose acetate (Kroschwitz, 1990)	13.1–58.6	0.6–1.8	6–50	–	306	2.0–6.5	–	Hemodialysis membrane
Collagen (Pins et al., 1997)[e] (uncrosslinked fibers) (crosslinked fibers)	0.70–1.12 29.7–63.9	$(1.5–2.2) \times 10^{-3}$ 0.271–0.495	61.1–74.8 12.9–18.3	–	–	–	–	Hemostatic agent; vascular prosthesis; heart valves; tendons and ligaments; wound and burn dressings; absorbable sutures (Li, 2000)
Silk (Perez-Rigueiro et al., 2000; Vepari & Kaplan, 2007)[f] (with sericin) (without sericin)	500 610–690	5–12 15–17	19 4–16	–	–	–	–	Nonabsorbable sutures; wound healing dressings; scaffolds for regeneration of bone, cartilage, tendon, and ligaments tissues (Vepari & Kaplan, 2007)
Chitosan (Lim et al., 1998)[g] (M_v: $(8.73 \pm 0.55) \times 10^5$) (Deacetylation (%): 8.17 ± 0.35)	56.2–67.6	2.93–3.30	26.9–33.3	50.8–53.2	–	–	–	Surgical sutures; dental implants; artificial skin; rebuilding of bone; corneal contact lenses; drug release devices (Rinaudo, 2006)

[a]There are several medical concerns about PVC due to phthalate plasticizer di(2-ethylhexyl) phthalate (DEHP) that is released to the ambience and dissolves in the lipid bilayers of cells (Maitz, 2015).
[b]Values are averages of advancing and receding contact angles.
[c]Flexural modulus.
[d]Transcyclohexane dimethanol (t-CDM):1,6-hexanediol (1,6-HD) = 35:65.
[e]Acid-soluble collagen obtained from rat tail tendons. Collagen fibers coextruded using NaCl (coagent).
[f]*Bombyx mori* single-brin silkworm silk.
[g]Chitosan films.

TABLE C1 **Properties of Metals and Alloys Used for Surgical Implants[a]**

Material	Nominal Composition (w/o)	Modulus of Elasticity (GPa)	Tensile Strength (MPa)	Elongation to Fracture (%)
Titanium (Ti) and alloys	99⁺Ti (Grades I–IV)	100	240–550	15–24
	90Ti–6Al–4V	120	860–930	8–10
	90Ti–6Al–4V (ELI)		825–860	8–10
	87Ti–6Al–7Nb		900–1100	10
	74Ti–13Nb–13Zr		550–860	8–15
	80Ti–12Mo–6Zr–2Fe		930	12
	85Ti–15Mo		690–900	10–20
	Ti–3Al–2.5V		620–860	10–15
Cobalt–chromium (Co–Cr) alloys	66Co–28Cr–6Mo	235	520–1170	8–20
	35Co–35Ni–20Cr–10Mo		790–1580	3–50
	40Co–20Cr–16Fe–15Ni–7Mo		450–2245	1–65
	55Co–20Cr–15W–10Ni		310–1730	15–45
Stainless steel (316L)	70Fe–18Cr–12Ni	190	480–1000	>30
Zirconium (Zr) and alloys	99⁺Zr	100	450–550	15–20
	97.5Zr–2.5Nb		450	15–30
Tantalum (Ta)	99⁺Ta	–	170–520	1–30
Nickel–titanium (Ni–Ti) alloy	45Ni–57Ti		550	10–15
Gold (Au)	99⁺Au	100	210–310	>30
Platinum (Pt)	99⁺Pt	165	130	40

[a]Minimum values from the American Society for Testing and Materials Committee F4 Annual Book of Standards, Volume 13.01, Medical and Surgical Materials and Devices, 2013. Selected products provide a range of properties due to differences in processing (cast, forged, wrought), heat treatment, and section size.

TABLE C2 Properties of Inert Ceramic Biomaterials[a]

Material	Modulus of Elasticity (GPa)	Compressive Strength (MPa)	Flexural Strength (GPa)
Aluminum oxide	150–400	80–5000	6–640
Zirconium oxide (zirconia)	150–240	400–1750	50–900
Titanium oxide (titania)	280		69–103
Carbon	7–30	50–700	70–255
Carbon–silicon (LTI)	25–40	900	200–700

LTI, Low-temperature isotropic.
[a]These high ceramics have 0% permanent elongation at fracture. Selected products have a range of properties due to differences in porosity, density, and whether single crystal or polycrystalline.

TABLE C3 Properties of Bioactive and Biodegradable Ceramics[a]

Material	Modulus of Elasticity (GPa)	Compressive Strength (MPa)	Flexural Strength (MPa)
Hydroxyapatite	10–120	60–800	15–300
Tricalcium phosphate	30–120	120	15–120
Bioglass or Ceravital	40–140		20–350
A/W ceramic	124		213

A/W, Apatite/wollastonite.
[a]These ceramics and carbons have 0% permanent elongation at fracture. Selected products have a range of properties due to differences in porosity and density.

Appendix D

The Biomaterials Literature

WILLIAM R. WAGNER

McGowan Institute for Regenerative Medicine, Departments of Surgery, Bioengineering & Chemical Engineering, University of Pittsburgh, Pittsburgh, PA, United States

An excellent way to get a sense of the current directions in biomaterials research is to peruse the table of contents for recent issues of some of the leading journals in the field. One will find research reports that fall within most of the topics covered in this textbook regarding biomaterials development, new biomaterials applications, and ongoing efforts to define the mechanisms underlying the biological response to biomaterials placed in the body. A noncomprehensive list of journals publishing in the field is found in Table D1. Many of the journals in this list were not publishing at the turn of the century, reflecting how the biomaterials field has rapidly grown in the past 20 years. This growth is not surprising. Global research output has increased as government and industrial funding has been directed to the field in recognition of the role it will play for an aging population with rising economic resources at their disposal to dedicate to healthcare. With more research output comes the demand for more forums for publication, thus not only have the number of biomaterials journals increased, the spectrum of subtopic coverage has increased, and the selectivity and broader scientific impact of the leading journals continue to grow. All of these are healthy indicators of a vibrant, promising field.

While the diverse literature of today provides an effective snapshot of current trends and thinking, it is also a worthwhile exercise to look back 10, 20, or even 50+ years and read the manuscripts in some of the leading journals of those periods. While in the earliest days many of the advancements were reported in clinically related journals, one pioneering journal where some of the most impactful biomaterials and medical device research was reported in the 1950s and 1960s was the *American Society for Artificial Internal Organs* (*ASAIO*) *Journal*. It is a humbling experience to read about the researchers of that time tackling many of the same problems (e.g., blood biocompatibility, material degradation) as today, with a much more limited tool set, but excellent clinical and engineering insight and careful methodologies.

Anyone who has served as a referee in the manuscript peer-review process has had the experience of finding authors who are unaware of similar published efforts. Today's literature databases offer unprecedented tools to find relevant reports on a given topic area. Offsetting this, the number of papers to search is growing in a nonlinear fashion, and authors may not devote adequate time and care to find and consider how their work fits in the body of knowledge. Searching and reading the biomaterials literature in one's area of work is necessary not only to prevent expending resources on previously well-investigated topics, but it can stimulate creativity when the reader brings to bear their advantage of unique perspective and progress with time to chart an important step forward.

Looking to the more recent past of 10–20 years ago, surveying the literature can lead to the question, "so what happened?" So many reports show good outcomes, often in relevant preclinical models. Why then did most of this work never translate to today's standard of clinical care? While part of the answer may be scientific, the other factors are why the editors of this textbook have sought to emphasize the broader context in which biomaterials science exists. Manufacturability, intellectual property position, regulatory pathway, disruption of standard of care, investment return potential, legal liability, and other not strictly scientific considerations have all served to dissuade or block the progress of promising literature reports from ever making it to the intended patients. The literature does not routinely publish such stories, but knowledge of how such considerations effectively prevent translation is critical for any biomaterials scientist to understand and to weigh against the optimistic reports that continue to be published in growing numbers.

With respect to the long list of journals in Table D1, just by the titles one can glean the focus area; but how does one compare the "quality" or "impact" of the papers in the various journals? There are numerous parameters devised to reflect such markers of impact, but it is important to note that such indicators are averages and subject to peripheral factors. The most common indicator, the journal impact factor (from Journal Citation Reports and updated annually), provides a measure of the average number of times articles published in the 2 years preceding the most recently completed year have been cited in the most recently completed year. Higher impact factor journals will generally be more selective and may have more rigorous peer-review procedures, but this is not absolute. For instance, a topic that has fewer overall papers published will have fewer papers that could cite an earlier paper and thus that topic may have

lower impact factor journals. Authors are well served to carefully consider where they seek to publish their work, but in doing so consider more than the journal's current impact factor. How does your paper fit within the journal scope? Are you better suited to targeting a more clinically focused journal? Is the peer-review process rigorous and generally fair? Is the time to publish reasonably fast? Is the journal large enough to be carried by libraries and appear on databases? Is there an option for open-access publication if you have the desire or need to publish in this manner and is the publication fee reasonable?

In addition to the journals that cover biomaterials-related topics, there are many books that have been published seeking both to generally cover the field and to provide overviews of the growing number of subtopics. An exhaustive list is again not possible, but Table D2 may provide the reader with a sense of recent texts and those that have been well received by the community. A well-prepared text can provide an excellent foundation when seeking to learn about a new field. The growing number of peer-reviewed review articles in the literature is also useful for timely coverage on a given subtopic.

Finally, it is worth mentioning the patent literature. Given the importance of intellectual property protection in the commercialization process and achieving the goal of impacting the patient, a biomaterials scientist may encounter this literature in academic, industrial, and legal settings. Progressing through the examination process to be awarded a patent is much different than the scientific peer-review process. However, an understanding of the principles covered in the textbook comes into play, for instance, when arguing whether a patent claim can be anticipated by one skilled in the art based on prior patents and the biomaterials literature.

Assessment of Cell and Matrix Components in Tissues

RICHARD N. MITCHELL, FREDERICK J. SCHOEN

Department of Pathology, Brigham and Women's Hospital, Boston, MA, United States of America

Techniques commonly used to study the structure of tissues—and the purpose of each mode of analysis—are summarized in Table F1. While not completely comprehensive, Table F1 reflects the traditional morphologic approaches to tissue assessment, in addition to the more recent genetic, proteomic, metabolomic, physicochemical, and quantitative techniques that can inform and direct biomaterials and device development.

The most widely used—and most broadly informative—technique is still light microscopy, described in greater detail later. Several additional tissue analysis techniques are also available to address specific questions concerning cell and tissue structure and function (see later). Although microscopy can be a purely qualitative evaluation of cell and tissue pathology (e.g., cell death, regeneration, inflammation, neoplasm, etc.), quantitative information can be gleaned from tissue sections using various manual or computer-aided methods. Such morphometric approaches can be extremely useful in providing an objective basis for otherwise subjective measurements (Loud, 1984).

It is frequently necessary to accurately ascertain or verify the identity of a cell, or to determine some aspect of its function, including the synthesis of specific molecules. For such an assay, either isolated cells or whole tissues are used, depending on the objective of the study. *Isolated cells* have the advantage of allowing molecular and/or biochemical analyses on individual cells or synthetic products—often yielding quantitative data. Gene expression profiling allows the analysis of the genes expressed in cells or tissues; the technology may identify pathogenetically distinct cellular subtypes and suggest fundamental mechanisms even when candidate genes are unknown (Duggal, 2009). Increasingly, mass spectroscopy techniques also provide a functional assessment of the metabolic pathways that are the integrated output of all the genetic influences. Conversely, *whole tissue preparations* allow the investigator to spatially localize molecules of interest in the context of architectural features of the tissue; such information is lost in most cases when tissues are digested to release individual components.

Light Microscopy

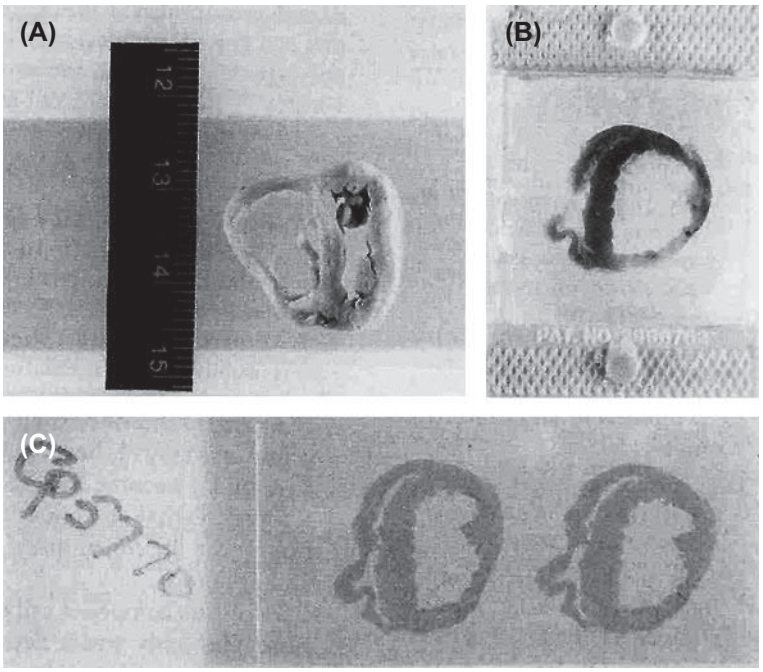
Conventional light microscopy starts with obtaining tissue samples by surgical excision (removal), biopsy (sampling), or autopsy (postmortem examination). This is followed by fixation, embedding in paraffin, thin sectioning (5–50 μ), adherence to a glass slide, staining with various vital dyes, and microscopic examination (Fig. F1). Photographs of conventional tissue sections taken through a light microscope (photomicrographs) are illustrated in Fig. F2.

To preserve the structural integrity of cells, subcellular structures, and extracellular matrix (ECM), excised tissues are "fixed," typically by denaturing and cross-linking protein amino groups with aldehyde reagents (forming Schiff base and Amadori rearrangement adducts). Formaldehyde is the typical fixative for light microscopy, while glutaraldehyde preserves subcellular structural elements better for scanning or transmission electron microscopy (TEM). Fixative solutions prevent degradation of tissue (*autolysis*—typically caused by release of intracellular hydrolytic enzymes) after samples have been removed from their normal sources of oxygen and nutrition. Fixation also variably immobilizes fats and carbohydrates, and kills microorganisms present in tissues. However, such denaturation and cross-linking can also adversely impact enzymatic and antigenic reactivity that might be targets of interest when analyzing the tissue. It is noteworthy that for tissues like bone with a highly calcified matrix, specimens must usually be *decalcified* (by prolonged immersion in acid) prior to sectioning; such treatment also adversely impacts antigenicity and subsequent analysis.

To provide a more solid substrate for sectioning, water in a tissue specimen (approximately 70% of tissue mass) must be substituted for paraffin wax or other embedding media (e.g., glycolmethacrylate). This is done through several steps, beginning with dehydration of the specimen through increasing concentrations of ethanol (eventually to absolute). Since alcohol is not miscible with paraffin (the most common final embedding medium), xylol (an organic solvent) is used as an intermediate solution before embedding in paraffin. All this is important to understand because the organic solvent steps will cause the variable loss of lipids and other lipophilic materials in the tissues.

TABLE F1 **Techniques Used to Study Tissue**

Technique	Purpose
Microbiologic cultures	Diagnose the presence of infectious organisms
Morphology	
Gross examination	Determines overall specimen configuration; many diseases and processes can be diagnosed at this level
Light microscopy (LM)	Studies overall microscopic tissue architecture and cellular structure; different stains allow analysis of, e.g., calcium, fat, matrix, apoptotic cell death, etc.
Transmission electron microscopy (TEM)	Studies ultrastructure (fine structure) and identifies cells and their organelles and environment
Scanning electron microscopy	High-resolution 3D imaging
Optical coherence tomography	Visualizes microscopic structures using lightwave diffraction; can be applied to tissues in situ
Microscopic computed tomography	High-resolution 3D microscopy
High-resolution microscopy	Super-resolution, two-photon microscopy, confocal microscopy
Morphometric studies (gross, LM, or TEM levels)	Quantitate the amounts, configuration, and distribution of specific structures
Genetic Analysis (Genomics)	
Maintaining Tissue Architecture Relationships	
In situ hybridization	Identifies the presence and location of mRNA or DNA within cells and tissues in histological sections
Laser capture microdissection	Procures specific microscopic regions of tissue sections containing small collections of cells to apply molecular analysis methods
Information on Total Tissue Without Architecture	
Northern blot	Detects the presence, amount, and size of specific mRNA molecules
Southern blot	Detects and identifies specific DNA sequences
Polymerase chain reaction	Cyclical amplification of DNA to produce sufficient material for analysis
DNA microarray	Identifies sequence (gene/gene mutation) and determines expression level (abundance) of genes; also known as DNA chip or gene array; microarray on a single chip of tiny spots, each representing a unique cloned cDNA or oligonucleotide
Single cell sequencing	Allows identification of unique RNA expression profiles; can characterize rare cells or cellular heterogeneity (e.g., in tumors)
Protein Analysis (Proteomics)	
Maintaining Tissue Architecture Relationships	
Enzyme histochemistry	Demonstrates the presence and location of enzymes in gross or microscopic tissue sections
Immunohistochemistry	Identifies and locates specific molecules, usually proteins, for which a specific antibody is available
Tissue microarray	Permits study of multiple lesions simultaneously using tissues from multiple patients or blocks on the same slide; produced using a needle to biopsy conventional paraffin blocks and placing the cores into an array on a recipient paraffin block
Information on Total Tissue Without Architecture	
Western blot	Identifies the presence and amount of specific proteins
Flow cytometry	Isolated cells are characterized by surface or intracellular protein expression patterns; cells may be sorted and subsequently analyzed by other techniques (e.g., RNA, metabolites, etc.)
Mass spectroscopy	Can identify a broad spectrum of metabolic products, thus integrating functional genetic and protein outputs (metabolomics); newer techniques may allow analysis on tissue sections, preserving architectural information
Physicochemical Analysis	
Maintaining Tissue Architecture Relationships	
Energy dispersive X-ray analysis	Performs site-specific elemental analysis on surfaces of tissue sections
Collagen orientation	Allows microscale analysis of matrix organization
Information on Total Tissue Without Architecture	
Chemical, biochemical, and spectroscopic analysis	Assesses bulk concentration of molecular or elemental constituents



• **Figure F1** Steps in tissue processing for light microscopy. (A) Tissue section. (B) Tissue in a paraffin block. (C) Resulting stained histologic section on a glass slide.

Tissue specimens are routinely sectioned on a *microtome*; 5 μ thick slices are then adhered to glass slides. Sections for light microscopic analysis must be thin enough to both transmit light and avoid superimposition of various tissue components. Since 5 μ is thinner than the diameter of most cells, structures may not be entirely represented depending on where a cut is made (for example, a cell may appear to lack a nucleus; Fig. F3). Thus interpretation of tissue sections depends on the reconstruction of three-dimensional information from two-dimensional observations on tissue sections. A particular structure (even a very simple one) can look very different, depending on the plane of section. Thicker sections (up to 100 μ) may be used for special analyses to evaluate three-dimensional architecture and require different microscopic techniques. If extremely thin sections are required for TEM analysis (e.g., approximately 0.06 μ), a harder embedding medium (usually epoxy plastic) and a correspondingly harder knife (usually diamond) are used. Alternatively, if immediate evaluation of a tissue is required (typical processing takes 12–24 h), samples can be frozen in special embedding media that allows 5–10 μ sections to be made and instantly examined. Although quick, the quality of the appearance of such *frozen section analysis* is inferior to that obtained by conventional methods due to ice expansion and the ensuing displacement artifacts. For sections examining the interface of bone or metal with soft tissue, tissues can be prepared by embedding in epoxy followed by sectioning or grinding to 50–100 μ thickness.

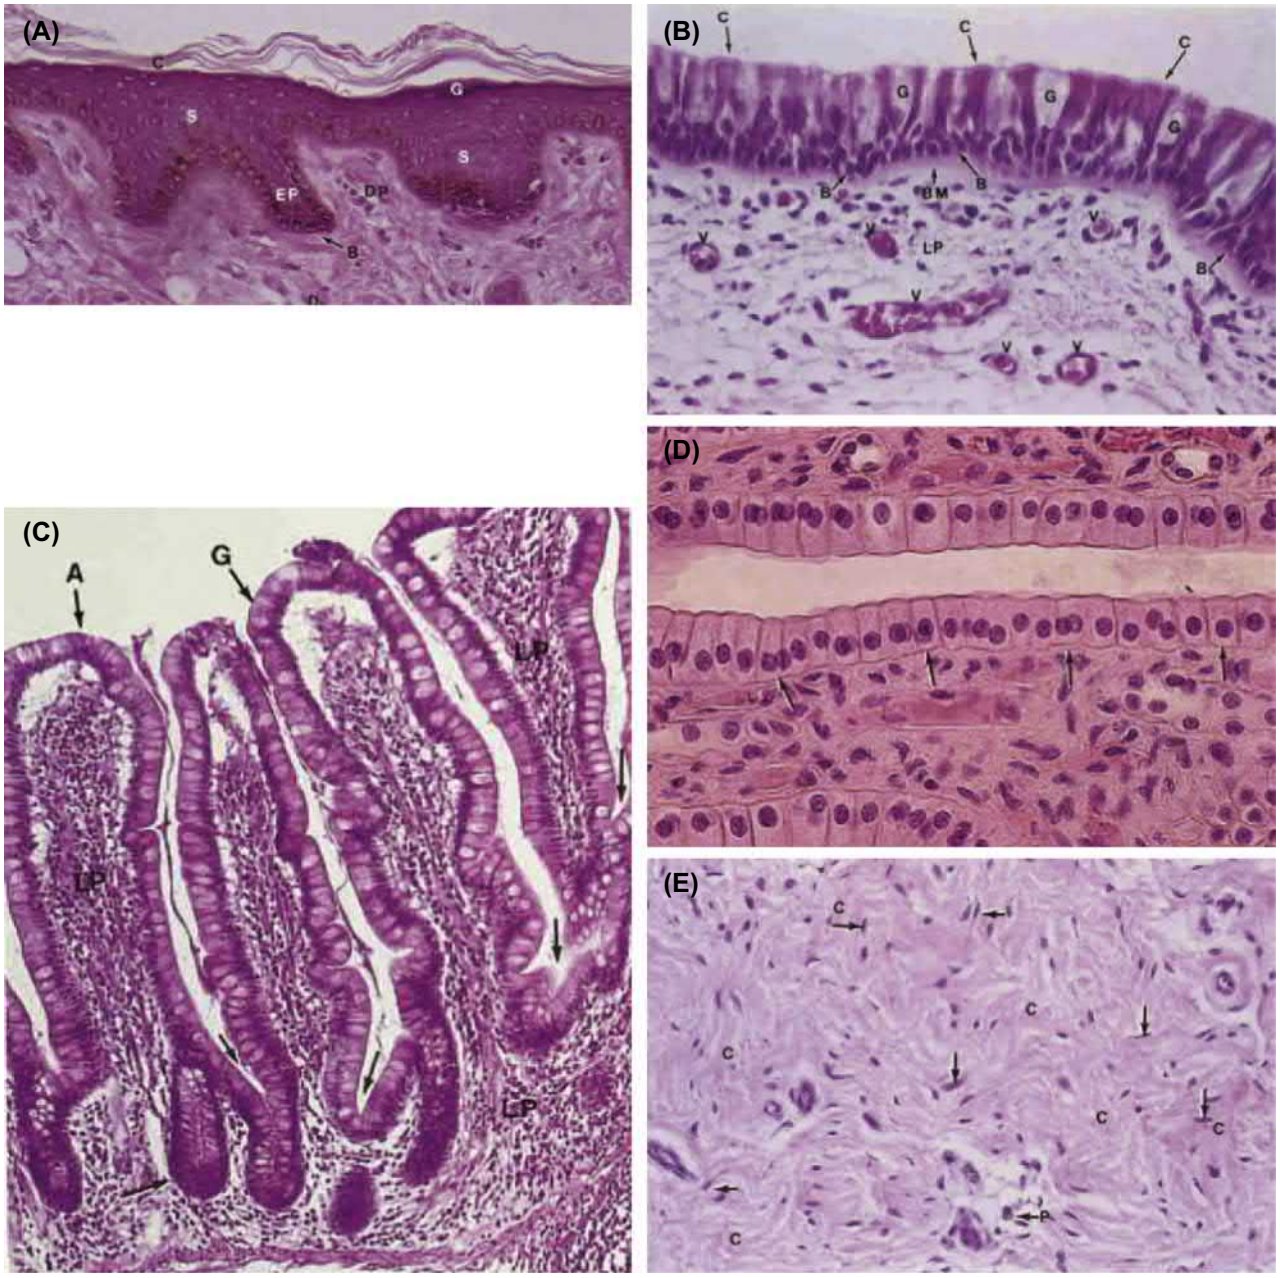
Tissue components have no intrinsic contrast and are of fairly uniform optical density. Consequently, for tissues to be visualized and distinguished by light microscopy, they are differentially stained by selective adsorption of dyes. Since most stains are aqueous dye solutions, staining requires that the paraffin in the tissue section be removed and replaced by water (rehydration). The stain used routinely in histology involves sequential exposure to hematoxylin and eosin. Hematoxylin is a basophilic dye that stains negatively charged molecules (e.g., DNA, RNA, calcium phosphate, etc.) blue–purple. In contrast, eosin is an acidophilic counterstain that colors positively charged materials (e.g., cell cytoplasmic or ECM proteins) pink–orange. The tissue sections shown in Fig. F1 are all H&E stained.

Special Staining

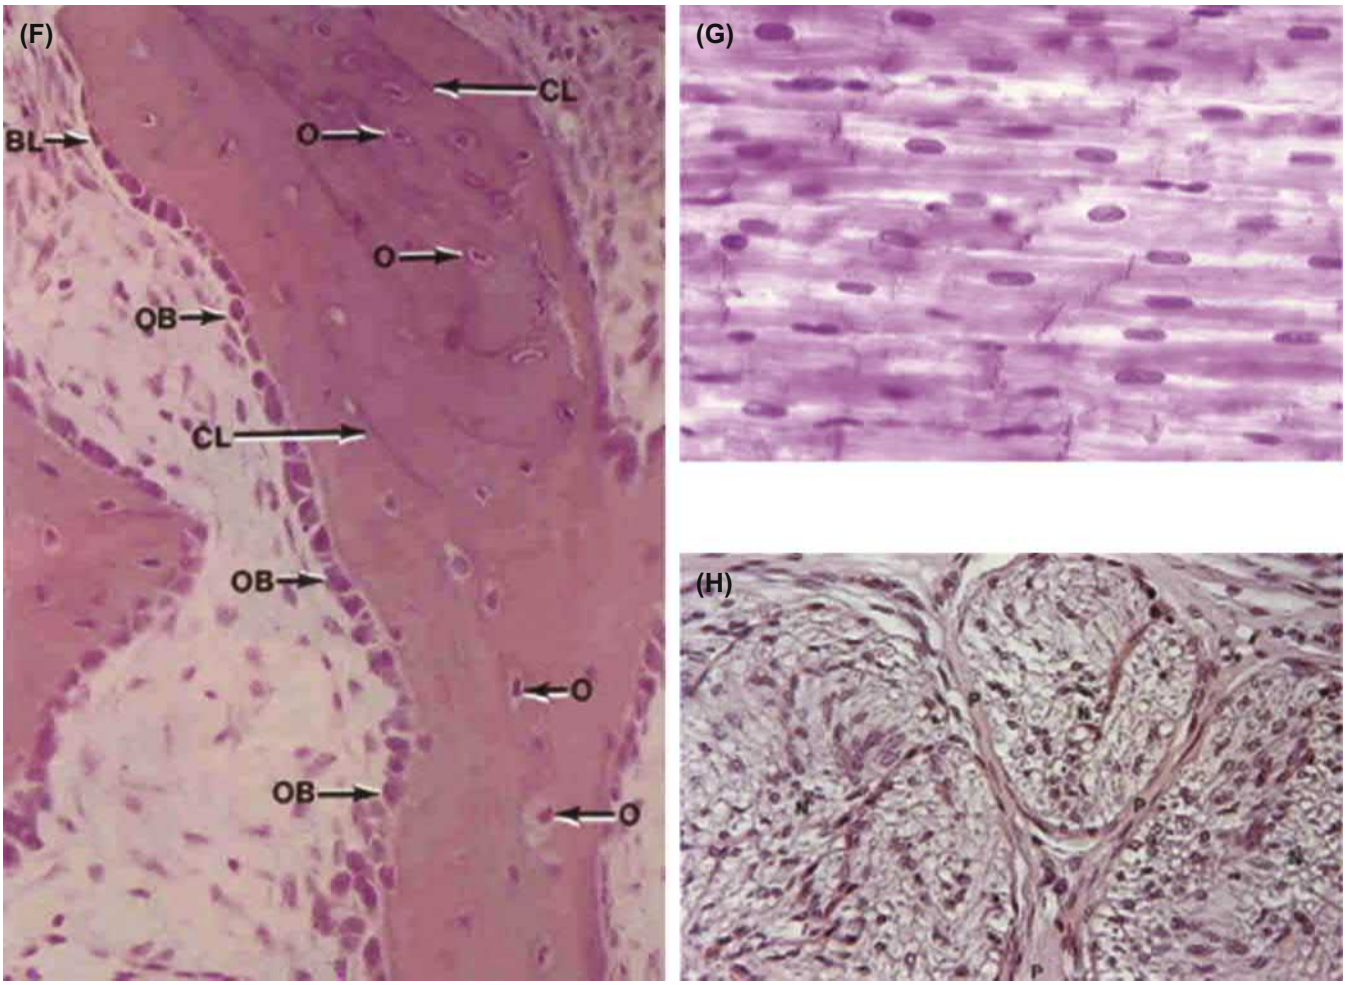
This methods can highlight components that would not otherwise stain well using routine histochemistry (e.g., microorganisms) or to indicate the chemical nature of a specific tissue component (e.g., collagen, elastin, calcium, fat, glycogen, iron, fibrin, etc.). There are also commonly available techniques for demonstrating the specific chemical activity of an enzyme in tissues (e.g., esterases in neutrophils and macrophages); the substrate for an enzyme of interest is reacted with the tissue, and a colored precipitate deposits at the site of expression. Still other stains offer the ability to quantify apoptotic cell death, mitochondria, and nuclei.

Immunohistochemical Staining

This method takes advantage of the antigenicity of a tissue component to demonstrate its location and rough abundance (although the technique is at best only semiquantitative). Antibodies to a given cell or tissue constituent are attached to a fluorescent molecule (*immunofluorescence*) or an enzyme (typically horseradish peroxidase; *immunoperoxidase* technique) and reacted with tissue sections.



• **Figure F2** Photomicrographs of various tissues, emphasizing key structural features. (A)–(D) different epithelia; (E) and (F) connective tissue; (G) muscle; and (H) nervous tissue. (A) Skin—An example of a stratified squamous epithelium. A thin superficial acellular *stratum corneum* (C) rests on the *stratum granulosum* (G) and *stratum spinosum* (S) layers, the latter constituting the bulk of the skin epithelium thickness. The *stratum basale* (B) contains proliferating skin adult stem cells and rests on the basement membrane separating the *epidermis* from the *dermis* (D); EP represents *epidermal pegs*; DP represents *dermal papillae.* (B) Trachea—The epithelium here is composed of a single "pseudostratified" layer of cells sitting on the basement membrane (BM); the cells in the epithelium include mucous-rich *goblet cells* (G), ciliated *columnar cells* (C), and *basal stem cells* (B). Deep into the epithelium is the submucosa containing extracellular matrix (*lamina propria*; LP), and punctuated by multiple blood vessels (V). (C) Mucosa of the small intestine (ileum)—The epithelium here is composed of a single layer of *columnar absorptive cells* (C), interspersed with *goblet cells* (G); to increase the overall absorptive surface area, the epithelium is organized into elongated villi and invaginated crypts (*arrows*), the latter containing the adult stem cells of the small bowel. The epithelium is attached to a basement membrane that rests over the underlying LP. (D) Epithelium of a kidney collecting duct—This is composed of relatively uniform cuboidal cells sitting atop the basement membrane (*arrows*). (E) Dense irregular connective tissue, with wavy unoriented collagen bundles (C) synthesized by the interspersed fibroblasts (*arrows*)—(P) represents plasma cells—terminally differentiated antibody-secreting cells of B lymphocyte lineage. (F) Cancellous bone–(O) are quiescent osteocytes within a calcified bony matrix; (OB) are proliferating osteoblasts that are synthesizing new bone; (BL) represents inactive bone-lining osteoblasts; (CL) represents *cement lines* between adjacent fascicles of bone. (G) Myocardium (cardiac muscle) composed of rectangular striated cells (striations represent actin–myosin sarcomeres responsible for cellular contraction) with centrally placed nuclei and connected end to end by *intercalated discs*. (H) Cross-sections of nerve bundles (N) separated by *perineurium* (P). Most of the nuclei here are from myelinating *Schwann cells* surrounding the individual neuronal axons. ((A)–(F) and (H) reproduced with permission from Berman, I. (1993) *Color Atlas of Basic Histology*, Appleton and Lange; (G) reproduced by permission from Schoen, F.J. (2005). The Heart in Cotran, R.S., Kumar, V., and Fausto, N. (eds.) *Robbins and Cotran Pathologic Basis of Disease,* 7th Ed. Saunders: Philadelphia, PA.)



• **Figure F2 cont'd.**

Subsequent fluorescence microscopy or peroxidase substrate precipitation allows the identification of particular antigens. The general approach can be expanded by the use of *tissue microarrays*; cores of tissue from several different samples or patients are embedded together in a single paraffin block. Subsequent thin sections of these multiple cores allow the simultaneous multiplex staining of 100's of samples to evaluate the concordance of antigen and histologic patterns.

Although some antigens and enzymatic activity can survive conventional fixation and histological processing, many are rendered inactive by denaturation and cross-linking. Consequently, histochemistry and immunohistochemistry must either be performed on frozen sections, or special *antigen recovery techniques* need to employed.

In Situ Hybridization

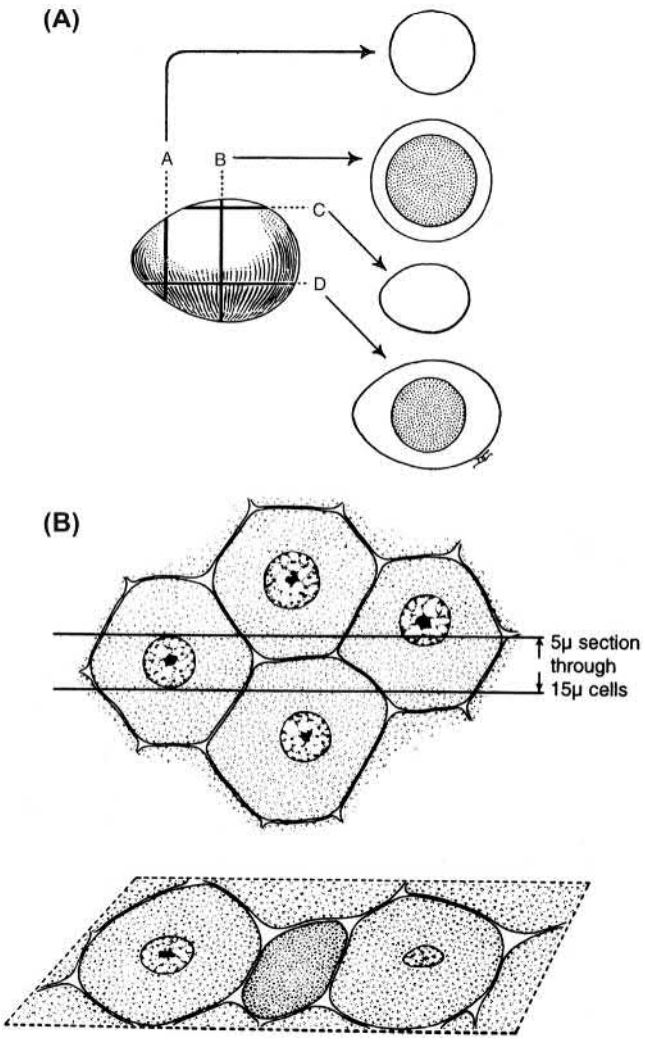
Cells can also be characterized by their nucleic acid products (e.g., mRNA); thus specific DNA or RNA probes are labeled with fluorophores or enzymes and allowed to bind to complementary sequences. Like immunohistochemistry, the approach is semiquantitative, and subject to a number of artifacts, including DNA/RNA fragmentation from poor preservation.

Electron Microscopy

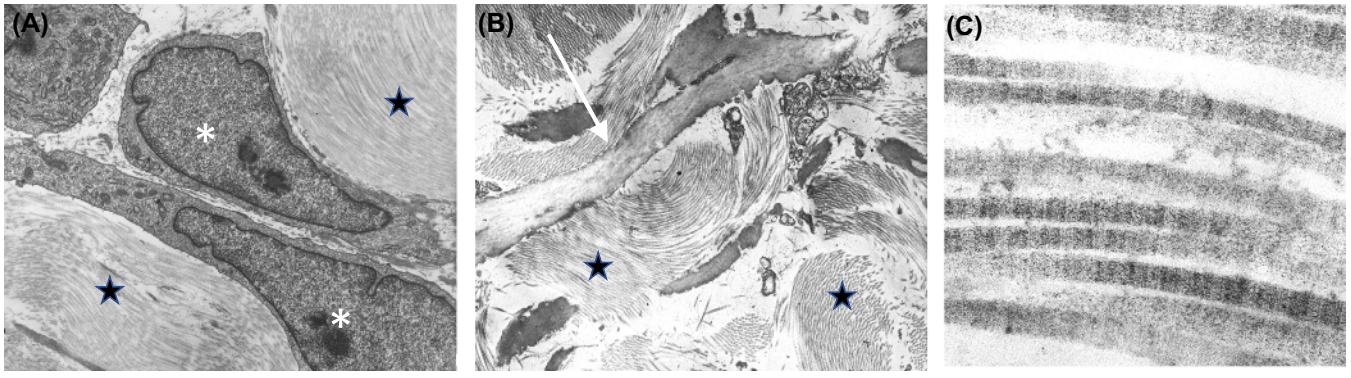
Providing contrast for TEM depends on relative electron densities of tissue components. Sections are stained with salts of heavy metals (osmium, lead, and uranium), which react differentially with different structures, creating patterns of electron density that reflect tissue and cellular architecture. An example of an electron photomicrograph is shown in Fig. F4. Immunoelectron microscopy can be done using antibodies tagged with various size beads of heavy metals (e.g., gold).

Special Techniques

Higher resolution of structures (two-photon and superresolution microscopy), simultaneous evaluation of several antigenic markers (multiplexed immunohistochemical techniques), three-dimensional evaluation (confocal microscopy), and live cell imaging (e.g., using optical coherence tomography) provide additional approaches to interpret structure and function. Laser capture microdissection is a means to carve out specific portions of a tissue adherent on a slide; in that manner, the specific genetic expression pattern of selected cells can be evaluated without confounding background, e.g., from fibroblasts or normal tissue elements. Single cell sequencing allows the identification of unique cell types within heterogeneous populations.



• **Figure F3** Interpreting three-dimensional structure from two-dimensional representations. Sections through a structure at different levels and orientations can give different appearances. (A) Example with a hard-boiled egg; (B) section through a tissue with uniform cells, where the final image suggests heterogeneity. (Modified by permission from Cormack, D.H. (1993). *Essential Histology*. Lippincott.)



• **Figure F4** Transmission electron micrographs demonstrating ability to see fine structure of cells and extracellular matrix. (A) cells (asterisk), surrounded by fibrous collagen (stars). (B) Elastin fibril (arrow), surrounded by fibrous collagen (stars). (C) Collagen at very high magnification, showing individual collagen fibrils with typical banding pattern. Original magnifications: (a and b) 8000X; (c) 120,000X.
