Society For Biomaterials
Giving life to a world of materials

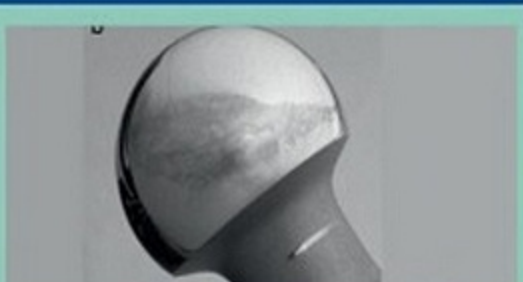
FOURTH EDITION

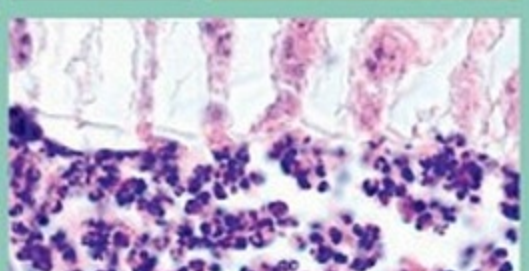
BIOMATERIALS SCIENCE

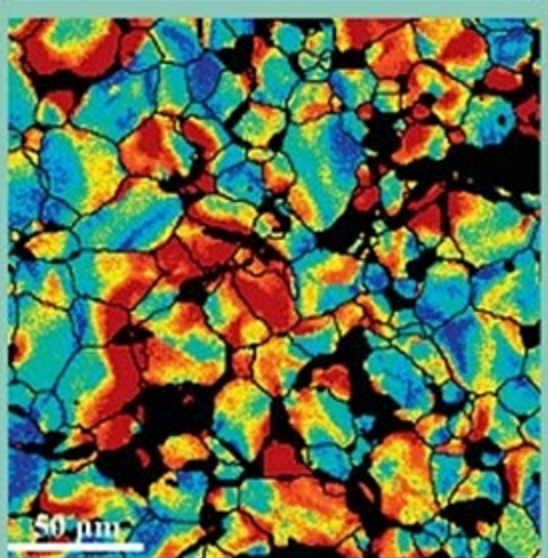
An Introduction to Materials in Medicine

EDITED BY
WILLIAM R. WAGNER, SHELLY E. SAKIYAMA-ELBERT
GUIGEN ZHANG, MICHAEL J. YASZEMSKI

FOUNDING EDITORS
BUDDY D. RATNER, ALLAN S. HOFFMAN
FREDERICK J. SCHOEN, JACK E. LEMONS







Biomaterials Science

An Introduction to Materials in Medicine

Fourth Edition

Edited By

William R. Wagner

Distinguished Professor of Surgery
Bioengineering & Chemical Engineering
University of Pittsburgh
Director
McGowan Institute for Regenerative Medicine
Pittsburgh, PA, United States

Shelly E. Sakiyama-Elbert

Professor and Department Chair
Fletcher Stuckey Pratt Chair in Engineering
Department of Biomedical Engineering
The University of Texas at Austin
Austin, TX, United States

Guigen Zhang

Professor and F Joseph Halcomb III, M.D. Endowed Chair, Chair of the F. Joseph Halcomb III, M.D.
Department of Biomedical Engineering
University of Kentucky
Lexington, KY, United States

Michael J. Yaszemski

Krehbiel Family Endowed Professor of Orthopedics and Biomedical Engineering, Mayo Clinic
Rochester, MN, United States

Founding Editors

Buddy D. Ratner, Allan S. Hoffman

Frederick J. Schoen, Jack E. Lemons

Notices
Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

List of Contributors

Abhinav Acharya
School for Engineering of Matter, Transport and Energy, Biodesign Center for Immunotherapy, Vaccines and Virotherapy, Arizona State University, Tempe, AZ, United States

Marian A. Ackun-Farmmer
Department of Biomedical Engineering, University of Rochester, Rochester, NY, United States; Department of Orthopaedics and Center for Musculoskeletal Research, University of Rochester, Rochester, NY, United States

John R. Aggas
Center for Bioelectronics, Biosensors and Biochips (C3B), Department of Biomedical Engineering, Texas A&M University, College Station, TX, United States; Department of Biomedical Engineering, Texas A&M University, College Station, TX, United States

Phillip J. Andersen
Andersen Metallurgical, LLC, Madison, WI, United States

James M. Anderson
Department of Pathology, Case Western Reserve University, Cleveland, OH, United States

Kristi Anseth
Department of Chemical and Biological Engineering, University of Colorado, Boulder, CO, United States; Biofrontiers Institute, University of Colorado, Boulder, CO, United States

Paul A. Archer
Parker H. Petit Institute for Bioengineering and Bioscience, Georgia Institute of Technology, Atlanta, GA, United States; School of Chemical and Biomolecular Engineering, Georgia Institute of Technology, Atlanta, GA, United States

Nureddin Ashammakhi
Center for Minimally Invasive Therapeutics (C-MIT), California NanoSystems Institute (CNSI), University of California-Los Angeles, Los Angeles, CA, United States

Jose D. Avila
W. M. Keck Biomedical Materials Research Laboratory, Washington State University, Pullman, WA, United States

Julia E. Babensee
Wallace H. Coulter Department of Biomedical Engineering, Georgia Institute of Technology and Emory University, Atlanta, GA, United States

Stephen f. Badylak
University of Pittsburgh, Pittsburgh, PA, United States

Kiheon Baek
Department of Biomedical Engineering, University of Rochester, Rochester, NY, United States; Center for Musculoskeletal Research, University of Rochester Medical Center, Rochester, NY, United States

Aaron B. Baker
Department of Biomedical Engineering, University of Texas at Austin, Austin, TX, United States

Syeda Mahwish Bakht
3B's Research Group, I3Bs–Research Institute on Biomaterials, Biodegradables and Biomimetics, University of Minho, Headquarters of the European Institute of Excellence on Tissue Engineering and Regenerative Medicine, Guimarães, Portugal; ICVS/3B's–PT Government Associate Laboratory, Braga/Guimarães, Portugal; The Discoveries Centre for Regenerative and Precision Medicine, Headquarters at University of Minho, Guimarães, Portugal

Amit Bandyopadhyay
W. M. Keck Biomedical Materials Research Laboratory, Washington State University, Pullman, WA, United States

Aaron Barchowsky
Department of Environmental and Occupational Health, University of Pittsburgh, Pittsburgh, PA, United States

Garrett Bass
Departments of Chemistry, Mechanical Engineering and Materials Science, Biomedical Engineering and Orthopaedic Surgery, Duke University, Durham, NC, United States

Matthew L. Becker
Departments of Chemistry, Mechanical Engineering and Materials Science, Biomedical Engineering and Orthopaedic Surgery, Duke University, Durham, NC, United States

Sarah Miho Van Belleghem
University of Maryland College Park; NIH/NIBIB Center for Engineering Complex Tissues

Danielle S.W. Benoit
Department of Biomedical Engineering, University of Rochester, Rochester, NY, United States; Department of Orthopaedics and Center for Musculoskeletal Research, University of Rochester, Rochester, NY, United States; Materials Science Program, University of Rochester, Rochester, NY, United States; Department of Chemical Engineering, University of Rochester, Rochester, NY, United States; Department of Biomedical Genetics and Center for Oral Biology, University of Rochester, Rochester, NY, United States; Translational Biomedical Science Program, University of Rochester, Rochester, NY, United States

Arne Biesiekierski
School of Engineering, RMIT University, Bundoora, VIC, Australia

Kristen L. Billiar
Biomedical Engineering Department, Worcester Polytechnic Institute, Worcester, MA, United States

Susmita Bose
W. M. Keck Biomedical Materials Research Laboratory, Washington State University, Pullman, WA, United States

Christopher Bowman
Department of Chemical and Biological Engineering, University of Colorado, Boulder, CO, United States

Steven Boyce
Department of Surgery, University of Cincinnati and Shriners Hospitals for Children – Cincinnati, Cincinnati, OH, United States

Bryan N. Brown
Department of Bioengineering, University of Pittsburgh, Pittsburgh, PA, United States; McGowan Institute for Regenerative Medicine, University of Pittsburgh, Pittsburgh, PA, United States

Justin L. Brown
Department of Biomedical Engineering, The Pennsylvania State University, University Park, PA, United States

Jeffrey R. Capadona
Department of Biomedical Engineering, Case Western Reserve University, Cleveland, OH, United States; Advanced Platform Technology Center, Rehabilitation Research and Development, Louis Stokes Cleveland VA Medical Center, Cleveland, OH, United States

David G. Castner
University of Washington, Seattle, WA, United States

Calvin Chang
Department of Biomedical Engineering, Johns Hopkins University, Baltimore, MD, United States; Translational Tissue Engineering Center, Johns Hopkins School of Medicine, Baltimore, MD, United States; Institute for NanoBioTechnology, Johns Hopkins University, Baltimore, MD, United States

Philip Chang
Department of Surgery, University of Cincinnati and Shriners Hospitals for Children – Cincinnati, Cincinnati, OH, United States

Ashutosh Chilkoti
Department of Biomedical Engineering, Duke University, Durham, NC, United States

Karen L. Christman
Department of Bioengineering, Sanford Consortium of Regenerative Medicine, University of California San Diego, La Jolla, CA, United States

Sangwon Chung
Department of Textile Engineering, Chemistry & Science, North Carolina State University, Raleigh, NC, United States; Biomedical Engineering, Joint Department of Biomedical Engineering, North Carolina State University and University of North Carolina at Chapel Hill, Chapel Hill, NC, United States

Kelly P. Coleman
Medtronic, Physiological Research Laboratories, Minneapolis, MN, United States

Dan Conway
Department of Biomedical Engineering, Virginia Commonwealth University, Richmond, VA, United States

Keith E. Cook
Department of Biomedical Engineering, Carnegie Mellon University, Pittsburgh, PA, United States

Stuart L. Cooper
William G. Lowrie Department of Chemical and Biomolecular Engineering, The Ohio State University, Columbus, OH, United States

Elizabeth Cosgriff-Hernandez
The University of Texas at Austin, Austin, TX, United States

Arthur J. Coury
Northeastern University, Boston, MA, United States

Joseph D. Criscione
Department of Biomedical Engineering, University of Rochester, Rochester, NY, United States

Heidi Culver
Department of Chemical and Biological Engineering, University of Colorado, Boulder, CO, United States

Jim Curtis
DuPont Health Care Solutions, Midland, MI, United States

Feiyang Deng
Department of Biomedical Engineering, University of Rochester, Rochester, NY, United States

Prachi Dhavalikar
The University of Texas at Austin, Austin, TX, United States

Luis Diaz-Gomez
Department of Bioengineering, Rice University, Houston, TX, United States

Rui M.A. Domingues
3B's Research Group, I3Bs–Research Institute on Biomaterials, Biodegradables and Biomimetics, University of Minho, Headquarters of the European Institute of Excellence on Tissue Engineering and Regenerative Medicine, Guimarães, Portugal; ICVS/3B's–PT Government Associate Laboratory, Braga/Guimarães, Portugal; The Discoveries Centre for Regenerative and Precision Medicine, Headquarters at University of Minho, Guimarães, Portugal

Elaine Duncan
Paladin Medical, Inc., Stillwater, MN, United States; Joseph Halcomb III, MD. Department of Biomedical Engineering, College of Engineering, University of Kentucky, Lexington, KY, United States

Pamela Duran
Department of Bioengineering, Sanford Consortium of Regenerative Medicine, University of California San Diego, La Jolla, CA, United States

Pedro Esbrit
Chemical Department of Pharmaceutical Sciences, Faculty of Pharmacy, Universidad Complutense of Madrid, Spain

Suzanne G. Eskin
Wallace H. Coulter Department of Biomedical Engineering, Georgia Institute of Technology, Atlanta, GA, United States

Michael Y. Esmail
Tufts Comparative Medicine Services, Tufts University, Boston, MA, United States

Jack L. Ferracane
Department of Restorative Dentistry, Oregon Health & Science University, Portland, OR 97201

Claudia Fischbach
Nancy E. and Peter C. Meinig School of Biomedical Engineering, Cornell University, Ithaca, NY, United States; Kavli Institute at Cornell for Nanoscale Science, Cornell University, Ithaca, NY, United States

Gary Fischman, PhD
Future Strategy Solutions, LLC, Gambrills, MD, United States

John P. Fisher
University of Maryland College Park; NIH/NIBIB Center for Engineering Complex Tissues

Iolanda Francolini
Department of Chemistry, Sapienza University of Rome, Rome, Italy

Steven J. Frey
School of Chemical and Biomolecular Engineering, Georgia Institute of Technology, Atlanta, GA, United States

Akhilesh K. Gaharwar
Texas A&M University, College Station, TX, United States

Andrés J. García
George W. Woodruff School of Mechanical Engineering, Georgia Institute of Technology, Atlanta, GA, United States; Parker H. Petit Institute of Bioengineering and Biological Science, Georgia Institute of Technology, Atlanta, GA, United States

Iain R. Gibson
Institute of Medical Sciences, School of Medicine, Medical Sciences and Nutrition, University of Aberdeen, Aberdeen, United Kingdom

Jeremy L. Gilbert
Department of Bioengineering, Clemson University, Charleston, SC, United States

Brian Ginn
Secant Group, Telford, PA, United States

Zachary E. Goldblatt
Biomedical Engineering Department, Worcester Polytechnic Institute, Worcester, MA, United States

Seth J. Goldenberg
Veeva Systems, Pleasanton, CA, United States

Manuela E. Gomes
3B's Research Group, I3Bs–Research Institute on Biomaterials, Biodegradables and Biomimetics, University of Minho, Headquarters of the European Institute of Excellence on Tissue Engineering and Regenerative Medicine, Guimarães, Portugal; ICVS/3B's–PT Government Associate Laboratory, Braga/Guimarães, Portugal; The Discoveries Centre for Regenerative and Precision Medicine, Headquarters at University of Minho, Guimarães, Portugal

Manuel Gómez-Florit

Preface

Biomaterials Science: An Introduction to Materials in Medicine was launched as an educational project to provide a nascent biomaterials community with an authoritative tool for training and education. Conceptual background material and a broad overview of applications were both envisioned as being integral to the textbook. In the late 1980s, biomaterials was in transition from an emerging field to a respected discipline embracing convergence (i.e., the merging of expertise from different "silos," such as provided by engineers, biomedical scientists, and physicians)—the biomaterials community was in need of an integrated, comprehensive, and definitive educational resource. This rationale for launching the textbook has been validated by the success of the first three editions of *Biomaterials Science*: *An Introduction to Materials in Medicine*. With well over 33,000 print copies, numerous online readers through institutional subscriptions, and the thousands who have bought the e-book version, the text has made consequential contributions to the biomaterials education of students and researchers around the world. The previous editions have been widely adopted for classroom use and serve as a reference resource for thousands of biomaterials professionals.

Biomaterials Science: *An Introduction to Materials in Medicine* strives for a balanced view of the biomaterials field. When this project was first launched, monographs available at that time did articulately address biomaterials, but they tended to strongly emphasize the authors' areas of expertise, while only superficially addressing other important subjects outside of their intellectual sphere. Balanced presentation means appropriate representation of:

- hard and soft biomaterials, with coverage of all major material classes both synthetic and biologically derived;
- the common application areas, including orthopedic, cardiovascular, ophthalmologic, dental, and emerging applications;
- a balance of fundamental biological and materials science concepts, contemporary medical/clinical concerns, and regulatory/commercial/societal issues that reflect the complex environment in which biomaterials are developed and used;
- coverage of the past, present, and future of biomaterials, their applications, and key challenges that lie ahead.

In this way, the reader can embrace the broad field, absorb the unifying principles common to all materials in contact with biological systems, and gain a solid appreciation for the special significance of the word *biomaterial*.

Biomaterials Science: *An Introduction to Materials in Medicine*, *fourth edition*, strives for curricular cohesion. By integrating the experience of many leaders in the biomaterials field, we endeavor to present a balanced yet comprehensive perspective on an exciting and rapidly evolving discipline—and present this information in a graphically attractive and readable format, intended to be useful as an educational resource to a broad array of students, teachers, and practicing professionals.

With this fourth edition a new set of four editors has taken on the challenge of moving the textbook forward. It is a humbling task to take over editor responsibilities from the four pioneers and visionaries in the field who launched the text and thoughtfully guided what became the quintessential biomaterials textbook through three editions. The new editor team recognized that the book could not physically grow any further than the size of the third edition (as any student who has carried that edition for a semester in a backpack would appreciate). Thus a balanced approach had to be implemented to both grow and cut back. Furthermore, with broad adoption of online access, the opportunity to place some supplementary content online was utilized (e.g., end-of-chapter questions and a further reading section).

First and foremost, the new editors wished to retain continuity with previous editions of the text and changed little where revision was not required. Moderate updates were made in many chapters, often keeping existing author teams and enlisting new coauthors. However, where a fresh direction seemed appropriate for a chapter given the state of the science, or the introduction of new chapters was indicated for where the field had expanded, new author teams were recruited. Overall there are 17 new chapters and 43 chapters with a new set of authors. To balance this growth, some topics were consolidated. A change the reader may notice in content is that the editors have elected to reduce the depth of emphasis on tissue engineering and some device topics, believing that there are now excellent texts devoted exclusively to the maturing tissue engineering field. With medical devices, the desire was not only to cover the critical application areas in overview and to include major new advances, but also to recognize that readers will be able to find field-specific, in-depth device coverage elsewhere. Finally, particular attention was given to the third section of the book, where guidance is provided that seeks to prepare the reader for the development pathway beyond the demonstration

of a proof-of-concept. Here our hope was that the disconnect between the vast biomaterials scientific literature and the reality of what devices are used clinically and how they are implemented can be appreciated. Such understanding is critical if scientific advances are to ultimately reach the target patient population.

The founding editors are still very much a part of this textbook. They have provided wise counsel as the new editors developed the plan for the fourth edition, but also authored revisions in several chapters from previous editions. Much of the excellent content and perspective that has made this text so useful to the community has come from the writings of the founding editors. We have sought to preserve and update this valued content.

Acknowledgments and thanks are in order. First, the Society for Biomaterials (SFB), sponsor and inspiration for this book, is a model of "multidisciplinary cultural diversity." Composed of engineers, physicians, scientists, veterinarians, industrialists, inventors, regulators, attorneys, educators, ethicists, and others, the SFB provides the nidus for the intellectually exciting, humanistically relevant, and economically important biomaterials field. As was the case for all of the previous editions, the editors recognize the importance of the SFB by donating all royalties from sales of this volume to the Society, to directly support education and career development related to biomaterials. For information on the SFB, visit the SFB website at http://www.biomaterials.org/.

We offer special thanks to those who have generously invested time, energy, experience, and intelligence to author the chapters of this textbook. The over 100 scientists, physicians, engineers, and industry leaders who contributed their expertise and perspectives are clearly the backbone of this work, and they deserve high praise—their efforts will strongly impact the education of the next generation of biomaterials scientists. It is only with such a distinguished group of authors that this text can provide the needed balance, scope, and perspective. We also pay respect and homage to biomaterials pioneers who have contributed to this or previous editions, but have since passed on; their contributions and collegiality are remembered and will be missed.

The organizational skills, experience, and encouragement of the staff at Elsevier Publishers have led this fourth edition from a broad and complex challenge to a valuable volume—a tangible resource for the community. Thank you, Elsevier, for this contribution to the field of biomaterials.

The biomaterials field, since its inception in the 1950s, has been ripe with opportunity, intellectual stimulation, compassion, creativity, and rich collaboration. In this field we look to the horizons where the new ideas from science, technology, and medicine arise. Importantly, we strive to improve the survival and quality of life for billions through biomaterials-based medical devices and treatments. We, the new editors, together with the founding editors hope that the biomaterials textbook you are now reading will stimulate you as much as it has us.

How to Use this Book

Biomaterials Science: An Introduction to Materials in Medicine, fourth edition, was conceived as a learning tool to "compatibilize" through common language and fundamental principles, a number of independent communities (basic sciences, engineering, medicine, dentistry, industry, regulatory, legal, etc.). Although the book has 98 chapters, 4 appendices, there is a logic of organization and curriculum that should make the book straightforward to use in an academic course or as a reference work.

A guiding principle in assembling this multiauthor, multidisciplinary textbook is that fundamental and translational progress in the field of biomaterials necessitates integration of concepts and tools from the full spectrum of the physical sciences, engineering, clinical medicine, biology, and life sciences. Indeed, the discipline of biomaterials utilizes a convergence of multidisciplinary elements to enable the development of specific diagnostic or therapeutic devices—i.e., using biomaterials science and technology to create and implement real medical devices and other products that solve clinical problems and improve patient outcomes. Nevertheless, the editors believe (and the book has been assembled so) that a physician should be able to pick up the textbook and glean a baseline knowledge of the science, engineering, and commercialization aspects of biomaterials. A chemist could use this book to appreciate the biology behind biomaterials, the physiology associated with medical devices, and the applications in medicine. An engineer hired by a medical device company might learn the basic science underlying the technological development and details on medical applications. Similarly, for other disciplines that interface with biomaterials, this book can guide the reader through diverse but related topics that are generally not found in one volume.

The textbook has well over 100 authors. The field of biomaterials is so diverse in subject matter that a guiding principle has been that no one author can write it all—let us use the experience and wisdom of acknowledged masters of each subject to communicate the best information to the reader. But, to prevent this book from appearing to be simply a collection of review papers, considerable editorial effort has gone into ensuring logical curricular organization, continuity of ideas, and extensive cross-referencing between chapters.

Biomaterials Science: An Introduction to Materials in Medicine, fourth edition, is divided into three parts: Materials Science and Engineering, Biology and Medicine, and The Medical Product Life Cycle. Sections then serve to subdivide each of these three parts (for example, under the part called "Materials Science and Engineering" there are sections on properties of materials and classes of materials used in medicine). And finally, within these sections can be found chapters, for example, on the major types of materials that are used in medicine (hydrogels, polyurethanes, titanium alloys, etc.). Each section begins with an introduction by one of the editors that will guide the reader through the chapters, giving cohesion to the sections and highlighting key issues that are worthy of attention. Finally, there are appendices that tabulate useful data and information.

For most chapters, exercises are provided for classroom use and for self-testing. These can be accessed via the companion website at https://www.elsevier.com/books-and-journals/book-companion/9780128161371. This site makes it possible to update problems and add new ones, and provides other resource materials, including a full artwork catalog and downloadable images used in the text. For instructors, solutions to the end-of-chapter exercises are provided on an Instructor Site at http://textbooks.elsevier.com/web/Manuals.aspx?isbn=9780128161371.

We hope that the textbook organization, the extensive editorial effort, and the expertly authored chapters will serve their intended purpose—to guide the reader into and through this complex field of biomaterials science. The editors always appreciate feedback and commentary—contact information is provided for them.

And now it is time to delve into the rich world of biomaterials science.

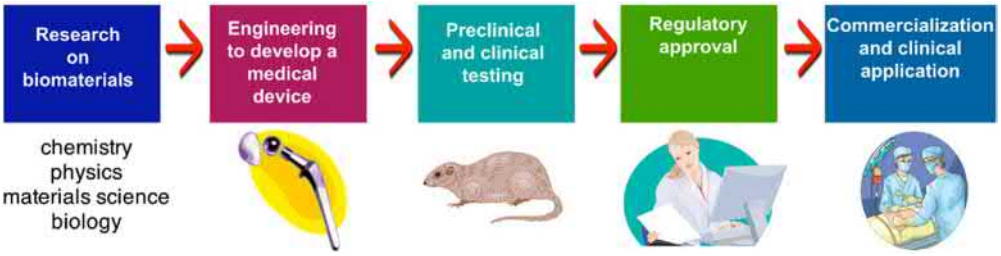
Biomaterials and Biomaterials Science

Biomaterials Science: *An Introduction to Materials in Medicine*, fourth edition, addresses the design, fabrication, testing, applications, and performance as well as nontechnical considerations integral to the translation of synthetic and natural materials that are used in a wide variety of implants, devices, and process equipment that contact biological systems. These materials are referred to as biomaterials.

> The compelling, human side to biomaterials is that millions of lives are saved, and the quality of life is improved for millions more.

The field of biomaterials is some 70–80 years old at the time of publication of this fourth edition. It significantly impacts human health, the economy, and many scientific fields. Biomaterials and the medical devices comprised of them are now commonly used as *prostheses* in cardiovascular, orthopedic, dental, ophthalmological, and reconstructive surgery, and in other interventions such as surgical sutures, bioadhesives, and controlled drug release devices. The compelling, human side to biomaterials is that millions of lives have been saved, and the quality of life improved for millions more, based on devices fabricated from biomaterials. The biomaterials field has seen accelerating growth since the



• **Figure 1.1.1.1** The path from the basic science of biomaterials, to a medical device, to clinical application.

first medical devices that were based on accepted medical and scientific principles made their way into human usage in the late 1940s and early 1950s. And the growth of the field is ensured, with the aging population, the increasing standard of living in developing countries, and the growing ability to address previously untreatable medical conditions.

Biomaterials science addresses both therapeutics and diagnostics. It encompasses basic sciences (biology, chemistry, physics) and engineering and medicine. The translation of biomaterials science to clinically important medical devices is dependent on: (1) sound engineering design; (2) testing in vitro, in animals and in humans; (3) clinical realities; and (4) the involvement of industry permitting product development and commercialization. Fig. 1.1.1.1 schematically illustrates the path from scientific development to the clinic.

Biomaterials science, in its modern incarnation, is an example of the emerging *convergence* paradigm that pushes multidisciplinary collaboration among experts and multidisciplinary integration of concepts and practice (Sharp and Langer, 2011). Not only biomaterials, but also bioinformatics, synthetic biology, computational biology, nanobiology, systems biology, molecular biology, and other forefront fields depend on convergence for their continued progress. This textbook aims to introduce these diverse multidisciplinary elements, particularly focusing on interrelationships rather than disciplinary boundaries, to systematize the biomaterials subject into a cohesive curriculum—a true convergence.

The title of this textbook, *Biomaterials Science*: *An Introduction to Materials in Medicine*, is accurate and descriptive. The intent of this work is: (1) to focus on the scientific and engineering fundamentals behind biomaterials and their applications; (2) to provide sufficient background knowledge to guide the reader to a clear understanding and appreciation of the clinical context where biomaterials are applied; and (3) to highlight the opportunities and challenges in the field. Every chapter in this text can serve as a portal to an extensive contemporary literature that expands on the basic ideas presented here. The magnitude of the biomaterials endeavor, its broadly integrated multidisciplinary scope, and examples of biomaterials applications will be revealed in this introductory chapter and throughout the book.

The common thread in biomaterials is the physical and chemical interactions between complex biological systems and synthetic or modified natural materials.

Although biomaterials are primarily used for medical applications (the focus of this text), they are also used to grow cells in culture, to assay for blood proteins in the clinical laboratory, in processing equipment for biotechnological applications, for implants to regulate fertility in cattle, in diagnostic gene arrays, in the aquaculture of oysters, and for investigational cell–silicon "neuronal computers." How do we reconcile these diverse uses of materials into one field? The common thread is the physical and chemical interactions between complex biological systems and synthetic materials or modified natural materials.

In medical applications, biomaterials are rarely used as isolated materials, but are more commonly integrated into devices or implants, and complex devices may use multiple biomaterials, often selected from several classes (e.g., metal and polymer). Chemically pure titanium can be called a biomaterial, but shaped (machined) titanium in conjunction with ultrahigh molecular weight polyethylene becomes the device, a hip prosthesis. Although this is a text on biomaterials, it will quickly become apparent that the subject cannot be explored without also considering biomedical devices and the biological response to them. Indeed, both the material and the device impact the recipient (patient) and, as we will see, the patient's host tissue impacts the device. These interactions can lead to device success or, where there is inappropriate choice of biomaterials or poor device design, device failure. Moreover, specific patient characteristics may influence the propensity to failure (e.g., obesity increasing the likelihood of fracture or excessive wear of a hip joint prosthesis, or clotting of a mechanical heart valve in a patient with a genetic mutation that causes hyper-coagulability).

Furthermore, a biomaterial must always be considered in the context of its final fabricated, sterilized form. For example, when a polyurethane elastomer is cast from a solvent onto a mold to form the pump bladder of a heart assist device, it can elicit different blood reactions compared to when injection molding is used to form the same device. A hemodialysis system serving as an artificial kidney requires materials that must function in contact with a patient's blood, and also exhibit appropriate membrane permeability and mass transport characteristics. Much fabrication technology is applied to convert the biomaterials of the hemodialysis system (polysulfone, silicone rubber, polyethylene) into the complex apparatus that is used for blood purification.

Due to space limitations and the materials focus of this work, many aspects of medical device design are not addressed in this book. Consider the example of the hemodialysis system. This textbook will overview membrane materials and

their biocompatibility; there will be little coverage of mass transport through membranes, the burst strength of membranes, dialysate water purification, pumps, flow systems, and monitoring electronics. Other books and articles cover these topics in detail, and chapter authors provide references useful to learn more about topics not explicitly covered.

Key Definitions

The words "biomaterial" and "biocompatibility" have already been used in this introduction without formal definition. A few definitions and descriptions are in order, and will be expanded upon in this and subsequent chapters.

A definition of "biomaterial" endorsed by a consensus of experts in the field is:

> *A biomaterial is a nonviable material used in a medical device, intended to interact with biological systems.*
>
> **WILLIAMS (1987).**

A biomaterial is a nonviable material used in a medical device, intended to interact with biological systems.

Although biomaterials are most often applied to meet a therapeutic or diagnostic medical need, if the word "medical" is removed, this definition becomes broader and can encompass the wide range of applications already suggested. If the word "nonviable" is removed, the definition becomes even more general, and can address many new tissue-engineering and hybrid artificial organ applications where living cells are used.

"Biomaterials science" is the study (from the physical and/or biological perspective) of materials with special reference to their interaction with the biological environment. Traditionally, emphasis in the biomaterials field has been on synthesis, characterization, and the host–material interactions biology. Yet, most biomaterials (which meet the special criteria of biocompatibility—see Chapters 2.3.2 and 2.3.4) induce a nonspecific biological reaction that we refer to as the foreign-body reaction (Chapter 2.2.2). This leads us to consider a widely used definition of biocompatibility:

> *"Biocompatibility" is the ability of a material to perform with an appropriate host response in a specific application.*
>
> **WILLIAMS (1987).**

"Biocompatibility" is the ability of a material to perform with an appropriate host response in a specific application.

Examples of "appropriate host responses" include resistance to blood clotting, resistance to bacterial colonization, and normal, uncomplicated healing. Examples of "specific applications" include a hemodialysis membrane, a urinary catheter, or a hip joint replacement prosthesis. Note that the hemodialysis membrane might be in contact with the patient's blood for 5 h (and outside the body), the catheter may be inserted for a week (inside the body, and designed to be easily removed), and the hip joint may be in place for the life of the patient (deeply implanted and meant to be long-term). This general concept of biocompatibility has been extended to tissue engineering, in which in vitro and in vivo processes are harnessed by careful selection of cells, materials, and metabolic and biomechanical conditions to regenerate functional tissues. Ideas central to biocompatibility are elaborated upon in Ratner (2011) and Chapter 2.3.2.

In the discussion of these definitions, we are introduced to considerations that set biomaterials apart from most materials explored in materials science. Table 1.1.1.1 lists a few applications for biomaterials in the body. It includes many classes of materials used as biomaterials. Note that metals, ceramics, polymers, glasses, carbons, and natural and composite materials are listed. Such materials are used as molded or machined parts, coatings, fibers, films, membranes, foams, fabrics, and particulates. Table 1.1.1.1 also gives estimates of the specific device global market size and, where available, an estimate of the number of medical devices utilized annually. The human impact, and the size of the commercial market for biomaterials and the broad array of medical devices, is impressive (Tables 1.1.1.1 and 1.1.1.2).

TABLE 1.1.1.1 Key Applications of Synthetic Materials and Modified Natural Materials in Medicine

Application	Biomaterials Used	Number/Year—Global (or Global Market in US$)
Skeletal System		
Joint replacements (hip, knee, and shoulder)	Titanium, CoCr, polyethylene, alumina, zirconia	4,000,000 ($16B)
Trauma fixation devices (plates, screws, pins, and rods)	Titanium, stainless steel, CoCr, polyether ether ketone, poly(lactic acid) (PLA)	1,500,000 ($5.5B)
Spine disks and fusion hardware	Nitinol, titanium, polyether ether ketone, stainless steel	1,100,000 ($8.5B)
Bone defect repair	Calcium phosphates, human bone products	($4.5B)
Bone cement (fixation)	Polymethyl methacrylate (PMMA), glass polyalkenoate (ionomer), calcium phosphate cements	($1.1B)
Cartilage, tendon, or ligament repair and replacement	Decellularized porcine tissue, poly(lactide) and metallic fixation devices, collagen, hyaluronic acid lubricants	($8.6B)
Dental implant-tooth fixation	Titanium, zirconium	10,000,000 ($4B)

(Continued)

TABLE 1.1.1.1 Key Applications of Synthetic Materials and Modified Natural Materials in Medicine—cont'd

Application	Biomaterials Used	Number/Year—Global (or Global Market in US$)
Cardiovascular System		
Vascular grafts, patches, and endovascular devices (stent grafts)	Dacron, expanded poly(tetrafluoroethylene), Nitinol, CoCr, stainless steel, fixed tissue	($2.5B)
Heart valves: mechanical and bioprosthetic (transcatheter and traditional)	Dacron, carbon, CoCr, fixed bovine and porcine tissue, stainless steel, Nitinol	600,000 ($5.5B)
Pacemakers	Titanium, polyurethane	1,000,000 ($6.5B)
Implantable defibrillators	Titanium, polyurethane	300,000 ($9.0B)
Stents: coronary, peripheral vasculature, and nonvascular	Stainless steel, Nitinol, CoCr, Pt, tantalum, Mg alloys, poly(styrene-*b*-isobutylene-*b*-styrene), poly(*n*-butyl methacrylate), polyethylene-*co*-vinyl acetate, phosphoryl choline containing block copolymers, poly(lactic-*co*-glycolic acid), PLA	5,000,000 ($10.6B)
Catheters: cardiovascular, urologic, and others	Polytetrafluoroethylene (PTFE), poly(vinyl chloride), silicone, polyurethane	($28B)
Organs		
Cardiac assist devices (acute and chronic)	Titanium alloy, polycarbonate, PTFE, poly(ethylene terephthalate), stainless steel	($1.7B)
Hemodialysis	Polysulfone, modified cellulose, polyacrylonitrile, polycarbonate, silicone, polyvinylchloride	2,000,000 patients ($12B)
Blood oxygenator	Polymethylpentene, polypropylene, polysiloxane, poly(vinyl chloride), polycarbonate	($300M)
Skin substitute (chronic wounds, burns)	Collagen, cadaver skin, alginate, polyurethane, carboxymethylcellulose, nylon, silicone	($1.3B)
Ophthalmologic		
Contact lens	PMMA, polyhydroxyethylmethacrylate (PHEMA), polyvinyl alcohol, polyvinyl pyrrolidone, silicone (polydimethyl siloxane [PDMS])	($7.5B)
Intraocular lens	PMMA, PDMS, polyacrylate-PMMA, PHEMA	25,000,000 ($4.5B)
Glaucoma drains	Silicone, polypropylene, cross-linked collagen, stainless steel	($500M)
Other		
Cochlear prostheses	Platinum, platinum–iridium, PDMS, titanium, aluminum oxide	45,000 ($2.7B)
Breast implants	PDMS	3,600,000 ($1.2B)
Hernia and body wall repair meshes	Polypropylene, polyester, expanded PTFE, decellularized porcine/bovine tissue	($4.2B)
Sutures	Silk, nylon, poly(glycolic acid), PLA, polydioxanone, polyester copolymers, polypropylene, PTFE, processed bovine tissue	($3.9B)
Blood bags	Poly(vinyl chloride)	($170M)
Ear tubes (tympanostomy)	Silicone, PTFE	1,500,000 ($70M)
Intrauterine device	Polyethylene, copper, stainless steel, PDMS	168,000,000 ($2.9B)

Data compiled from multiple sources—these numbers should be considered rough estimates that are changing with growing markets and new technologies. Where only US numbers were available, world usage was estimated at approximately 2.5× US. *B*, Billion; *M*, million.

TABLE 1.1.1.2 The Medical Device Global Market by Segment With Projected Compound Annual Growth Rate (CAGR) ($ Millions)

Segments	2016	2017	2022	CAGR 2017–2022 (%)
Drug delivery devices	200,072	207,814	243,367	3.2
Urology and renal	75,378	82,668	109,003	5.7
In vitro diagnostics	66,143	72,816	99,357	6.4
Orthopedics and spine	65,756	72,086	99,559	6.7
Imaging devices	41,194	45,816	64,282	7.0
Cardiovascular devices	25,384	29,658	45,260	8.8
Endoscopy	9,573	10,372	13,693	5.7
Total	483,500	521,230	674,521	5.3

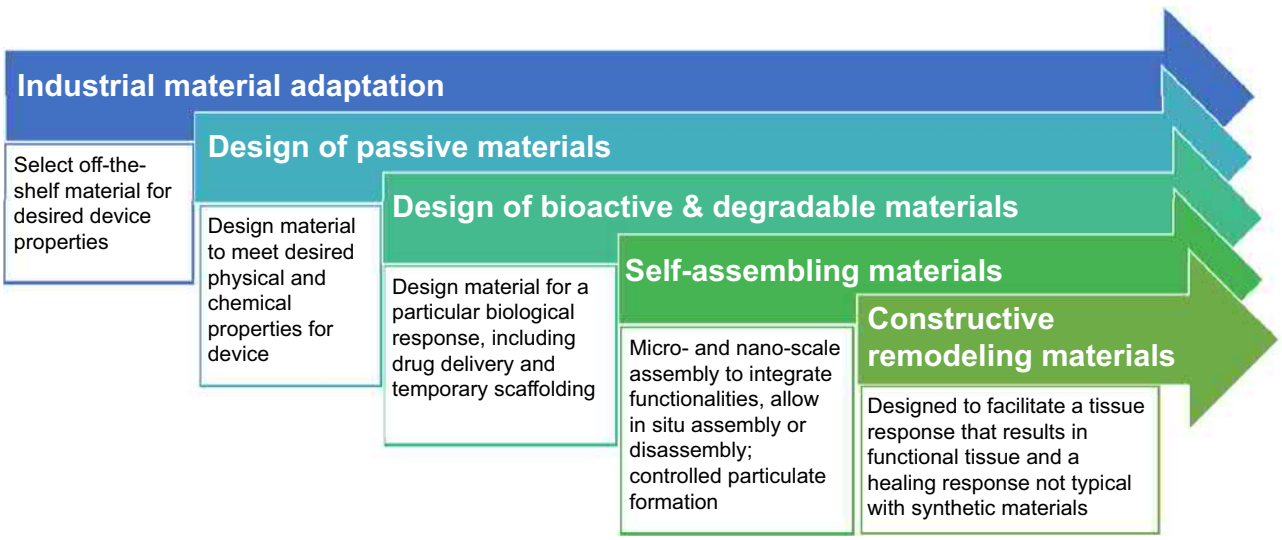
The Expansion of the Biomaterials Field

Biomaterials research and development have been stimulated and guided by advances in cell and molecular biology, pathology, clinical medicine and dentistry, chemistry, materials science, and engineering. The biomaterials community has been the major contributor to the understanding of the interactions of materials with the physiological environment (often referred to as the biointerface). The development of biomaterials for medical and dental applications has evolved with time, as new concepts and understandings are applied to offer a broadening repertoire of choices to meet device design objectives (Fig. 1.1.1.2).

Early applications of biomaterials sought to achieve a suitable combination of functional properties to adequately meet the design needs for the medical device under development. Generally, this would involve the layering of biocompatibility concerns from host–material interactions on top of those more readily understood physical and chemical requirements. For instance, for a mechanical cardiac valve, materials could be selected and integrated to provide the functional response in an altering pressure flow field, resistance to cyclic mechanical wear, and suturability. In these early applications, industrial materials were typically taken off the shelf, i.e. "medical grade" biomaterials were not yet available. Nevertheless from the array of industrially available materials that might meet these requirements, considerations of blood and tissue compatibility would be included.

Pioneers in the device field effectively applied empirical approaches to arrive at materials that could meet both the traditional (nonbiological) design requirements and



• **Figure 1.1.1.2** The growing palette of biomaterials. Generally moving with time from the 1940s adaptation of industrially available materials for early medical devices to the present, the breadth of described biomaterials continues to grow. In device development a biomaterial may be selected to leverage recent progress. However, it is important to note that major advances in the medical device field continue to be made with materials that could be considered first generation. The growing palette provides the design engineer with more tools to optimize device functionality in concert with other concerns such as manufacturability, regulatory burden, and economic considerations.

exhibit adequate levels of biocompatibility. Materials would generally be selected because they were tolerable (i.e., they elicited minimal response from the host tissues), and this would be consistent with *biocompatibility* for many applications (see Chapter 2.3.2). While the understanding of biomaterials science has evolved substantially from these early days, it is important to recognize that industrially repurposed materials continue to be utilized in many widely used medical devices today, including poly(tetrafluoroethylene) and poly(ethylene terephthalate), from which virtually all synthetic vascular grafts are made, stainless steel, cobalt–chromium alloys and titanium alloys, from which many orthopedic devices are constructed, and the polyurethanes and polysiloxanes that are utilized in a broad array of catheters and medical tubing. Furthermore, industrially adapted materials continue to be the biomaterials of choice for many revolutionary *new* devices introduced in recent years such as many of the components related to neurostimulatory devices and structural heart repair.

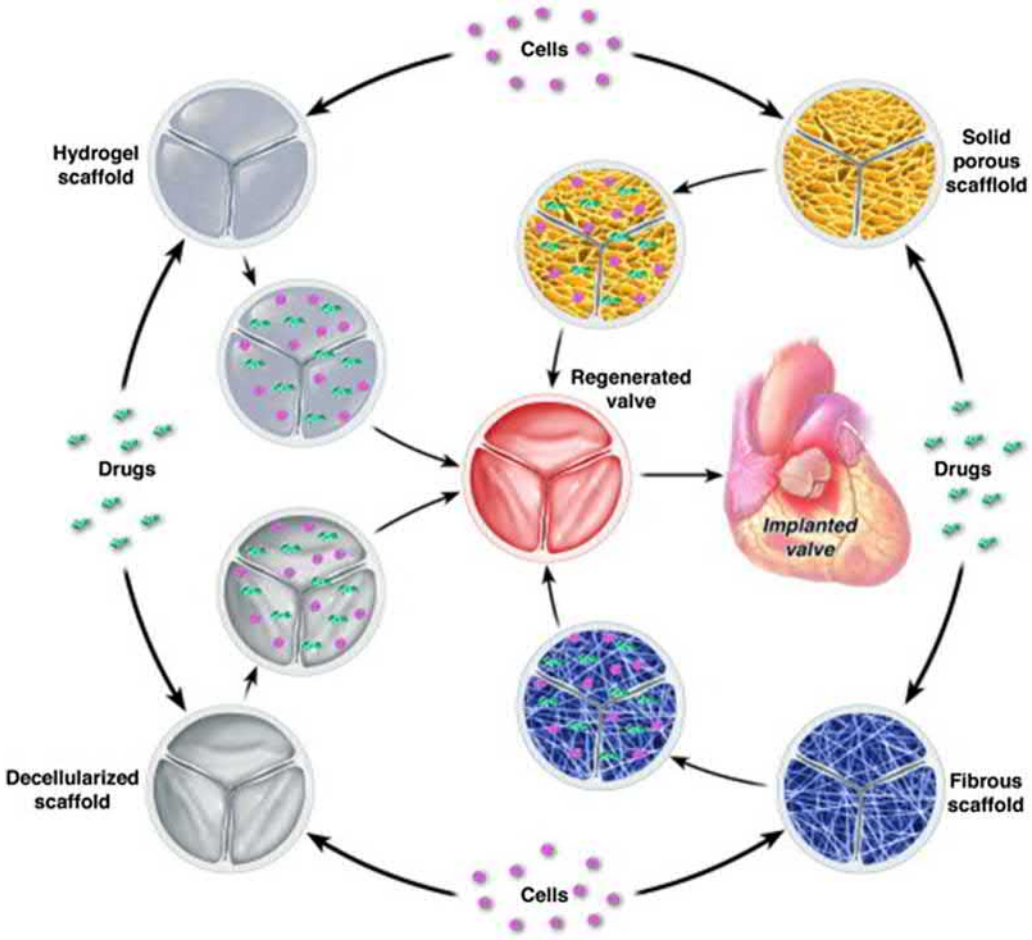
In this early period it would also occasionally be noted where an off-the-shelf material or class of materials might not fully achieve the target device design objectives and novel materials would be designed or refined specifically for a biomedical purpose. As highlighted in Chapter 1.1.2, biomaterials scientists would, for instance, create polyurethanes with segments selected for the purpose of improving blood biocompatibility. Hydrogels would be synthesized for soft tissue applications. Pyrolytic carbon, originally developed in the 1960s as a coating material for nuclear fuel particles, was studied and tuned for what is now in wide use in modified compositions to coat components of mechanical cardiac valves. These designed materials broadened the biomaterials palette, but the materials were still designed to be passive in achieving biocompatibility. As with early adapted industrial materials, these types of biomaterials continue to play an important part in device design and active research continues to seek to develop materials that are better suited for specific device applications while still targeting a passive, bioinert posture. For instance, efforts to find more degradation-resistant polymers for challenging device applications are ongoing (Chapter 2.4.2).

As knowledge of biological interactions with materials evolved, new types of biomaterials were developed with the intention of eliciting a controlled reaction with the tissues they contacted to induce a desired therapeutic effect. In the 1980s, these *bioactive* materials were in clinical use in orthopedic and dental surgeries as various compositions of bioactive glasses and ceramics (Hench and Pollak, 2002, Chapter 1.3.4), in controlled localized drug release applications such as the Norplant hormone-loaded contraceptive formulation (Meckstroth and Darney, 2001), and in the attachment of the anticoagulant heparin to the surfaces of membrane oxygenators with various modification strategies (Chapter 1.4.3B). Vascular stents have also been profoundly impacted by the implementation of a bioactive approach, with the application of polymer coatings that release antiproliferative agents and markedly reduce a major failure mechanism of tissue overgrowth and vessel occlusion (Chapter 2.5.2B).

Bioactive biomaterial development has also included the synthesis of resorbable polymeric biomaterials, with rates of degradation that could be tailored to the requirements of a desired application (Chapter 1.3.2F). Thus the discrete interface between the implant site and the host tissue could be eliminated in the long term, because the foreign material would ultimately be degraded to soluble, nontoxic products by the host. Many groups continue to develop new biodegradable polymers designed with defined objectives in strength, flexibility, a chemical composition conducive to tissue development, and a degradation rate consistent with the specific application. Degradable materials have been integral to the tissue-engineering paradigm where a scaffold, alone or in combination with cells and drugs, may provide for the generation of functional tissue. This paradigm as applied to the engineering of a cardiac valve is presented in Fig. 1.1.1.3 and is covered in the chapters of Section 2.6. Tissue-engineering approaches often leverage degradable biomaterials scaffolds, drug-releasing biomaterials, and in some cases utilize specific cell receptor–ligand interactions or enzymatic degradability to build bioactivity into the biomaterials scaffold (Chapters 1.4.4 and 1.4.5).

A characteristic of bioactive biomaterials development over the past several decades has been the leverage of fundamental knowledge from molecular biology. As this knowledge base has grown, biomaterials scientists and engineers have translated the understanding of biomolecular interactions to engineer biological interactions with designed materials. An early example of this was the application of knowledge of the adhesion peptide sequences from proteins such as fibronectin (e.g., Arg-Glu-Asp-Val) to engineer peptide-modified surfaces that would support specific types of cell adhesion (Hubbell et al., 1991). Polymeric materials with other novel properties such as shape-memory and programmable and interactive surfaces that control the cellular microenvironment are areas of development (Chapter 1.3.2G). In addition to having implications for medical applications, such engineered smart biomaterials systems have been used to advance our understanding of molecular biology principles, for instance, in elucidating the roles of substrate stiffness, ligand density, and three-dimensional culture in mammalian cell behavior.

The need for maximally effective pharmacologic dosing regimens and minimization of systemic toxicities has stimulated development of innovative particulate systems for targeted drug delivery and gene therapy (Chapter 1.3.8). Such systems may also provide the basis for targeted imaging or the combination of targeted imaging and therapeutic delivery, representing the growing field of theranostics. This focus area is experiencing a great deal of research attention at present by the biomaterials community and many of the approaches involve the production of nano- and microscale particulates using the principles of self-assembling materials. Several factors are driving this effort to design better biomaterials-based approaches: advances in protein and nucleic acid-based drugs (which cannot be taken in classical pill form, have high cost, and are labile); a better understanding of transport mechanisms systemically, within

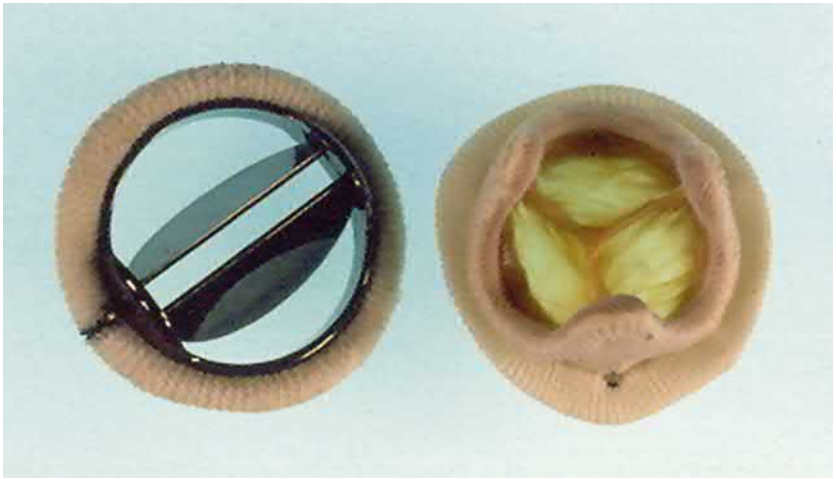


• **Figure 1.1.1.3** An example of various tissue-engineering paradigms applied to a cardiac valve. Current approaches for many tissues, including heart valves, may involve scaffolds, cells, and drugs. These components may be used alone or in combination. For each component, different material types, drugs, or cells may be used. Again, alone or in combination, bioreactors may be employed to allow some level of tissue construct maturation, or the body may serve as the bioreactor. (From Jana, S., Tefft, B.J., Spoon, D.B., Simari, R.D., 2014. Scaffolds for tissue engineering of cardiac valves. Acta Biomater. 10, 2877–2893.)

specific tissues or tumors, and intracellularly; and an increasing ability to create precise structures at macromolecular scales through controlled polymerization techniques and specific orthogonal reaction schemes.

Self-assembled biomaterials have allowed design at the nanoscale to protect drug payloads that are released with an appropriate signal (e.g., pH, radiation, intracellular environmental cues) upon delivery at the desired site through the surface presentation of targeting moieties and molecules that reduce fouling and improve pharmacokinetics. Self-assembled biomaterials have also found broad interest as injectable networks for the creation of scaffolds and depots in regenerative medicine, drug delivery, and immunoengineering (Sahoo et al., 2018). Here, by switching out functional groups on larger self-assembling molecules, the specific bioactivity and mechanical properties of an assembled network may be designed. Interest is also growing in the structural and functional tailoring of self-assembled two-dimensional organic biomaterials to open new opportunities by controlling biomaterials at the nanoscale for highly specific, spatially orchestrated biological interactions (Zhang et al., 2019).

A final category in the growing repertoire of biomaterials is what could be termed constructive remodeling materials. Such materials have been designed or processed to facilitate a healing response that does not follow the classic foreign-body response found with most synthetic tissues, but is characterized by remodeling of the tissue with minimal scarring. This response has been observed and well documented in biomaterials derived from animal-based tissues that have been decellularized to reduce immunogenicity, but which have not been chemically cross-linked. Chemical cross-linking is a critical part of maintaining structural viability for many biomaterials (e.g., bioprosthetic cardiac valves from bovine or porcine source tissues), but in this approach a tissue, such as porcine bladder or dermis, is meant to be degraded and remodeled at the implantation site, and in this remodeling process, be replaced with host tissue that is functional as opposed to fibrotic. These types of materials are described in Chapter 1.3.6, and the role of the immune response with these types of natural materials versus most synthetic materials or cross-linked natural materials is addressed in Chapter 2.2.2. As the biomaterials community better understands the mechanisms



• **Figure 1.1.1.4** Prosthetic heart valves. *Left*: A bileaflet tilting disk mechanical heart valve (St. Jude Medical Inc., St. Paul, MN). *Right*: A bioprosthetic (xenograft) tissue heart valve (Hancock valve, Medtronic Inc., MN).

by which constructive remodeling can be achieved, this knowledge is being applied in materials designed to orchestrate specific interactions with the immune system to moderate the host response. More broadly, biomaterials are being developed in the area of immunoengineering (Chapter 2.5.10) to impact the immune system in applications related to immunization, cancer, infection, and autoimmune diseases.

Examples of Today's Biomaterials Applications

Five examples of biomaterials applications now follow to illustrate important ideas. The specific devices discussed were chosen because they are widely used in humans with good success. However, key limitations with these biomaterial devices are also highlighted. Each of these examples is also discussed in detail in later chapters in this textbook.

Heart Valve Prostheses

Diseases and degeneration of the heart valves often make surgical repair or replacement necessary. The natural heart valve opens and closes over 40 million times per year, and can require replacement due to disease or wear. Approximately 4,500,000 replacement valves are implanted each year worldwide, because of acquired damage to the natural valve and congenital heart anomalies. There are many types of heart valve prostheses, and they are fabricated from carbons, metals, elastomers, plastics, fabrics, and animal or human tissues chemically pretreated to reduce their immunologic reactivity, and to enhance durability. Fig. 1.1.1.4 shows a bileaflet tilting disk mechanical heart valve and a bioprosthetic (porcine xenograft) tissue heart valve, two of the most widely used designs. Generally, as soon as the valve is implanted, cardiac function is restored to near normal levels, and the patient shows rapid improvement. In spite of the overall success seen with replacement heart valves, there are problems, many of them specific to a certain type of valve; they include

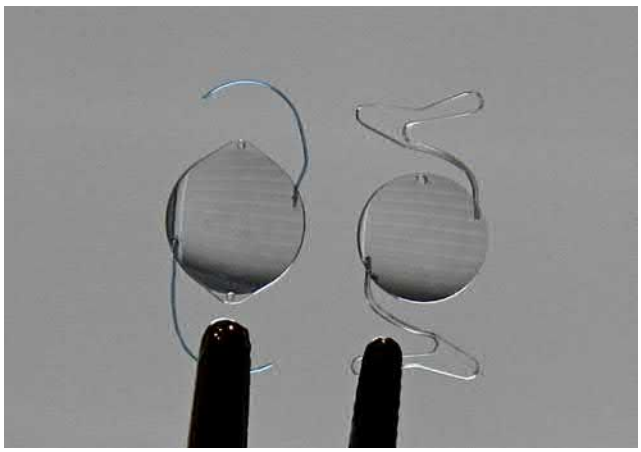
• **Figure 1.1.1.5** A hip prosthesis. Microplasty titanium alloy femoral stem, Biolox alumina–zirconia ceramic femoral head, and ultrahigh molecular weight polyethylene acetabular cup infused with vitamin E antioxidant. (Image courtesy of Biomet, Inc.)

induction of blood clots, predominantly with mechanical valves (sometimes shed into the bloodstream as emboli and creating an ongoing risk for stroke, thus necessitating long-term therapy with potentially dangerous anticoagulant drugs), degeneration of valve tissue leaflets, mechanical failure, and infection. This biomaterial application continues to be an active area of innovation, most recently with growing clinical use of valve designs implanted through a catheter and in the advancement of tissue-engineering approaches for valve replacement (Zhang et al., 2019). Heart valve substitutes are discussed in Chapter 2.5.3A.

Total Hip Replacement Prostheses

The human hip joint is subjected to high levels of mechanical stress and receives considerable abuse in the course of normal and extraordinary activity. It is not surprising that after 50 or more years of cyclic mechanical stress or because of degenerative or rheumatoid disease, the natural joint wears out, leading to loss of mobility and sometimes confinement to a wheelchair. Hip joint prostheses are fabricated from a variety of materials, including titanium, stainless steel, special high-strength alloys, ceramics, composites, and ultrahigh molecular weight polyethylene. Replacement hip joints (Fig. 1.1.1.5) are implanted

• **Figure 1.1.1.6** Schematic images of early dental root form implants and a photograph of several designs used in clinical practice.



• **Figure 1.1.1.7** Two styles of multipiece intraocular lenses.

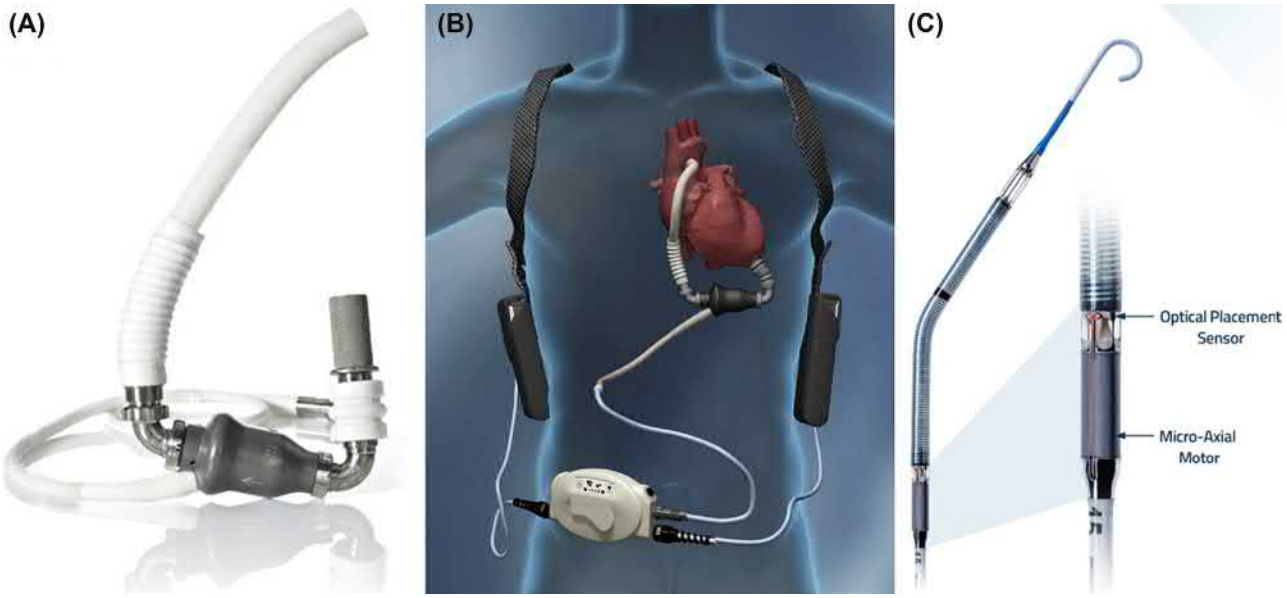
in more than 300,000 humans each year in the United States alone. With some types of replacement hip joints and surgical procedures that use a polymeric cement, ambulatory function is restored within days after surgery. For other types, a healing-in period is required for integration between bone and the implant before the joint can bear the full weight of the body. In most cases, good function is restored. Even athletic activities are possible, although those activities that subject the repaired joint to high stress are generally not advisable. After 10–15 years, many of these implants fail by loosening, which usually necessitates another operation (a revision procedure). Metal-on-metal implants also experience problems of corrosion and adverse responses to released metal ions. Artificial hip joint prostheses are discussed in Chapter 2.5.4.

Dental Implants

The development of root form designs of titanium implants (Fig. 1.1.1.6) by Per-Ingvar Brånemark revolutionized dental implantology (Carlsson et al., 1986). These devices form an implanted artificial tooth anchor upon which a crown is affixed and are implanted in 5,000,000 people each year in the United States alone, according to the American Dental Association. A special requirement of a material in this application is the ability to form a tight seal against bacterial invasion where the implant traverses the gingiva (gum). Other issues are associated with the rapidly growing junctional epithelium inhibiting regrowth of the slower growing bone. Also, in normal physiology, the tooth is connected to the jaw by the periodontal ligament and is not directly attached to the jawbone. One of the primary advantages originally cited for the titanium implant was its osseous integration with the bone of the jaw. In recent years, however, this attachment has been more accurately described as a tight apposition or mechanical fit, and not true bonding. Loss of tissue support leading to loosening remains an occasional problem, along with infection and issues associated with the mechanical properties of unalloyed titanium that is subjected to long-term cyclic loading. Dental implants are discussed in Chapter 2.5.5.

Intraocular Lenses

Implants to replace lenses in the eye that have clouded due to cataracts are called intraocular lenses (IOLs). They have been fabricated from a variety of transparent materials, including poly(methyl methacrylate), silicone elastomer, soft acrylic polymers, and hydrogels (Fig. 1.1.1.7). By the age of 75, more than 50% of the population suffers from cataracts severe enough to warrant IOL implantation. This now translates to an estimated 25 million implants worldwide as cataract treatment is expanding rapidly in healthcare systems with growing economies and aging populations. Good vision is generally restored almost immediately after the lens is inserted, and the success rate with this device is high. IOL surgical procedures are well developed, and implantation is most often performed on an outpatient



• **Figure 1.1.1.8** A commonly utilized chronic ventricular assist device (VAD). (A) Continuous flow pump with associated inflow/outflow grafts and electrical drive line (Heartmate II device). (B) Schematic of VAD implanted as a left ventricular assist device with associated external power source. (C) A catheter-based rotary blood pump from Impella for acute cardiac support. The tip of the device is placed in the ventricle where openings allow blood flow into the lumen of the device. Blood is pumped with a microaxial rotary motor and expelled through catheter openings in the region of the device that rests in the aorta. (Images A and B obtained with permission from Thoratec Corporation. Image C obtained from https://mms.businesswire.com/media/20190831005001/en/740858/5/SmartAssist_Press_release_image.jpg?download=1.)

basis. Observations of implanted lenses through the cornea using a microscope to directly study the implants show that inflammatory cells such as macrophages migrate to the surface of the lenses after implantation. Thus the conventional healing pathway is seen with these devices, similar to that observed with materials implanted in other sites in the body. Outgrowth of cells onto the IOL from the posterior lens capsule, stimulated by the presence of the IOL, can cloud vision, and this is a significant complication. IOLs are discussed in Chapter 2.5.6.

Ventricular Assist Devices

Nearly 5,000,000 Americans are living with seriously failing hearts (congestive heart failure), and 300,000 individuals will die each year from this disease. According to the American Heart Association, 50,000–100,000 of these individuals might benefit from cardiac transplantation or mechanical circulatory support. Since the available pool of donor hearts for transplantation is only ~3500 per year (United States), effective and safe mechanical cardiac assist or replacement seems like a desirable option. Ventricular assist devices (VADs) have evolved from a daring experimental concept, the mechanical total heart, to a life-prolonging tool (see Chapter 2.5.2A). A number of devices have received regulatory approval and designs have evolved from bulky pulsatile pumps with chambers and opposing valves (mimicking the human heart) to much smaller rotary devices compatible with a broader array of patients. VADs are now used in multiple ways: to maintain ("bridge") a patient with a failing heart while awaiting a donor organ, as a permanent source of support for patients not destined for a heart transplant, and as temporary support where cardiac function is at risk due to a procedure, or when a weakened heart is expected to recover in the short term and device support can be withdrawn. A commonly utilized rotary VAD for extended cardiac support and a catheter-based device used for temporary support are illustrated in Fig. 1.1.1.8. Recipients of VADs designed for chronic support can have considerable mobility and freedom, with most being discharged from the hospital setting. Despite patients being supported in some cases for several years, there remains an elevated risk for device-related infection (particularly in the region where the control and power line crosses the skin) and stroke related to the embolization of clots formed within the device. Furthermore, although VAD therapy that sends a patient home with a device may be economically more efficient and provide better outcomes than an extended period in an intensive care unit, the therapy remains expensive and is not feasible for broad application in the health systems of many countries. Can so expensive an innovation be made available to the wide patient base that could benefit from them? Wider adoption and increased entries into the market are reducing costs, but the fact of profound global disparities in medical device adoption remains for VADs and other complex and new device technologies. Developing approaches for best practices in medical device management are an area of interest and study within the World Health Organization and the reader is referred to an ongoing series of publications and forums from this source that consider how to best translate medical device advances across disparate healthcare economies.

These five cases, only a small fraction of the important medical devices that could have been used as examples,

spotlight central ideas and themes relevant to most medical devices interfacing with the human biology. A few generalizations are:

- Implantation in hundreds of thousands of patients with good success is noted.
- A broad range of synthetic materials of varying properties are used.
- Most anatomical sites can be interfaced with a device.
- The normal response by which the body responds to foreign bodies is observed.
- Problems, concerns, unexplained observations, or unintended consequences may be noted for each device.
- Most device complications are related to biomaterials–tissue interactions.
- Companies are manufacturing devices and bringing value to shareholders (and patients).
- Regulatory agencies are carefully assessing device performance, and making policy decisions to monitor the device industry, ensure quality, and protect the patient.
- Ethical and societal issues are associated with each device.

These ideas are relevant to nearly all medical devices. As you work through this text, consider how these ideas impact the specific topic you are studying.

Characteristics of Biomaterials Science

Now that we have defined key terms and reviewed specific examples highlighting successes and also complications, we can examine core characteristics of the field of biomaterials.

Multidisciplinary

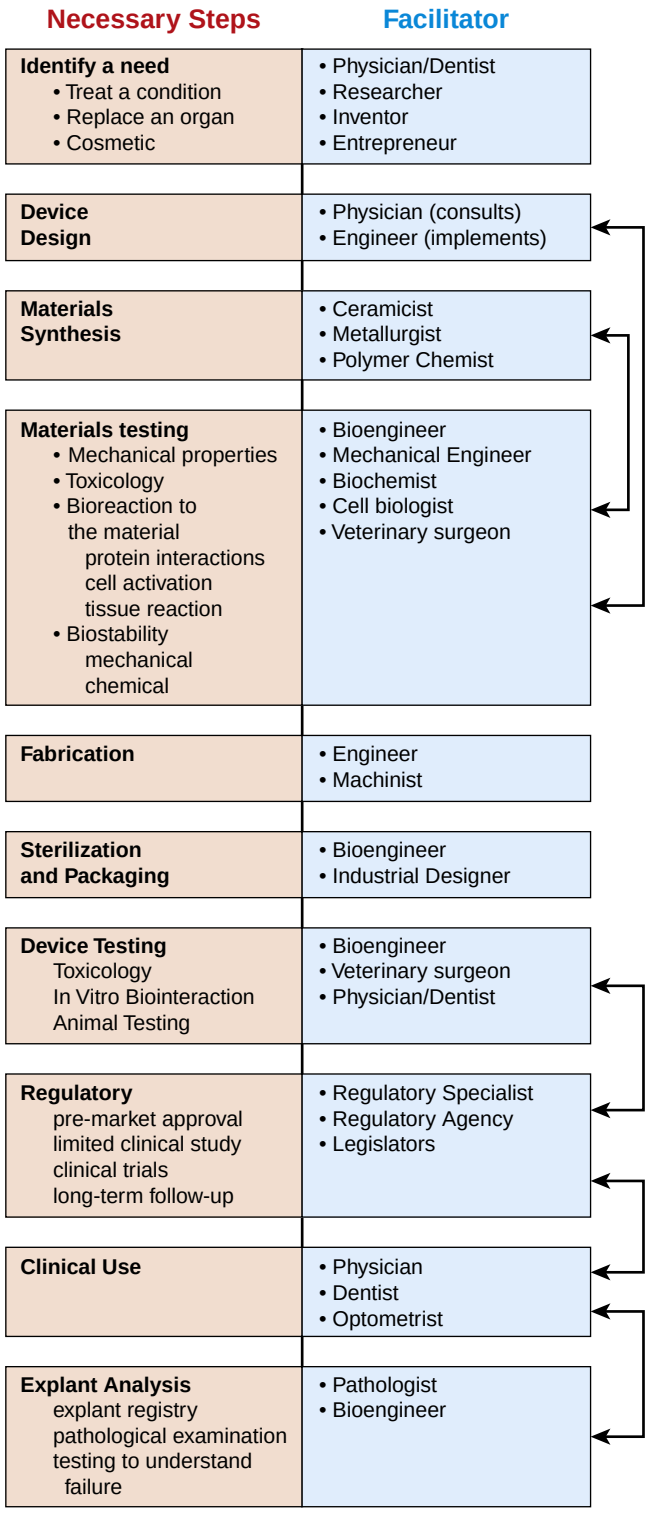
More than any other field of contemporary technology, biomaterials science brings together teams of researchers from diverse academic and industrial backgrounds, who characteristically speak different "languages" yet must clearly communicate and integrate complex concepts and data. Fig. 1.1.1.9 lists some of the disciplines and key steps that are encountered in the progression from identifying the need for a biomaterial or device to its testing, regulation, manufacture, sale, and implantation.

Diverse Materials Are Used

The biomaterials scientist must have an appreciation of materials science, including polymers, metals, ceramics, glasses, composites, and biological materials. This may range from an impressive command of the theory and practice of the field demonstrated by the professional materials scientist to a general understanding of the properties of materials that should be possessed by the physician or biologist investigator involved in biomaterials-related research.

A wide range of materials is routinely used in medical devices (Table 1.1.1.1), and no one researcher will be comfortable synthesizing, processing, characterizing, designing, and fabricating with all these materials. Thus specialization is common and appropriate. However, a broad appreciation of the properties and applications of these materials, the palette from which the biomaterials scientist "creates" medical devices, is a hallmark of professionals in the field.

There is a tendency to group biomaterials and researchers into the "hard tissue replacement" camp, typically represented by those involved in orthopedic and dental materials, and the "soft tissue replacement" camp, frequently associated with cardiovascular implants and general plastic surgery materials.



• **Figure 1.1.1.9** The path from an identified need to a clinical product, and some of the disciplines that facilitate this developmental process.

TABLE 1.1.1.3 Cardiovascular Device Market by Region and With Projected Compound Annual Growth Rate (CAGR) ($ Millions)

Region	2016	2017	2020	CAGR 2017–2022 (%)
North America	9,811	11,329	16,543	7.9
Europe	7,293	8,458	12,084	7.4
Asia	5,610	6,709	11,406	11.2

Total	25,384	29,658	45,260	8.8

Source: BCC Research.

Hard tissue biomaterials researchers are thought to focus on metals and ceramics, while soft tissue biomaterials researchers are considered polymer experts. In practice, this division is artificial: a heart valve may be fabricated from polymers, metals, and carbons (and processed tissue). A hip joint will also be composed of metals and polymers (and sometimes ceramics), and may be interfaced with the body via a polymeric bone cement. There is a need for a general understanding of all classes of materials and the common conceptual theme of their interaction with the biological milieu. This text provides a background to the important classes of materials, hard and soft, and their interactions with the biological environment.

Biomaterials to Devices to Markets and Medicine

Thomas Edison once said that he would only invent things that people would buy. In an interesting way, this idea is central to biomaterials device development. The process of biomaterials/medical device innovation is driven by clinical need: an informed engineer, patient, or physician defines a need and then initiates an invention. However, someone must test and manufacture the device, and shepherd it though the complex and expensive development process, which includes rigorous regulatory requirements. This "someone" is generally a company, and a company exists (by law) to return value to its shareholders. Fig. 1.1.1.9 illustrates multidisciplinary interactions in biomaterials, and shows the progression in the development of a biomaterial or device. It provides a perspective on how different disciplines work together, starting from the identification of a need for a biomaterial through development, manufacture, implantation, and (possibly) removal from the patient. Note that the development process for medical devices is very different from that for drugs. There are insightful reference works available to help understand this specialized device commercialization process (Yock et al., 2015) and this pathway is the general focus of Part 3 of this text.

Magnitude of the Field

The magnitude of the medical device field expresses both the magnitude of the need and a sizable and growing commercial market (Table 1.1.1.2). Of particular note is how various medical devices are seeing growth occurring in more recently expanding economies. This is exemplified by the cardiovascular device market (Table 1.1.1.3) and reflects economic growth, extending lifespans, and (unfortunately) increased cardiovascular disease burden in these regions.

Consider four commonly used biomaterial devices: a contact lens; a hip joint; a hydrocephalous drainage shunt; and a heart valve. Let us examine these devices in the contexts of human needs and commercial markets. The contact lens offers improved vision and, some will argue, a cosmetic enhancement. The hip joint offers mobility to the patient who would otherwise need a cane or crutch or be confined to a bed or wheelchair. The hydrocephalus shunt will allow an infant to survive without brain damage. The heart valve offers a longer life with improved quality of life. A disposable contact lens may sell for less than $0.50, and the hip joint, hydrocephalus shunt, and heart valve may sell for $1000–$5000 each. Each year there will be hundreds of millions of contact lenses purchased worldwide, 4,500,000 heart valves, 160,000 hydrocephalus shunts, and 1,400,000 total artificial hip prostheses. Here are the issues for consideration: (1) the large number of devices (an expression of both human needs and commercial markets); (2) medical significance (cosmetic to life saving); and (3) commercial potential (who will manufacture it and why, for example, what is the market for the hydrocephalus shunt?). Always, human needs and economic issues color this field we call "biomaterials science." Medical practice, market forces, and bioethics come into play almost every day.

Lysaght and O'Laughlin (2000) estimated the magnitude and economic scope of the contemporary organ replacement enterprise to be much larger than was generally recognized. In the year 2000, the lives of over 20 million patients were sustained, supported, or significantly improved by functional organ replacement. The impacted population grows at over 10% per year. Worldwide, first-year and follow-up costs of organ replacement and prostheses exceed US$300 billion per year and represent between 7% and 8% of total worldwide healthcare spending. In the United States, the costs of therapies enabled by organ replacement technology exceed 2% of the gross national product. The costs are also impressive when reduced to the

needs of the individual patient. For example, the cost of an implanted heart valve is roughly $5000. The surgery to implant the device entails a hospital bill and first-year follow-up costs upward of at least $40,000. Reoperation for replacing a failed valve will have these same costs. Reoperations for failed valves now exceed 10% of all valve operations. Global expenditures on medical devices by category are summarized in Table 1.1.1.2.

Success and Failure

Most biomaterials and medical devices perform satisfactorily, improving the quality of life for the recipient or saving lives. However, no artificial construct is perfect. All manufactured devices have a failure rate. Also, all humans are different, with differing ethnicities, ages, genetics, gender, body chemistries, living environments, and degrees of physical activity. Furthermore, physicians implant or use these devices with varying degrees of skill. The other side to the medical device success story is that there are problems, compromises, complications, and unintended consequences that often occur with medical devices. Central issues for the biomaterials scientist, manufacturer, patient, physician, and attorney are: (1) is the design competent and optimal; (2) who should be responsible when devices perform "with an inappropriate host response"; and (3) what are the risk/benefit or cost/benefit ratios for the implant or therapy?

Some examples may clarify these issues. Clearly, heart valve disease is a serious medical problem. Patients with diseased aortic heart valves have a 50% chance of dying within 3 years. Surgical replacement of the diseased valve leads to an expected survival of 10 years in 70% of the cases. However, of these patients whose longevity and quality of life have clearly been enhanced, approximately 60% will suffer a serious valve-related complication within 10 years after the operation. Another example involves VADs. A clinical trial called Randomized Evaluation of Mechanical Assistance for the Treatment of Congestive Heart Failure (REMATCH) led to the following important statistics (Rose et al., 2001). Patients with an implanted Heartmate VAD had a 52% chance of surviving for 1 year, compared with a 25% survival rate for patients who took medication. Survival for 2 years in patients with the Heartmate was 23% versus 8% in the medication group. Also, the VAD enhanced the quality of life for the patients—they felt better, were less depressed, and were mobile. Importantly, patients participating in the REMATCH trial were not eligible for a heart transplant. In the cases of the heart valve and the VAD, clinical complications possibly associated with less than stellar biomaterials performance do not preclude widespread clinical acceptance.

Biomaterials science:
- multidisciplinary;
- multibiomaterial;
- clinical need driven;
- substantial world market; and
- risk/benefit issues.

Thus, these five characteristics of biomaterials science:
- multidisciplinary
- multibiomaterial
- clinical need driven
- substantial world market, and
- risk/benefit issues

color all aspects of the field.

In addition, there are certain unique subjects that are particularly prominent in our field and help delineate the biomaterials endeavor as a unique field of science and engineering. Let us review a few of these.

Subjects Integral to Biomaterials Science

Toxicology

A biomaterial should not be toxic, unless it is specifically engineered for such requirements (e.g., a "smart" drug delivery system that targets cancer cells with a toxic drug). Since the nontoxic requirement is the norm, toxicology for biomaterials has evolved into a sophisticated science. It deals with the substances that migrate out of biomaterials or result from their degradation. For example, for polymers, many low molecular weight "leachables" exhibit some level of physiologic activity and cell toxicity. It is reasonable to say that a biomaterial should not give off anything from its mass unless it is specifically designed to do so. Toxicology also deals with methods to evaluate how well this design criterion is met when a new biomaterial is under development. Chapter 2.2.5 provides an overview of methods in biomaterials toxicology. Implications of toxicity are addressed in Chapters 2.3.2–2.3.4.

Biocompatibility

The understanding and measurement of biocompatibility are unique to biomaterials science. Unfortunately, we do not have precise definitions or accurate measurements of biocompatibility. More often than not, biocompatibility is defined in terms of performance or success at a specific task. Thus for a patient who is doing well with an implanted large diameter Dacron fabric vascular prosthesis, few would argue that this prosthesis is not "biocompatible." However, the prosthesis probably did not recellularize, and may also generate a small amount of surface-bound clot that may embolize, usually with little clinical consequence. This operational definition of biocompatible ("the patient is alive and not experiencing complications, so it must be biocompatible") offers us little insight in designing new or improved vascular prostheses. It is probable that biocompatibility may have to be specifically defined for applications in soft tissue, hard tissue, and the cardiovascular system (blood compatibility, Chapters 2.2.6 and 2.3.5). In fact, biocompatibility may have to be uniquely defined for each application. The problems and meanings of biocompatibility will be explored and expanded upon throughout this textbook; in particular see Chapters 2.3.1 and 2.3.2.

Inflammation and Healing

Specialized biological mechanisms are triggered when a material or device interfaces with the body. Injury to tissue will

stimulate the well-defined inflammatory reaction sequence that ultimately leads to healing. Healing can be normal (physiological) or abnormal (pathological). Where a foreign body (e.g., an implant) is present in the wound site (the surgical incision), the reaction sequence is referred to as the "foreign-body reaction" (Chapters 2.2.2 and 2.3.4). The normal response of the body will be modulated because of the solid implant. Furthermore, this reaction will differ in intensity and duration, depending upon the anatomical site involved. An understanding of how a foreign object shifts the normal inflammatory reaction sequence is an important concern for the biomaterials scientist, and how some classes of materials may avoid this reaction is an area of growing interest, as already noted.

Functional Tissue Structure and Pathobiology

Biomaterials-based medical devices are implanted into almost all tissues and organs. Tissues and organs vary widely in cell composition, morphological organization, vascularization, and innervation. Implantation of a biomaterial into bone, liver, or heart will have special physiological consequences. Therefore key principles governing the structure of normal (and abnormal) cells, tissues, and organs are important to biomaterials researchers. Also, techniques by which the structure and function of normal and abnormal tissue are studied must be mastered. In addition, fundamental mechanisms leading to abnormal cell, tissue, and organ structures (i.e., diseases and other pathologies) are critical considerations to biomaterials researchers (see Chapters 2.1.4 and 2.1.5).

Dependence on Specific Anatomical Sites of Implantation

Consideration of the anatomical site of an implant is essential. An intraocular lens may be implanted into the lens capsule or the anterior chamber of the eye. A hip joint will be implanted in bone across an articulating joint space. A prosthetic heart valve will be sutured into cardiac muscle and will contact both soft tissue and blood. A catheter may be placed in an artery, a vein, or the urinary tract. Each of these sites challenges the biomedical device designer with special requirements for anatomy, physiology, geometry, size, mechanical properties, and bioresponses.

Mechanical Requirements and Physical Performance Requirements

Each biomaterial and device has mechanical and performance requirements originating from the need to perform a physiological function. These requirements can be divided into three categories: mechanical performance, mechanical durability, and physical properties.

First, consider mechanical performance. A hip prosthesis must be strong and rigid. A tendon material must be strong and flexible. A tissue heart valve leaflet must be flexible and tough. A dialysis membrane must be strong and flexible, but not elastomeric. An articular cartilage substitute must be soft and elastomeric. One significant example of a controlled micromechanical interface is the contact zone between a synthetic biomaterial (titanium, tantalum, alumina, zirconia, and hydroxyapatites) and oral bones. Microstrain magnitudes have been controlled through macro/micro/nanosurface topographies and construct designs to be within the microstrain limits of bone. The result has been decades of chemical stability, now called osseous integration.

Then, we must address mechanical durability. A catheter may only have to perform for 3 days. A bone plate may fulfill its function in 6 months or longer. A leaflet in a heart valve must flex 60 times per minute without tearing for the lifetime of the patient (realistically, at least for 10 or more years). A hip joint must not fail under heavy loads for 20 years or more.

Finally, the bulk physical properties impact other aspects of performance as they meet the physical and/or mechanical demands of the medical devices for which they are designed. In addition to mechanical durability, the dialysis membrane has a specified permeability, the acetabular cup of the hip joint must have high lubricity, and the intraocular lens has transparency and refraction requirements. To meet these requirements, design principles are borrowed from physics, chemistry, mechanical engineering, chemical engineering, and materials science.

Industrial Involvement

A significant basic research effort is now under way, primarily at universities, to understand how biomaterials function and how to optimize them. At the same time, companies are producing implants for use in humans and, appropriate to the mission of a company, earning profits on the sale of medical devices. Thus although we are now only learning about the fundamentals of biointeraction, we manufacture millions of devices for implantation in humans. How is this dichotomy explained? Basically, as a result of 50 or more years of experience we now have a set of materials that perform satisfactorily in the body. The medical practitioner can use them with reasonable confidence, and the performance in the patient is largely acceptable (generally considerably better than other alternatives). Though the devices and materials are far from perfect, the complications associated with the devices are fewer or of less impact than the complications of the original diseases.

Risk/Benefit and Corporate Realities

A risk/benefit analysis must be considered in developing new devices and improving existing devices. Central to biomaterials science is the desire to alleviate suffering and death, and also the desire to improve the quality of life for patients. These considerations are convoluted with the excitement of new scientific ideas, the corporate imperative to turn a profit, and the mandate of the regulatory agencies to protect the public. Indeed, although failure of biomaterials and medical devices is common, benefit to risk ratio in individual cases is often high, and despite a device complication, a patient may have had a markedly improved outcome (enhanced survival and/or quality of life) over the natural history of the disease.

The acceptable risk varies with different types of medical devices. Moreover, the acceptable risk of devices that sustain life (e.g., heart valve, defibrillator, cardiac assist device, hemodialysis device/access graft, hydrocephalus shunt) is greater than that of devices that alleviate pain/disability or enhance function (e.g., hip joint, drug delivery device, intraocular lens, intrauterine contraceptive device). Then consider the

acceptable risk for devices that have only cosmetic application (e.g., collagen injections, breast implants). Obviously, ethical concerns enter into the risk/benefit picture. Remember that companies have large investments in the development, manufacture, quality control, clinical testing, regulatory clearance, and distribution of medical devices. How much of an advantage (for the company and the patient) will be realized in introducing an improved device? The improved device may indeed work better for the patient. However, the company will incur a large expense (development and regulatory costs) that will be perceived by the stockholders as reduced profits. The development of a new or improved device, as well as offering benefits, entails risks that months or years after introduction some unforeseen complication will compromise the device. Product liability issues are a major concern to manufacturers. Consider questions about the ethics of withholding improved devices from people who could benefit from them because of development costs and regulatory hurdles, the market share advantages of having a better product, and the gargantuan costs (possibly nonrecoverable) of introducing a new product into the medical marketplace. If companies did not have the profit incentive, would there be any medical devices, let alone improved ones, available for clinical application?

From the biomaterials industry we see specialized, essential contributions to our field. Industry deals well with technologies such as packaging, sterilization, storage, distribution, quality control, and analysis. These subjects are grounded in specialized technologies, often ignored in academic communities, but having the potential to generate stimulating research questions. Also, many companies support in-house basic research laboratories, and contribute in important ways to the fundamental study of biomaterials science.

Ethics

A wide range of ethical considerations impact biomaterials science. Some key ethical questions in biomaterials science are summarized in Table 1.1.1.4. Typical of ethical questions, an absolute answer may be difficult to come by. Some articles have addressed ethical questions in biomaterials and debated the important points (Saha and Saha, 1987; Schiedermayer and Shapiro, 1989; Merryman, 2008). Chapter 3.1.11 introduces moral and ethical issues related to biomaterials and medical devices.

Regulation

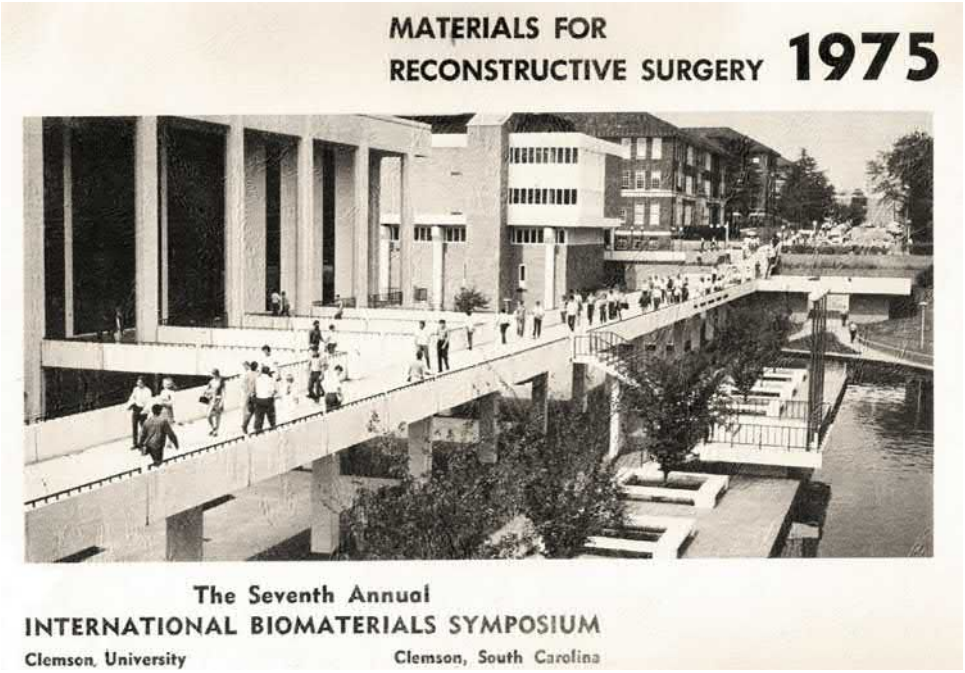
The consumer (the patient) and the physician demand safe medical devices. To prevent inadequately tested devices and materials from coming on the market, and to screen out those clearly unqualified to produce biomaterials, the US government has evolved a complex regulatory system administered by the US Food and Drug Administration. In the United States, medical device regulatory requirements were introduced less than 50 years ago (with the 1976 Medical Device Amendments legislation). Most nations of the world have similar medical device regulatory bodies. The International Standards Organization has introduced international standards for the world community. Obviously, a substantial base of biomaterials knowledge went into establishing these standards. The costs to comply with the standards and to implement materials, biological, and clinical testing are enormous. Introducing a new biomedical device to the market requires a regulatory investment of tens of millions of dollars. Are the regulations and standards truly addressing the safety issues? Is the cost of regulation inflating the cost of healthcare and preventing improved devices from reaching those who need them? Under this regulation topic, we see the intersection of all the players in the biomaterials community: government, industry, scientists, physicians, and patients. The answers are not simple, but the problems must be addressed every day. Part 3 of this text contains several chapters that expand on standards and regulatory concerns to provide a whole-spectrum view, including issues related to device life cycle, safety and risk, sterilization and disinfection, verification and validation, commercialization, and legal concepts.

TABLE 1.1.1.4 Ethical Concerns Relevant to Biomaterials Science

Animals	Is the animal model relevant to human physiology? Specifically, is the experiment well designed and the outcome sufficiently important so that the data obtained will justify the suffering and sacrifice of the life of a living creature?
Human Subjects	How should human subject research be conducted to minimize negative outcomes to the patient and offer a reasonable risk/benefit ratio? How can we best ensure informed consent?
Industrial Involvement	Companies fund much biomaterials research and also own proprietary biomaterials. How can the needs of the patient be best balanced with the financial goals of a company? Consider that someone must manufacture devices—these would not be available if a company did not choose to manufacture them.
Researchers	Since researchers often stand to benefit financially from a successful biomedical device, and sometimes even have devices named after them, how can investigator bias be minimized in biomaterials research?
Patients	For life-sustaining devices, what is the trade-off between sustaining life and the quality of life with the device for the patient? Should the patient be permitted to "pull the plug" if the quality of life is not satisfactory?
Regulatory Agencies	With so many unanswered questions about the basic science of biomaterials, do government regulatory agencies have sufficient information to define adequate tests for materials and devices and to properly regulate biomaterials?

Biomaterials Literature

Over the past 70 years, the field of biomaterials has evolved from individual physicians innovating to save the lives of their patients to the science-grounded multidisciplinary endeavor we see today. In 1950, there were no biomaterials or medical device journals, and few books. Concurrent with the evolution



• **Figure 1.1.1.10** The cover of the program book for the 1975 International Biomaterials Symposium, Clemson, South Carolina.

of the discipline, a literature has also developed addressing basic science, applied science, engineering, medicine, and commercial issues. A bibliography is provided in Appendix D to highlight some of the key reference works and technical journals in the biomaterials field. As might be expected, these journals stem from many disciplines and technical societies.

Biomaterials Societies

The biomaterials field evolved from individual researchers and clinicians who intellectually associated their efforts with established disciplines such as medicine, chemistry, chemical engineering, materials science, or mechanical engineering, to a modern field called "biomaterials." This evolution was paralleled by a growing sense of professionalism and the formation of biomaterials societies as homes for the profession to develop in. Probably the first biomaterials-related society was the American Society for Artificial Internal Organs. Founded in 1954, this group of visionaries established a platform to consider the development of devices such as the artificial kidney and the artificial heart. A Division of Interdisciplinary Studies, the administrative home of a nascent biomaterials effort, was established at Clemson University, Clemson, South Carolina, in 1969. Clemson began organizing annual International Biomaterials Symposia (IBS) in 1969. The first of these symposia was titled "Use of Ceramics in Surgical Implants." About 100 scientists and physicians attended, and 17 papers were presented. Between 1969 and 1975, seven IBS were held at Clemson. The cover of the 1975 International Biomaterials Symposium program is shown in Fig. 1.1.1.10.

The Society for Biomaterials (SFB) was chartered in San Antonio, Texas, in 1974 with 205 charter members from across the United States and nine other countries—a truly international society. One unique feature of the SFB founding members was that they included clinicians, engineers, chemists, and biologists. Their common interest, biomaterials, was the engaging focus for the multidisciplinary participants. Because of the founding of the SFB in 1974, the seventh IBS in 1975 was also known as the world's inaugural meeting of the SFB. Table 1.1.1.5 lists the timeline of events leading to the start of the SFB annual meetings and the quadrennial World Biomaterials Congress (WBC), as well as the establishment of Clemson Awards and the honorary status of "Fellow, Biomaterials Science and Engineering." The Canadian Biomaterials Society/Société Canadienne des Biomatériaux was established in 1973, a year earlier than the SFB. The European Society for Biomaterials was founded in 1975, and the Japanese Society for Biomaterials was formed in 1978. To promote international communication and cooperation, these four societies decided to establish an International Liaison Committee of Societies for Biomaterials (ILC) in 1980 to organize a WBC every 4 years and the first WBC was held in Baden, Vienna, Austria, that year. Six more international societies for biomaterials were established afterward: the Society for Biomaterials & Artificial Organs (India) in 1986, the Australasian Society for Biomaterials and Tissue Engineering in 1989, the Korean Society for Biomaterials in 1996, the Chinese Taipei Society for Biomaterials and Controlled Release in 1997, the Latin American Society for Biomaterials and Artificial Organs in 1998, and the Chinese Society for Biomaterials in 2011. In 1997, the constituent societies renamed the ILC to the International Union of Societies for Biomaterials Science and Engineering. Aside from these societies, there are other groups. For example, the Controlled Release Society is a group strongly rooted in biomaterials for drug delivery, and the Tissue Engineering and Regenerative Medicine International Society is also very active in biomaterials-related research.

FBSE, Fellow, Biomaterials Science and Engineering; *IBS*, International Biomaterials Symposia; *ILC*, International Liaison Committee of Societies for Biomaterials; *IUSBSE*, International Union of Societies for Biomaterials Science and Engineering; *SC*, South Carolina; *SFB*, Society for Biomaterials; *WBC*, World Biomaterials Congress.

The development of biomaterials professionalism and a sense of identity for the biomaterials field can be attributed to these societies and the researchers who organized and led them.

Summary

This chapter provides a broad overview of the biomaterials field. It offers a vantage point from which the reader can gain a perspective to see how the subthemes fit into the larger whole.

Biomaterials science may be the most multidisciplinary of all the sciences. Consequently, biomaterials scientists must master certain key material from many fields of science, technology, engineering, and medicine to be competent and conversant in this profession. The reward for mastering this volume of material is immersion in an intellectually stimulating endeavor that advances a new basic science of biointeraction and contributes to reducing human suffering.

1.1.2

A History of Biomaterials

BUDDY D. RATNER[1], GUIGEN ZHANG[2]

[1]Bioengineering and Chemical Engineering, Director of University of Washington Engineered Biomaterials (UWEB), Seattle, WA, United States

[2]F Joseph Halcomb III, M.D. Department of Biomedical Engineering, University of Kentucky, Lexington, KY, United States

History consists of a series of accumulated imaginative inventions.

Voltaire

At the turn of the third decade of the 21st century, biomaterials are still widely used throughout medicine, dentistry, and biotechnology. Just about 70 years ago, biomaterials as we think of them today did not exist. The word "biomaterial" was not used. There were no medical device manufacturers (except for external prosthetics such as limbs, fracture fixation devices, glass eyes, and dental fillings and devices), no formalized regulatory approval processes, no understanding of biocompatibility, and certainly no academic courses on biomaterials. Yet, crude biomaterials have been used, generally with poor to mixed results, throughout history. This chapter will broadly trace the history of biomaterials from the earliest days of human civilization to the third decade of the 21st century. It is convenient to organize the history of biomaterials into four eras: prehistory; the era of the surgeon-hero; designed biomaterials/engineered devices; and the contemporary era taking us into the new millennium. The emphasis of this chapter will be on the experiments and studies that set the foundation for the field we call biomaterials, largely between 1920 and 1980.

Biomaterials Before World War II

Before Civilization

The introduction of nonbiological materials into the human body took place throughout history. The remains of a human found near Kennewick, Washington, USA (often referred to as the "Kennewick Man"), were dated (with some controversy) to be 9000 years old. This individual, described by archeologists as a tall, healthy, active person, wandered through the region now known as southern Washington with a spear point embedded in his hip. It had apparently healed in and did not significantly impede his activity. This unintended implant illustrates the body's capacity to deal with implanted foreign materials. The spear point has little resemblance to modern biomaterials, but it was a "tolerated" foreign material implant. Another example of the introduction of foreign material into the skin, dated at over 5000 years ago, is the tattoo. The carbon particles and other substances probably elicited a classic foreign-body reaction. Moreover, one of the first surgical textbooks dated around 600 BC (Willyard, 2016) documented, arguably the first written record of skin-graft techniques, a method for repairing torn earlobes with skin from the cheek and the reconstruction of the nose from a flap of forehead skin.

Dental Implants in Early Civilizations

Unlike the spear point described earlier, dental implants were devised as implants and used early in history. The Mayan people fashioned nacre teeth from sea shells in roughly 600 AD, and apparently achieved what we now refer to as osseointegration (see Chapter 2.5.5), basically a seamless integration into the bone (Bobbio, 1972). Similarly, in France, a wrought iron dental implant in a corpse was dated to 200 AD (Crubezy et al., 1998). This implant, too, was described as properly osseointegrated. There was no materials science, biological understanding, or medicine behind these procedures. Still, their success (and longevity) is impressive and highlights two points: the adaptive nature of the human body and the pressing drive, even in prehistoric times, to restore the lost functions of physiologic/anatomic parts of the body with an implant.

Sutures Dating Back Thousands of Years

There is loose evidence that sutures may have been used even in the Neolithic period. Large wounds were closed early in history primarily by one of two methods—cautery or sutures. Linen sutures were used by the early Egyptians.

Catgut was used in the Middle Ages in Europe. In South Africa and India, the heads of large, biting ants clamped wound edges together.

Metallic sutures are first mentioned in early Greek literature. Galen of Pergamon (ca.130–200 AD) described ligatures of gold wire. In 1816, Philip Physick, University of Pennsylvania Professor of Surgery, suggested the use of lead wire sutures, noting little reaction. J. Marion Sims of Alabama had a jeweler fabricate sutures of silver wire, and in 1849 performed many successful operations with this metal.

Consider the problems that must have been experienced with sutures in times with no knowledge of sterilization, toxicology, immunological reaction to extraneous biological materials, inflammation, and biodegradation. Yet sutures were a relatively common fabricated or manufactured biomaterial for thousands of years.

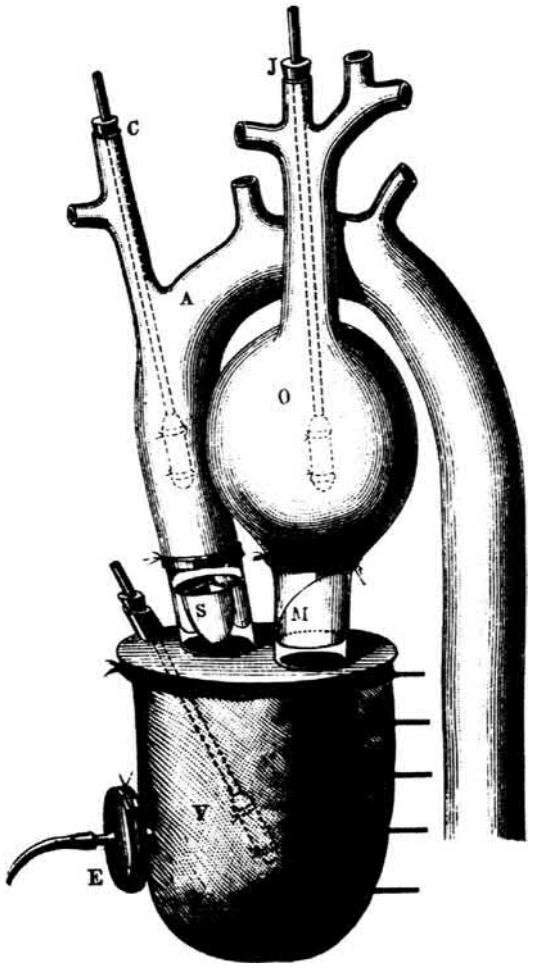
Artificial Hearts and Organ Perfusion

In the fourth century BC, Aristotle called the heart the most important organ in the body. Galen proposed that veins connected the liver to the heart to circulate "vital spirits throughout the body via the arteries." English physician William Harvey in 1628 espoused a relatively modern view of heart function when he wrote "the heart's one role is the transmission of the blood and its propulsion, by means of the arteries, to the extremities everywhere." With the appreciation of the heart as a pump, it was a logical idea to think of replacing the heart with an artificial pump. In 1812, the French physiologist Le Gallois expressed his idea that organs could be kept alive by pumping blood through them. A number of experiments on organ perfusion with pumps were performed from 1828 to 1868. In 1881, Étienne-Jules Marey, a brilliant scientist and thinker who published and invented in photographic technology, motion studies, and physiology, described an artificial heart device (Fig. 1.1.2.1), primarily oriented to studying the beating of the heart.

In 1938, aviator (and engineer) Charles Lindbergh and surgeon (and Nobel Prize winner) Alexis Carrel wrote a visionary book, *The Culture of Organs*. They addressed issues of pump design (referred to as the Lindbergh pump), sterility, blood damage, nutritional needs of perfused organs, and mechanics. This book is a seminal document in the history of artificial organs. In the mid-1950s, Dr. Paul Winchell, better known as a ventriloquist, patented an artificial heart. In 1957, Dr. Willem Kolff and a team of scientists tested the artificial heart in animals. More modern conceptions of the artificial heart (and left ventricular assist device) are presented in the following sections and in Chapter 2.5.2A and B).

Contact Lenses

Leonardo DaVinci, in the year 1508, developed the concept of contact lenses. Rene Descartes was credited with the idea of the corneal contact lens in 1632 and Sir John F.W. Herschel suggested in 1827 that a glass lens could protect the eye. Adolf Gaston Eugen Fick (nephew of Adolf Eugen Fick



• **Figure 1.1.2.1** An artificial heart by Étienne-Jules Marey, Paris, 1881.

of Fick's law of diffusion fame) was an optometrist by profession. One of his inventions (roughly 1860) was a glass contact lens, possibly the first contact lens offering real success. He experimented on both animals and humans with contact lenses. In the period from 1936 to 1948, plastic contact lenses were developed, primarily of poly(methyl methacrylate).

Basic Concepts of Biocompatibility

Most implants prior to 1950 had a low probability of success, because of a poor understanding of biocompatibility and sterilization. As will be elaborated upon throughout this book, factors that contribute to biocompatibility include the chemistry of the implant, leachables, shape, mechanics, and design. Early studies, especially with metals, focused primarily on ideas from chemistry to explain the observed bioreaction.

Possibly the first study assessing the in vivo bioreactivity of implant materials was performed by H.S. Levert (1829). Gold, silver, lead, and platinum specimens were studied in dogs, and platinum, in particular, was found to be well tolerated. In 1886, bone fixation plates of nickel-plated sheet steel with nickel-plated screws were studied. In 1924, A. Zierold published a study on tissue reaction to various

materials in dogs. Iron and steel were found to corrode rapidly, leading to resorption of adjacent bone. Copper, magnesium, aluminum alloy, zinc, and nickel discolored the surrounding tissue. Gold, silver, lead, and aluminum were tolerated, but were inadequate mechanically. Stellite, a Co–Cr–Mo alloy, was well tolerated and strong. In 1926, M. Large noted inertness displayed by 18-8 stainless steel containing molybdenum. By 1929 Vitallium alloy (65% Co–30% Cr–5% Mo) was developed and used with success in dentistry. In 1947, J. Cotton of the United Kingdom discussed the possible use of titanium and alloys for medical implants.

The history of plastics as implantation materials does not extend as far back as metals, simply because there were few plastics prior to the 1940s. What is possibly the first paper on the implantation of a modern synthetic polymer, nylon, as a suture appeared in 1941. Papers on the implantation of cellophane, a polymer made from plant sources, were published as early as 1939, documenting it being used as a wrap for blood vessels. The response to this implant was described as a "marked fibrotic reaction." In the early 1940s papers appeared discussing the reaction to implanted poly(methyl methacrylate) and nylon. The first paper on polyethylene as a synthetic implant material was published in 1947 (Ingraham et al.). The paper pointed out that polyethylene production using a new high-pressure polymerization technique began in 1936. This process enabled the production of polyethylene free of initiator fragments and other additives. Ingraham et al. demonstrated good results on implantation (i.e., a mild foreign-body reaction), and attributed these results to the high purity of the polymer they used. A 1949 paper commented on the fact that additives to many plastics had a tendency to "sweat out," and this might be responsible for the strong biological reaction to those plastics (LeVeen and Barberio, 1949). They found a vigorous foreign-body reaction to cellophane, Lucite, and nylon, but an extremely mild reaction to "a new plastic," Teflon. The authors incisively concluded: "Whether the tissue reaction is due to the dissolution of traces of the unpolymerized chemical used in plastics manufacture or actually to the solution of an infinitesimal amount of the plastic itself cannot be determined." The possibility that cellulose might trigger the severe reaction by activating the complement system could not have been imagined, because the complement system had not yet been discovered.

World War II to the Modern Era: The Surgeon/Physician-Hero

During World War I, and particularly at the end of the war, newly developed high-performance metal, ceramic, and especially polymeric materials, transitioned from wartime restriction to peacetime availability. The possibilities for using these durable, inert materials immediately intrigued surgeons with needs to replace diseased or damaged body parts. Materials, originally manufactured for airplanes, automobiles, clocks, and radios, were taken "off the shelf" by surgeons and applied to medical problems. These early biomaterials included silicones, polyurethanes, Teflon, nylon, methacrylates, titanium, and stainless steel.

A historical context helps us appreciate the contribution made primarily by medical and dental practitioners. Just after World War II, there was little precedent for surgeons to collaborate with scientists and engineers. Medical and dental practitioners of this era felt it was appropriate to invent (improvise) where the life or functionality of their patient was at stake. Also, there was minimal government regulatory activity, and human subject protections as we know them today were nonexistent (see Chapters 3.1.7 and 3.1.11). The physician was implicitly entrusted with the life and health of the patient and had much more freedom than is seen today to take heroic action when other options were exhausted. These medical practitioners had read about the post-World War II marvels of materials science. Looking at a patient open on the operating table, they could imagine replacements, bridges, conduits, and even organ systems based on such materials. Many materials were tried on the spur of the moment. Some fortuitously succeeded. These were high-risk trials, but usually they took place where other options were not available. The term "surgeon-hero" seems justified, since the surgeon often had a life (or a quality of life) at stake and was willing to take a huge technological and professional leap to repair the individual. This laissez faire biomaterials era quickly led to a new order characterized by scientific/engineering input, government quality controls, and a sharing of decisions prior to attempting high-risk, novel procedures. Still, a foundation of ideas and materials for the biomaterials field was built by courageous, fiercely committed, creative individuals, and it is important to look at this foundation to understand many of the attitudes, trends, and materials common today.

The regulatory climate in the United States in the 1950s was strikingly different from today. This can be appreciated in this recollection from Willem Kolff about a pump oxygenator he made and brought with him from Holland to the Cleveland Clinic (Kolff, 1998):

> *Before allowing Dr. Effler and Dr. Groves to apply the pump oxygenator clinically to human babies, I insisted they do 10 consecutive, successful operations in baby dogs. The chests were opened, the dogs were connected to a heart-lung machine to maintain the circulation, the right ventricles were opened, a cut was made in the interventricular septa, the septa holes were closed, the right ventricles were closed, the tubes were removed, and the chests were closed.*

Intraocular Lenses

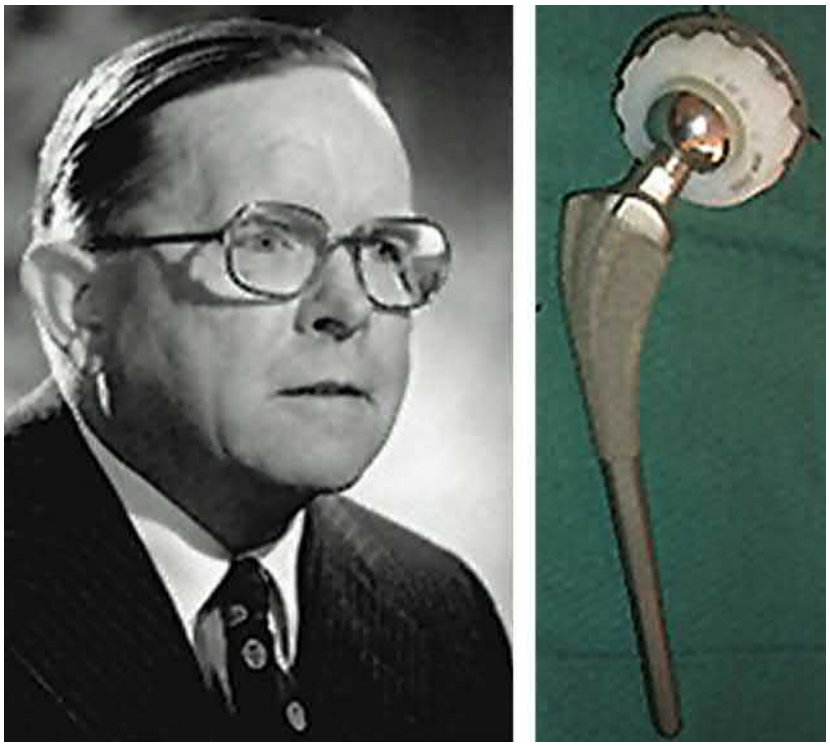
Sir Harold Ridley, MD (1906–2001) (Fig. 1.1.2.2), inventor of the plastic intraocular lens, made early, accurate observations of biological reaction to implants consistent with currently accepted ideas of biocompatibility. After World War II, he had the opportunity to examine aviators

• **Figure 1.1.2.2** *Left*: Sir Harold Ridley, inventor of the intraocular lens, knighted by Queen Elizabeth II for his achievement. *Right*: Shards from the canopy of the Spitfire airplane were the inspiration leading to intraocular lenses. (Image by Bryan Fury75 at fr.wikipedia [GFDL (www.gnu.org/copyleft/fdl.html), from Wikimedia Commons].)

who were unintentionally implanted in their eyes with shards of plastic from shattered canopies in Spitfire and Hurricane fighter planes (Fig. 1.1.2.2). Most of these flyers had plastic fragments years after the war. The conventional wisdom at that time was that the human body would not tolerate implanted foreign objects, especially in the eye—the body's reaction to a splinter or a bullet was cited as examples of the difficulty of implanting materials in the body. The eye is an interesting implant site, because you can look in through a transparent window to observe the reaction. When Ridley did so, he noted that the shards had healed in place with no further reaction. They were, by his standard, tolerated by the eye. Today, we would describe this stable healing without significant ongoing inflammation or irritation as "biocompatible." This is an early observation of "biocompatibility" in humans, perhaps the first, using criteria similar to those accepted today. Based on this observation, Ridley traced down the source of the plastic domes, ICI Perspex poly(methyl methacrylate). He used this material to fabricate implant lenses (intraocular lenses) that were found, after some experimentation, to function reasonably in humans as replacements for surgically removed natural lenses that had been clouded by cataracts. The first implantation in a human was on November 29, 1949. For many years, Ridley was the center of fierce controversy because he challenged the dogma that spoke against implanting foreign materials in eyes—it is hard to believe that the implantation of a biomaterial would provoke such an outcry. Because of this controversy, this industry did not instantly arise—it was the early 1980s before intraocular lenses became a major force in the biomedical device market. Ridley's insightful observation, creativity, persistence, and surgical talent in the late 1940s evolved into an industry that presently puts more than 7,000,000 of these lenses annually in humans. Through all of human history, cataracts meant blindness or a surgical procedure that left the recipient needing thick, unaesthetic spectacle lenses that poorly corrected the vision. Ridley's concept, using a plastic material found to be "biocompatible," changed the course of history and substantially improved the quality of life for millions of individuals with cataracts. Harold Ridley's story is elaborated upon in an obituary (Apple and Trivedi, 2002).

Hip and Knee Prostheses

The first hip replacement was probably performed in 1891 by a German surgeon, Theodore Gluck, using a cemented ivory ball. This procedure was not successful. Numerous attempts were made between 1920 and 1950 to develop a hip replacement prosthesis. Surgeon M.N. Smith-Petersen, in 1925, explored the use of a glass hemisphere to fit over the ball of the hip joint. This failed due to poor durability. Chrome–cobalt alloys and stainless steel offered improvements in mechanical properties, and many variants of these were explored. In 1938, the Judet brothers of Paris, Robert and Jean, explored an acrylic surface for hip procedures, but it had a tendency to loosen. The idea of using fast-setting dental acrylics to glue prosthetics to bone was developed by Dr. Edward J. Haboush in 1953. In 1956, McKee and Watson-Farrar developed a "total" hip with an acetabular cup of metal that was cemented in place. Metal-on-metal wear products probably led to high complication rates. It was John Charnley (1911–82) (Fig. 1.1.2.3), working at an isolated tuberculosis sanatorium in Wrightington, Manchester, England, who invented the first really successful hip joint prosthesis. The femoral stem, ball head, and plastic acetabular cup proved to be a reasonable solution to the problem of damaged joint replacement. In 1958, Dr. Charnley used a Teflon acetabular cup with poor outcomes due to wear debris. By 1961 he was using a high molecular weight polyethylene cup, and was achieving much higher success rates. Interestingly, Charnley learned of high molecular weight polyethylene from a salesman selling novel plastic gears to one of his technicians. Dr. Dennis Smith contributed in an important way to the development of the hip prosthesis by introducing Dr. Charnley to poly(methyl methacrylate) cements, developed in the dental community, and optimizing those cements for hip replacement use. Total knee replacements borrowed elements of the hip



• **Figure 1.1.2.3** *Left*: Sir John Charnley. *Right*: The original Charnley hip prosthesis. (Hip prosthesis photo courtesy of the South Australian Medical Heritage Society, Inc.)

prosthesis technology, and successful results were obtained in the period 1968–72 with surgeons Frank Gunston and John Insall leading the way.

Dental Implants

Some "prehistory" of dental implants has just been described. In 1809, Maggiolo implanted a gold post anchor into fresh extraction sockets. After allowing this to heal, he affixed to it a tooth. This has remarkable similarity to modern dental implant procedures. In 1887, this procedure was used with a platinum post. Gold and platinum gave poor long-term results, and so this procedure was never widely adopted. In 1937, Venable used surgical Vitallium and Co–Cr–Mo alloy for such implants. Also around 1937, Strock at Harvard used a screw-type implant of Vitallium, and this may be the first successful dental implant. A number of developments in surgical procedure and implant design (for example, the endosteal blade implant) then took place. In 1952, a fortuitous discovery was made. Per-Ingvar Brånemark, an orthopedic surgeon at the University of Lund, Sweden, was implanting an experimental cage device in rabbit bone for observing healing reactions. The cage was a titanium cylinder that screwed into the bone. After completing the experiment that lasted several months, he tried to remove the titanium device and found it tightly integrated in the bone (Brånemark et al., 1964). Dr. Brånemark named the phenomenon "osseointegration," and explored the application of titanium implants to surgical and dental procedures. He also developed low-impact surgical protocols for tooth implantation that reduced tissue necrosis and enhanced the probability of good outcomes. Most dental implants and many other orthopedic implants are now made of titanium and its alloys.

The Artificial Kidney

Kidney failure, through most of history, was a sentence to an unpleasant death lasting over a period of about a month. In 1910, at Johns Hopkins University, the first attempts to remove toxins from blood were made by John Jacob Abel. The experiments were with rabbit blood, and it was not possible to perform this procedure on humans. In 1943, in Nazi-occupied Holland, Willem Kolff (Fig. 1.1.2.4), a physician just beginning his career at that time, built a drum dialyzer system from a 100-L tank, wood slats, and 130 feet of cellulose sausage casing tubing as the dialysis membrane. Some successes were seen in saving lives where prior to this there was only one unpleasant outcome to kidney failure. Kolff took his ideas to the United States and in 1960, at the Cleveland Clinic, developed a "washing machine artificial kidney" (Fig. 1.1.2.5) taking advantage of Maytag washing machines purchased from Sears.

Major advances in kidney dialysis were made by Dr. Belding Scribner at the University of Washington (Fig. 1.1.2.6). Scribner devised a method to routinely access the bloodstream for dialysis treatments. Prior to this, after just a few treatments, access sites to the blood were used up and further dialysis was not possible. After seeing the potential of dialysis to help patients, but only acutely, Scribner tells the

story of waking up in the middle of the night with an idea to gain easy access to the blood—a shunt implanted between an artery and vein that emerged through the skin as a "U." Through the exposed portion of the shunt, blood access could be readily achieved. When Dr. Scribner heard about the new plastic, Teflon, he envisioned how to get the blood out of and into the blood vessels. His device, built with the assistance of Wayne Quinton (Fig. 1.1.2.6), used Teflon tubes to access the vessels, a Dacron sewing cuff through the skin, and a silicone rubber tube for blood flow. The Quinton–Scribner shunt made chronic dialysis possible, and is said to be responsible for more than a million patients being alive today. Interestingly, Dr. Scribner refused to patent his invention because of its importance to medical care. Additional important contributions to the artificial kidney were made by chemical engineering Professor Les Babb (University of Washington) who, working with Scribner, improved dialysis performance and invented a proportioning mixer for the dialysate fluid. The first dialysis center was opened in Seattle making use of these important technological advances (Fig. 1.1.2.6). The early experience with dialyzing patients where there were not enough dialyzers to meet the demand also made important contributions to bioethics associated with medical devices (Blagg, 1998).

The Artificial Heart

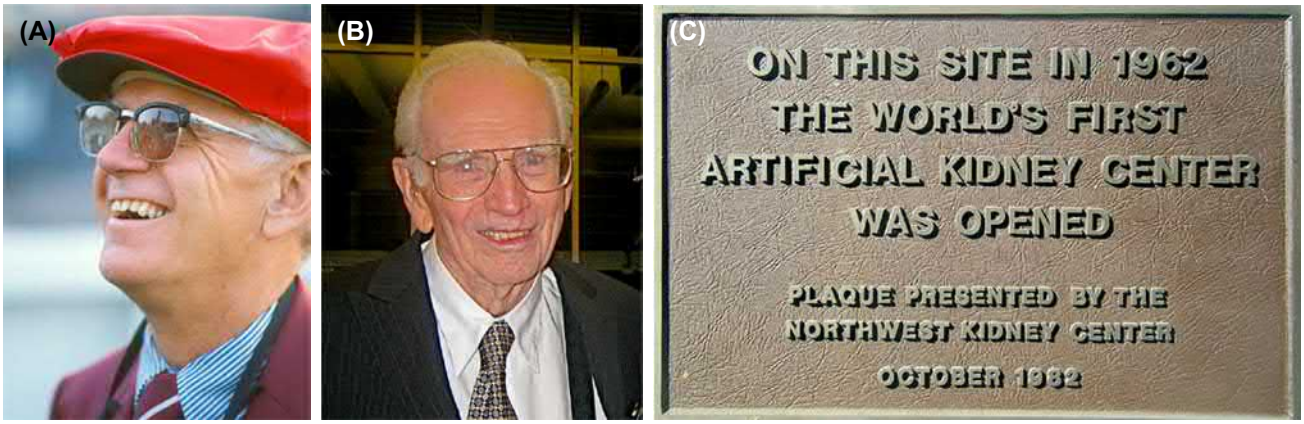
Willem Kolff was also a pioneer in the development of the artificial heart. He implanted the first artificial heart in the Western hemisphere in a dog in 1957 (a Russian artificial heart was implanted in a dog in the late 1930s). The Kolff artificial heart was made of a thermosetting poly(vinyl chloride) cast inside hollow molds to prevent seams. In 1953, the heart–lung machine was invented by John Gibbon, but this was useful only for acute treatment, such as during open heart surgery. In 1964, the National Heart and Lung Institute of the National Institutes of Health set a goal of a total artificial heart by 1970. Dr. Michael DeBakey implanted a left ventricular assist device in a human in 1966, and Dr. Denton Cooley and Dr. William Hall implanted a polyurethane total artificial heart in 1969. In the period 1982–85, Dr. William DeVries implanted a number of Jarvik hearts based upon designs originated by Drs. Clifford Kwan-Gett and Donald Lyman—patients lived up to 620 days on the Jarvik 7 device.

Breast Implants

The breast implant evolved to address the poor results achieved with direct injection of substances into the breast for augmentation. In fact, in the 1960s, California and Utah classified use of silicone injections as a criminal offense. In the 1950s, poly(vinyl alcohol) sponges were implanted as breast prostheses, but results with these were also poor. University of Texas plastic surgeons Thomas Cronin and Frank Gerow invented the first silicone breast implant in the early 1960s, a silicone shell filled with silicone gel. Many variations of this device have been tried over the years, including cladding the device with polyurethane foam (the Natural Y implant). This variant of the breast implant was fraught with problems. However, the basic silicone rubber–silicone gel breast implant was generally acceptable in performance (Bondurant et al., 1999).

Vascular Grafts

Surgeons have long needed methods and materials to repair damaged and diseased blood vessels. Early in the century,



• **Figure 1.1.2.6** (A) Belding Scribner; (B) Wayne Quinton; (C) plaque commemorating the original location in Seattle of the world's first artificial kidney center. ((A) Courtesy of Dr. Eli Friedman. (B) Photo by B. Ratner.)

Dr. Alexis Carrel developed methods to anastomose (suture) blood vessels, an achievement for which he won the Nobel Prize in medicine in 1912. In 1942 Blackmore used Vitallium metal tubes to bridge arterial defects in war-wounded soldiers. Columbia University surgical intern Arthur Voorhees (1922–92), in 1947, noticed during a postmortem that tissue had grown around a silk suture left inside a lab animal. This observation stimulated the idea that a cloth tube might also heal by being populated by the tissues of the body. Perhaps such a healing reaction in a tube could be used to replace an artery? His first experimental vascular grafts were sewn from a silk handkerchief and then parachute fabric (Vinyon N), using his wife's sewing machine. The first human implant of a prosthetic vascular graft was in 1952. The patient lived many years after this procedure, inspiring many surgeons to copy the procedure. By 1954, another paper was published establishing the clear benefit of a porous (fabric) tube over a solid polyethylene tube (Egdahl et al., 1954). In 1958, the following technique was described in a textbook on vascular surgery (Rob, 1958): "The Terylene, Orlon or nylon cloth is bought from a draper's shop and cut with pinking shears to the required shape. It is then sewn with thread of similar material into a tube and sterilized by autoclaving before use."

Stents

Partially occluded coronary arteries lead to angina, diminished heart functionality, and eventually, when the artery occludes (i.e., myocardial infarction), death of a localized portion of the heart muscle. Bypass operations take a section of vein from another part of the body and replace the occluded coronary artery with a clean conduit—this is major surgery, hard on the patient, and expensive. Synthetic vascular grafts in the 3 mm diameter size that is appropriate to the human coronary artery anatomy will thrombose, and thus cannot be used. Another option is percutaneous transluminal coronary angioplasty (PTCA). In this procedure, a balloon is threaded on a catheter into the coronary artery and then inflated to open the lumen of the occluding vessel.

• **Figure 1.1.2.7** Dr. Julio Palmaz, inventor of the coronary artery stent. (Photograph by B. Ratner.)

However, in many cases the coronary artery can spasm and close from the trauma of the procedure. The invention of the coronary artery stent, an expandable mesh structure that holds the lumen open after PTCA, was revolutionary in the treatment of coronary occlusive disease. In his own words, Dr. Julio Palmaz (Fig. 1.1.2.7) describes the origins and history of the cardiovascular stent:

> *I was at a meeting of the Society of Cardiovascular and Interventional Radiology in February 1978 when a visiting lecturer, Doctor Andreas Gruntzig from Switzerland, was presenting his preliminary experience with coronary balloon angioplasty. As you know, in 1978 the mainstay therapy of coronary heart disease was surgical bypass. Doctor Gruntzig showed his promising new technique to open up coronary atherosclerotic blockages without the need for open chest surgery, using his own plastic balloon catheters. During his*

presentation, he made it clear that in a third of the cases, the treated vessel closed back after initial opening with the angioplasty balloon because of elastic recoil or delamination of the vessel wall layers. This required standby surgery facilities and personnel, in case acute closure after balloon angioplasty prompted emergency coronary bypass. Gruntzig's description of the problem of vessel reclosure elicited in my mind the idea of using some sort of support, such as used in mine tunnels or in oil well drilling. Since the coronary balloon goes in small (folded like an umbrella) and is inflated to about 3–4 times its initial diameter, my idealistic support device needed to go in small and expand at the site of blockage with the balloon. I thought one way to solve this was a malleable, tubular, crisscross mesh. I went back home in the Bay Area and started making crude prototypes with copper wire and lead solder, which I first tested in rubber tubes mimicking arteries. I called the device a BEIS or balloon-expandable intravascular graft. However, the reviewers of my first submitted paper wanted to call it a stent. When I looked the word up, I found out that it derives from Charles Stent, a British dentist who died at the turn of the century. Stent invented a wax material to make dental molds for dentures. This material was later used by plastic surgeons to keep tissues in place, while healing after surgery. The word "stent" was then generically used for any device intended to keep tissues in place while healing.

I made the early experimental device of stainless steel wire soldered with silver. These were materials I thought would be appropriate for initial laboratory animal testing. To carry on with my project I moved to the University of Texas Health Science Center in San Antonio (UTHSCSA). From 1983–1986 I performed mainly bench and animal testing that showed the promise of the technique and the potential applications it had in many areas of vascular surgery and cardiology. With a UTHSCSA pathologist, Doctor Fermin Tio, we observed our first microscopic specimen of implanted stents in awe. After weeks to months after implantation by catheterization under X-ray guidance, the stent had remained open, carrying blood flow. The metal mesh was covered with translucent, glistening tissue similar to the lining of a normal vessel. The question remained whether the same would happen in atherosclerotic vessels. We tested this question in the atherosclerotic rabbit model and to our surprise, the new tissue free of atherosclerotic plaque encapsulated the stent wires, despite the fact that the animals were still on a high cholesterol diet. Eventually, a large sponsor (Johnson & Johnson) adopted the project and clinical trials were instituted under the scrutiny of the Food and Drug Administration.

Coronary artery stenting is now performed in well over 1.5 million procedures per year.

Pacemakers

In London in 1788, Charles Kite wrote "An Essay Upon the Recovery of the Apparently Dead," where he discussed electrical discharges to the chest for heart resuscitation. In the period 1820–80 it was already known that electric shocks could modulate the heartbeat (and, of course, consider the *Frankenstein* story from that era). The invention of the portable pacemaker, hardly portable by modern standards, may have taken place almost simultaneously in two groups in 1930–31—Dr. Albert S. Hyman (USA) (Fig. 1.1.2.8) and Dr. Mark C. Lidwill (working in Australia with physicist Major Edgar Booth).

• **Figure 1.1.2.8** The Albert Hyman Model II portable pacemaker, c. 1932–33. (Courtesy of the NASPE-Heart Rhythm Society History Project (www.Ep-History.org).)

Canadian electrical engineer, John Hopps, while conducting research on hypothermia in 1949, invented an early cardiac pacemaker. Hopps' discovery was if a cooled heart stopped beating, it could be electrically restarted. This led to Hopps' invention of a vacuum tube cardiac pacemaker in 1950. Paul M. Zoll developed a pacemaker in conjunction with the Electrodyne Company in 1952. The device was about the size of a small microwave oven, was powered with external current, and stimulated the heart using electrodes placed on the chest—this therapy caused pain and burns, although it could pace the heart.

In the period 1957–58, Earl E. Bakken, founder of Medtronics, Inc., developed the first wearable transistorized (external) pacemaker at the request of heart surgeon Dr. C. Walton Lillehei. Bakken quickly produced a prototype that Lillehei used on children with postsurgery heart block. Medtronic commercially produced this wearable, transistorized unit as the 5800 pacemaker.

In 1959 the first fully implantable pacemaker was developed by engineer Wilson Greatbatch and cardiologist W.M. Chardack. He used two Texas Instruments transistors, a technical innovation that permitted small size and low power drain. The pacemaker was encased in epoxy to inhibit body fluids from inactivating it.

• **Figure 1.1.2.9** The Hufnagel heart valve consisting of a poly(methyl methacrylate) tube and nylon ball. (United States Federal Government image in the public domain.)

Heart Valves

The development of the prosthetic heart valve paralleled developments in cardiac surgery. Until the heart could be stopped and blood flow diverted, the replacement of a valve would be challenging. Charles Hufnagel, in 1952, implanted a valve consisting of a poly(methyl methacrylate) tube and nylon ball in a beating heart (Fig. 1.1.2.9). This was a heroic operation and basically unsuccessful, but an operation that inspired cardiac surgeons to consider that valve prostheses might be possible. The 1953 development of the heart–lung machine by Gibbon allowed the next stage in the evolution of the prosthetic heart valve to take place. In 1960, a mitral valve replacement was performed in a human by surgeon Albert Starr, using a valve design consisting of a silicone ball and poly(methyl methacrylate) cage (later replaced by a stainless-steel cage). The valve was invented by engineer Lowell Edwards. The heart valve was based on a design for a bottle stopper invented in 1858. Starr was quoted as saying: "Let's make a valve that works and not worry about its looks," referring to its design that was radically different from the leaflet valve that nature evolved in mammals. Prior to the Starr–Edwards valve, no human had lived with a prosthetic heart valve longer than 3 months. The Starr–Edwards valve was found to permit good patient survival. The major issues in valve development in that era were thrombosis and durability. In 1969, Warren Hancock started the development of the first leaflet tissue heart valve based upon glutaraldehyde-treated pig valves, and his company and valve were acquired by Johnson & Johnson in 1979.

Pyrolytic Carbon

Pyrolytic carbon (PyC) is a manmade material not found in nature. The term "pyrolytic" is derived from "pyrolysis"—a thermal decomposition process. In other words, PyC is formed from the thermal decomposition of hydrocarbons such as propane, propylene, acetylene, and methane in the absence of oxygen. The use of PyC as leaflets for blood contact application was an accidental event, according to the story told by Professor Robert E. Baier of the University at Buffalo in 2016 (Baier, 2016). Here are his own words:

> *It was in late 1967, early 1968, that a strange finding emerged from the pioneering "Gott Ring" studies in canine vena cavae being done at Johns Hopkins Hospital, in Baltimore, Maryland. Classical inorganic materials scientist, Dr. Jack Bokros, of San Diego's General Atomic Corp., had become "accidentally" a co-worker of Vincent Gott through Bill Ellis, who had read an abstract in Carbon by Gott et al.: "The Anticlot Properties of Graphite Coatings on Artificial Heart Valves" (Gott et al., 1964) and informed Bokros that colloidal graphite (carbon) coatings were being used as a "base" for blood anti-coagulant on Dr. Vincent Gott's short-ring implants, to good effect. Ellis was a bit offended by the choice of a commercial product which was much less pure than what had recently been developed at General Atomic, and so samples of the newly developed PyC at General Atomic Corp. were sent to Dr. Gott as "positive" (clot-provoking) controls. I was one of the "boys in the back room," providing surface analyses of all proposed new blood-contact materials. Early measurements predicted that these PyC rings would immediately cause both thrombosis and coagulation of slow-flowing dog blood. We were all surprised when the naked PyC rings stayed clean for 2-hours (most everything else had clotted solid by then), and then were amazed when the dogs were brought back after 2-weeks "at the farm!"*
>
> *The rings were still clean, clearly violating all that we had considered ample predictive data to the contrary. Carrying the tests further, I was able to show that the PyC material uniquely bound one of the blood's proteins in a configuration that expressed an outermost "Critical Surface Tension" in a zone prior identified as triggering the least thrombosis and coagulation. It was in that zone, and specifically for the PyC, that Surgeon Eugene Bernstein and Fred Schoen had shown that such PyC leaflets on a pioneering centrifugal blood pump least distorted attached blood platelets and thus did not trigger viscous metamorphosis and thrombus growth. Our colleague, Dr. Emery Nyilas, then working at AVCO-Everett Corporation near Boston, showed that the "heat of adsorption" was minimal during key blood protein trials (carried out in the middle of the night to avoid traffic vibrations) by micro-calorimetry. Drs. Andrade and Kim subsequently showed that the mode of protein adsorption and not the quantity of protein adsorbed on foreign surfaces was a key, consistent with Nyilas' micro-calorimetric studies. PyC adsorbed a layer of blood proteins rapidly without the expected denaturing of proteins on blood contacting surfaces which generally triggered the clotting cascade.*

• **Figure 1.1.2.10** An in vivo flow cell made of pyrolytic carbon, postcanine implantation.

Many others joined in, General Atomic became Gulf General Atomic which spun-off CarboMedics which inspired Medical Carbon Research Institute—and a large fraction of the world's synthetic heart valves have since been rendered from those pioneering contributions between academia and industry. The recently announced sale of St. Jude Medical to Abbott Laboratories for $25 Billion is predominantly owing to the initial success of St. Jude with these PyC heart valves, and subsequent copying of the technology. Fig. 1.1.2.10 is a contemporary photo of a PyC "flow cell" that had been implanted in a 27 kg dog by Dr. Gott, to establish the details of thromboresistance now shown in over 15 million successful valve implants.

Drug Delivery and Controlled Release

Throughout most of history drugs were administered orally or by hypodermic syringe. In general, there was no effort to modulate the rate of uptake of the drug into the body. In 1949, Dale Wurster invented what is now known as the Wurster process that permitted pills and tablets to be encapsulated and therefore slow their release rate. However, modern ideas of controlled release can be traced to a medical doctor, Judah Folkman. Dr. Folkman noted that dyes penetrated deeply into silicone rubber, and he surmised from this that drugs might do the same. He sealed isoproterenol (a drug used to treat heart block) into silicone tubes, and implanted these into the hearts of dogs (Folkman and Long, 1964). He noted the delayed release and later applied this same idea to delivering a birth control steroid. He donated this development, patent free, to the World Population Council. An entrepreneur and chemist, Alejandro Zaffaroni, heard of the Folkman work and launched a company in 1970, Alza (originally called Pharmetrics), to develop these ideas for the pharmaceutical industry. The company developed families of new polymers for controlled release, and also novel delivery strategies. Alza was a leader in launching this new field that is so important today; further details on the field of controlled release are provided in an excellent historical overview (Hoffman, 2008).

Designed Biomaterials

In contrast to the biomaterials of the surgeon-hero era, when largely off-the-shelf materials were used to fabricate medical devices, the 1960s on saw the development of materials designed specifically for biomaterials applications. Here are some key classes of materials and their evolution from commodity materials to engineered/synthesized biomaterials.

Silicones

Although the class of polymers known as silicones has been explored for many years, it was not until the early 1940s that Eugene Rochow of General Electric pioneered the scale-up and manufacture of commercial silicones via the reaction of methyl chloride with silicone in the presence of catalysts. In Rochow's 1946 book, *The Chemistry of Silicones* (John Wiley & Sons, Publishers), he comments anecdotally on the low toxicity of silicones, but did not propose medical applications. Possibly the first report of silicones for implantation was by Lahey (1946) (see also Chapter 1.3.2B). The potential for medical uses of these materials was realized shortly after this. In a 1954 book on silicones, McGregor has a whole chapter titled "Physiological Response to Silicones." Toxicological studies were cited suggesting to McGregor that the quantities of silicones that humans might take into their bodies should be "entirely harmless." He mentions, without citation, the application of silicone rubber in artificial kidneys. Silicone-coated rubber grids were also used to support a dialysis membrane (Skeggs and Leonards, 1948). Many other early applications of silicones in medicine are cited in Chapter 1.3.2B.

Polyurethanes

Polyurethane was invented by Otto Bayer and colleagues in Germany in 1937. The chemistry of polyurethanes intrinsically offered a wide range of synthetic options leading to hard plastics, flexible films, or elastomers (Chapter 1.3.2A). Interestingly, this was the first class of polymers to exhibit rubber elasticity without covalent cross-linking. As early as 1959, polyurethanes were explored for biomedical applications, specifically heart valves (Akutsu et al., 1959). In the mid-1960s a class of segmented polyurethanes was developed that showed both good biocompatibility and outstanding flex life in biological solutions at 37°C (Boretos and Pierce, 1967). Sold under the name Biomer by Ethicon and based upon DuPont Lycra, these segmented polyurethanes comprised the pump diaphragms of the Jarvik 7 hearts that were implanted in seven humans.

Teflon

DuPont chemist Roy Plunkett discovered a remarkably inert polymer, Teflon (polytetrafluoroethylene) (PTFE), in 1938. William L. Gore and his wife, Vieve, started a company in 1958 to apply Teflon for wire insulation. In 1969, their

son Bob found that Teflon, if heated and stretched, forms a porous membrane with attractive physical and chemical properties. Bill Gore tells the story that, on a chairlift at a ski resort, he pulled from his parka pocket a piece of porous Teflon tubing to show to his fellow ski lift passenger. The skier was a physician and asked for a specimen to try as a vascular prosthesis. Now, Goretex porous Teflon and similar expanded PTFEs are the leading synthetic vascular grafts, and are also used in numerous other applications in surgery and biotechnology (Chapters 1.3.2C and 2.5.2B).

Hydrogels

Hydrogels have been found in nature since life on earth evolved. Bacterial biofilms, hydrated extracellular matrix components, and plant structures are ubiquitous, water-swollen motifs in nature. Gelatin and agar were also known and used for various applications early in human history. But the modern history of hydrogels as a class of materials designed for medical applications can be accurately traced.

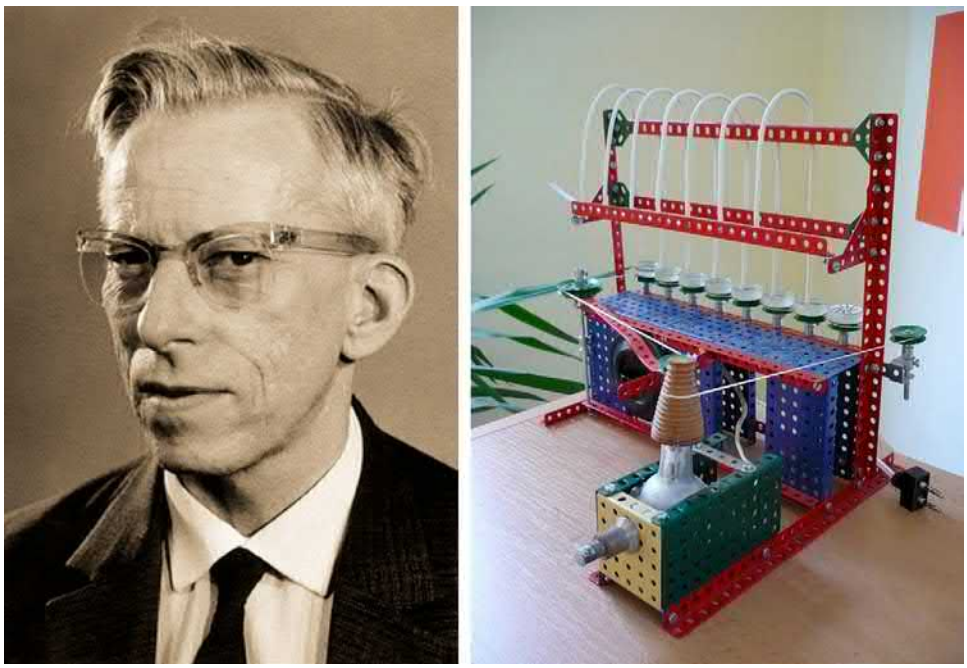
In 1936, DuPont scientists published a paper on recently synthesized methacrylic polymers. In this paper, poly(2-hydroxyethyl methacrylate) (polyHEMA) was mentioned. It was briefly described as a hard, brittle, glassy polymer, and clearly was not considered of importance. After that paper, polyHEMA was essentially forgotten until 1960. Wichterle and Lim published a paper in *Nature* describing the polymerization of HEMA monomer and a cross-linking agent in the presence of water and other solvents (Wichterle and Lim, 1960). Instead of a brittle polymer, they obtained a soft, water-swollen, elastic, clear gel. Wichterle went on to develop an apparatus (built originally from a children's construction set; Fig. 1.1.2.11) for centrifugally casting the hydrogel into contact lenses of the appropriate refractive power. This innovation led to the soft contact lens industry, and to the modern field of biomedical hydrogels as we know them today.

Interest and applications for hydrogels have steadily grown over the years, and these are described in detail in Chapter 1.3.2E. Important early applications included acrylamide gels for electrophoresis, poly(vinyl alcohol) porous sponges (Ivalon) as implants, many hydrogel formulations as soft contact lenses, and alginate gels for cell encapsulation.

Poly(Ethylene Glycol)

Poly(ethylene glycol) (PEG), also called poly(ethylene oxide), in its high molecular weight form, can be categorized as a hydrogel, especially when the chains are cross-linked. However, PEG has many other applications and implementations. It is so widely used today that its history is best discussed in its own section.

The low reactivity of PEG with living organisms has been known since at least 1944, when it was examined as a possible vehicle for intravenously administering fat-soluble hormones (Friedman, 1944). In the mid-1970s, Frank Davis and colleagues (Abuchowski et al., 1977) discovered that if PEG chains were attached to enzymes and proteins, they would a have a much longer functional residence time in vivo than biomolecules that were not PEGylated. Professor Edward Merrill of MIT, based upon what he called "various bits of evidence" from the literature, concluded



• **Figure 1.1.2.11** *Left*: Otto Wichterle (1913–98). (Wikipedia.) *Right*: The centrifugal casting apparatus Wichterle used to create the first soft, hydrogel contact lenses. (Photograph by Jan Suchy, Wikipedia public domain.)

that surface-immobilized PEG would resist protein and cell pickup. The experimental results from his research group in the early 1980s bore out this conclusion (Merrill, 1992). The application of PEGs to a wide range of biomedical problems was significantly accelerated by the synthetic chemistry developments of Dr. Milton Harris while at the University of Alabama, Huntsville.

Poly(Lactic-Glycolic Acid)

Although originally discovered in 1833, the anionic polymerization from the cyclic lactide monomer in the early 1960s made creating materials with mechanical properties comparable to Dacron possible. The first publication on the application of poly(lactic acid) in medicine may be by Kulkarni et al. (1966). This group demonstrated that the polymer degraded slowly after implantation in guinea pigs or rats, and was well tolerated by the organisms. Cutright et al. (1971) were the first to apply this polymer for orthopedic fixation. Poly(glycolic acid) and copolymers of lactic and glycolic acid were subsequently developed. Early clinical applications of polymers in this family were for sutures, based upon the work of Joe Frazza and Ed Schmitt at David & Geck, Inc (Frazza and Schmitt, 1971). The glycolic acid/lactic acid polymers have also been widely applied for controlled release of drugs and proteins. Professor Robert Langer's group at MIT was the leader in developing these polymers in the form of porous scaffolds for tissue engineering (Langer and Vacanti, 1993).

Hydroxyapatite

Hydroxyapatite is one of the most widely studied materials for healing in bone. It is a naturally occurring mineral, a component of bone, and a synthesized material with wide application in medicine. Hydroxyapatite can be easily made as a powder. One of the first papers to describe biomedical applications of this material was by Levitt et al. (1969), in which they hot pressed the hydroxyapatite power into useful shapes for biological experimentation. From this early appreciation of the materials science aspect of a natural biomineral, a literature of thousands of papers has evolved. In fact, the nacre implant described in the prehistory section may owe its effectiveness to hydroxyapatite—it has been shown that the calcium carbonate of nacre can transform in phosphate solutions to hydroxyapatite (Ni and Ratner, 2003).

Titanium

In 1791, William Gregor, a Cornish amateur chemist, used a magnet to extract the ore that we now know as ilmenite from a local river. He then extracted the iron from this black powder with hydrochloric acid, and was left with a residue that was the impure oxide of titanium. After 1932, a process developed by William Kroll permitted the commercial extraction of titanium from mineral sources. At the end of World War II, titanium metallurgy methods and titanium materials made their way from military application to peacetime uses. By 1940, satisfactory results had already been achieved with titanium implants (Bothe et al., 1940). The major breakthrough in the use of titanium for bony tissue implants was the Brånemark discovery of osseointegration, described earlier in the section on dental implants.

Bioglass

Bioglass is important to biomaterials as one of the first completely synthetic materials that seamlessly bonds to bone. It was developed by Professor Larry Hench and colleagues. In 1967 Hench was Assistant Professor at the University of Florida. At that time his work focused on glass materials and their interaction with nuclear radiation. In August of that year, he shared a bus ride to an Army Materials Conference in Sagamore, New York, with a US Army colonel who had just returned from Vietnam where he was in charge of supplies to 15 MASH units. This colonel was not particularly interested in the radiation resistance of glass. Rather, he challenged Hench with the following: hundreds of limbs a week in Vietnam were being amputated because the body was found to reject the metals and polymer materials used to repair the body. "If you can make a material that will resist gamma rays why not make a material the body won't resist?"

Hench returned from the conference and wrote a proposal to the US Army Medical R and D Command. In October 1969 the project was funded to test the hypothesis that silicate-based glasses and glass-ceramics containing critical amounts of Ca and P ions would not be rejected by bone. In November 1969 Hench made small rectangles of what he called 45S5 glass (44.5 wt% SiO_2), and Ted Greenlee, Assistant Professor of Orthopedic Surgery at the University of Florida, implanted them in rat femurs at the VA Hospital in Gainesville. Six weeks later Greenlee called: "Larry, what are those samples you gave me? They will not come out of the bone. I have pulled on them, I have pushed on them, I have cracked the bone and they are still bonded in place." Bioglass was born, and with the first composition studied! Later studies by Hench using surface analysis equipment showed that the surface of the bioglass, in biological fluids, transformed from a silicate-rich composition to a phosphate-rich structure, possibly hydroxyapatite (Clark et al., 1976).

The Contemporary Era (Modern Biology and Modern Materials)

It is probable that the modern era in the history of biomaterials, biomaterials engineered to control specific biological reactions, was ushered in by rapid developments in modern biology. As illustrated in Fig. 1.1.1.2, major advances in the medical device field continue to be made with materials that could be considered first generation with the incorporation of concepts and approaches from the later generations. In the 1960s, when the field of

biomaterials was laying down its foundational principles and ideas, concepts such as cell-surface receptors, growth factors, nuclear control of protein expression and phenotype, cell attachment proteins, stem cells, and gene delivery were either controversial observations or not yet discovered. Thus pioneers in the field could not have designed materials with these ideas in mind. It is to the credit of the biomaterials community that it has been quick to embrace and exploit new ideas from biology. Similarly, new ideas from materials science such as phase separation, anodization, self-assembly, surface modification, and surface analysis were quickly assimilated into the biomaterial scientists' toolbox and vocabulary. A few of the important ideas in biomaterials literature that set the stage for the biomaterials science we see today are useful to list:

- Protein adsorption
- Biospecific biomaterials
- Nonfouling materials
- Healing and the foreign-body reaction
- Controlled release (also, programmed release and release on demand)
- Tissue engineering
- Immunoengineering
- Regenerative materials
- Nanotechnology

Since these topics are addressed later in some detail in *Biomaterials Science*: *An Introduction to Materials in Medicine*, fourth edition, they will not be expanded upon in this history section. Still, it is important to appreciate the intellectual leadership of many researchers who promoted these ideas that comprise modern biomaterials—this is part of a recent history of biomaterials that will someday be completed. We practice biomaterials today immersed within an evolving history.

Conclusions

Biomaterials have progressed from adventurous practices by surgeon-heroes, sometimes working with engineers, to a field dominated by engineers, chemists, and physicists, to our modern era innovations with biologists and bioengineers as the key players. At the moment you are reading the fourth edition of Biomaterials Science: An Introduction to Materials in Medicine, many individuals who were biomaterials pioneers in the formative days of the field are well into their eighth or ninth decades of life. A number of leaders of biomaterials, pioneers who spearheaded the field with vision, creativity, and integrity, have passed away. Yet, since biomaterials is relatively a new field, the first-hand accounts of its roots are still available. We encourage readers of this book to document their conversations with pioneers of the field (many of whom still attend biomaterials conferences), so that the exciting stories and accidental discoveries that led to the successful and intellectually stimulating field we see today are not lost.

1.2.1 Introduction: Properties of Materials—the Palette of the Biomaterials Engineer

JACK E. LEMONS[1], GUIGEN ZHANG[2]

[1]Schools of Dentistry, Medicine and Engineering, University of Alabama at Birmingham, Birmingham, AL, United States

[2]F Joseph Halcomb III, M.D. Department of Biomedical Engineering, University of Kentucky, Lexington, KY, United States

The platform, or palette, upon which the biomaterials engineer arranges information into parts for subsequent blending has expanded and evolved significantly in content over the past several decades. The depth and breadth of what is now included on this palette go well beyond expectations expressed by the founding members of the Society for Biomaterials in the late 1960s and early 1970s. The *Science of Biomaterials* has expanded from dealing with the fundamental aspects of the physical, mechanical, chemical, electrical, electrochemical, thermal, optical, and biological (compatibility) properties of biomaterials of natural or synthetic origin, to the design principles of tissue/cell/molecule-synthesized or -engineered biomaterials and nanomaterials. Because of that, the methods for measuring and analyzing materials' properties have also evolved.

Following the recognition of the need by the pioneers of the biomaterials discipline in the 1960s, one focus of the science of biomaterials has been the fundamental structure versus property relationships leading to in vivo biocompatibility. These relationships, and the supporting scientific information, have changed with time and experience, especially as the biological and clinical disciplines have also expanded and evolved. For example, considerations for biocompatibility are very different for biomaterials listed within biotolerant, surface bioactive, and biodegradable categories. This shift of emphasis is reflected in the progression of content of the first four editions of this book. For example, initial considerations focused on materials were based primarily on substances of the metallics, ceramics, and polymerics available within various biomedical applications. Thus the emphasis in the first edition was on materials of natural and synthetic origin, including metals, ceramics, polymers, and composites, and the underlying science leading to biomedical applications. The second and third editions represent the transitions from combination products to the new areas of bioactives and biodegradables and tissue-engineered constructs. As an integrated, comprehensive, and authoritative text, this fourth edition reflects a broader range of biomaterials as well as basic properties of new classes of biomaterials that possess more of a resemblance to complex biological constructs formed by nature and constantly remodeled by biology in response to biophysical demands and biomechanical environments.

Considering relationships between biomaterial and biological systems (the interface) and the dynamics of change from nanoseconds to years, we now better understand many mechanisms of interaction at the dimensions and concentrations used to describe interactions of atoms and molecules. It is also realized that all biomaterial and host-environment interactions play a role in the broader aspects of biocompatibility, especially the functionality and longevity of implant devices. In this regard, Part 1 on "Materials Science and Engineering" emphasizes the more basic information on the bulk and surface properties of synthetic and natural origin biomaterials. Critical aspects of constitution

(chemistry) and structure (nano-, micro-, and macrodimension) relationships are presented as related to properties of implant systems. These basic considerations include the nature of the matters (Chapter 1.2.2), bulk (Chapter 1.2.3), and surface (Chapter 1.2.4) properties, and the role of water in biomaterials (Chapter 1.2.5). The science of interactions of synthetic and natural substances with water is recognized as one of the key aspects of surgical implant biocompatibilities. This is especially important for the evolution of the discipline to include new-generation biomaterials needed for future implant applications.

In short, the content of this Part 1 is broadly applicable to all parts of the fourth edition. Therefore students are advised to always consider the basic principles as provided in this section. This has been recognized as critical to the education of a specialist in biomaterials science leading to the selection of biomaterials for medical treatments utilizing all types of implant devices.

1.2.2

The Nature of Matter and Materials

BUDDY D. RATNER

Bioengineering and Chemical Engineering, Director of University of Washington Engineered Biomaterials (UWEB), Seattle, WA, United States

Introduction

Biomaterials are *materials*.

Biomaterials are *materials*. What are materials and how are they structured? This is the subject of this chapter, a lead into subsequent chapters with discussions of the bulk (including mechanical) properties of materials, surface properties, and the role of water (since biomaterials most commonly function in an aqueous environment, and that environment can alter both the nature of the material and the interactions that occur with the material). This chapter also considers fundamental atomic and molecular interactions that underlie subsequent chapters addressing specific classes of materials relevant to biomaterials (polymers, metals, ceramics, natural materials, and particulates).

Atoms and Molecules

The key to understanding matter is to understand attractive and interactive forces between atoms.

This "Nature of Matter" section aims to communicate an understanding of the basic structure of materials that will drive their properties—both the mechanical properties important for specific applications (strong, elastic, ductile, permeable, etc.), and the surface properties that will mediate reactions with the external biological environment.

The key to understanding matter is to understand attractive and interactive forces between atoms. Argon is a gas at room temperature—it must be cooled to extremely low temperatures to transition it into liquid form. An argon atom interacts (attracts) very, very weakly with another argon atom—so at room temperature, thermal fluctuations that randomly propel the atoms exceed attractive forces that might result in coalescence to a solid material. A titanium atom strongly interacts with another titanium atom. Extremely high temperatures are required to vaporize titanium and liberate those atoms from each other. The understanding of matter is an appreciation of interactive forces between atoms.

What holds those atoms and molecules together to make a strong nylon fiber or a cell membrane, or a hard, brittle hydroxyapatite ceramic, or a sheet of gold, or a drop of water? Even in the early 18th century, Isaac Newton was pondering this issue: "There are therefore Agents in Nature able to make the Particles of Bodies stick together by very strong Attractions."

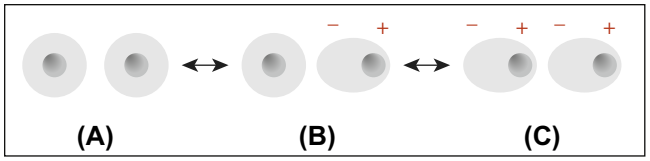
Entropy consideration would say these molecules and atoms should "fly apart" to increase randomness. However, there is an energy term contributing to the stability of the ensemble leading to a negative Gibbs free energy, which, according to the second law of thermodynamics, should make such solids energetically favorable (of course, we intuitively know this). Thus we must examine this energy term. We know of just four attractive forces in this universe:

- Gravitational
- Weak nuclear
- Strong nuclear
- Electromagnetic

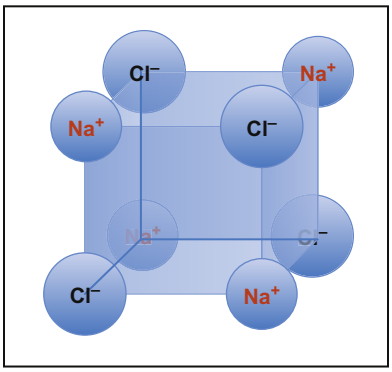
Gravity holds us to the surface of the planet Earth (a massive body), but the gravitational potential energy of two argon atoms is only about 10^{-52} J, 30 orders of magnitude weaker than is observed for intermolecular forces. The weak nuclear force and the strong nuclear force are only significant over 10^{-4} nm—but molecular dimensions are 5×10^{-1} nm. So these forces do not explain what holds atoms together. This leaves, by default, electromagnetic forces (positive charge attracts negative charge). Electromagnetic forces have appropriate magnitudes and distance dependencies to justify why atoms interact. Interactions can be weak, leading to liquids, or stronger, leading to solids.

TABLE 1.2.2.1 Forces That Hold Atoms Together

Interatomic Force	Explanation	Relative Strength	Examples
Van der Waals interactions	Transient fluctuations in the spatial localization of electron clouds surrounding atoms lead to transient positive and negative charges, and consequent interactive forces in molecules would seem to have no permanent polarity	Weak	Argon at cryogenic temperatures Polyethylene (the forces that hold the chains together to make a solid)
Ionic	Atoms with a permanent positive (+) charge attract atoms with a permanent negative (–) charge	Very strong	NaCl $CaCl_2$
Hydrogen (H) bonding	The interaction of a covalently bound hydrogen with an electronegative atom, such as oxygen or fluorine	Medium	Water ice Nylon (the forces that hold the chains together to make a strong, high-melting point solid)
Metallic	The attractive force between a "sea" of positively charged atoms and delocalized electrons	Medium–strong	Gold Titanium metal
Covalent	A sharing of electrons between two atoms	Strong	The carbon–carbon bond Cross-links in a polyacrylamide hydrogel



• **Figure 1.2.2.1** (A) Consider the electron clouds (charge density in space) of two atoms or molecules, both without permanent dipole moments. (B) Electron clouds are continuously in motion and can shift to one side of the atom or molecule; therefore, at any moment, the atoms or molecules can create a "fluctuating instantaneous dipole." (C) The "fluctuating instantaneous dipole" in one molecule electrostatically induces such an "instantaneous dipole" in the next molecule.



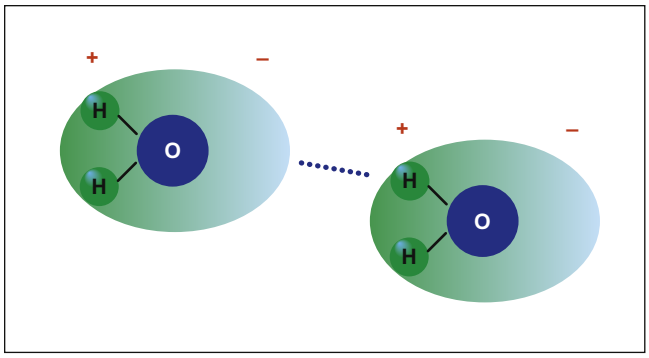
• **Figure 1.2.2.2** The unit cell of a sodium chloride crystal illustrating the plus–minus electrostatic interactions.

Electromagnetic forces manifest themselves in a number of ways. The types of interactions usually observed between atoms (all explained by electrostatics) are summarized in Table 1.2.2.1. We consider here van der Waals forces (also called induction or dispersion forces), ionic forces, hydrogen bonding, metallic forces, and covalent interactions.

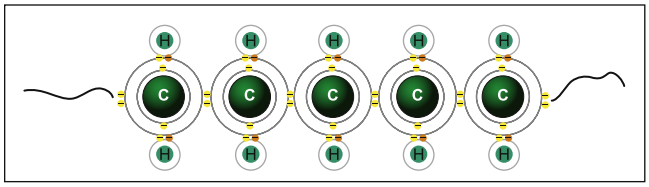
Van der Waals or dispersion forces rationalize the interaction of two atoms or molecules, each without a dipole (no plus or minus faces to the molecules). For example, argon atoms can be liquefied at low temperature. Why should this happen? Why should argon atoms want to interact with each other enough to form a liquid? Fig. 1.2.2.1 explains the origin of dispersive forces. Such forces are important, as they dictate the properties of many materials (for example, some polymers such as polyethylene, which has no obvious dipole), but they also explain why the lipids in cell membranes assemble into the bilayer structure described later in this textbook. A typical van der Waals interactive force (for example, $CH_4 \cdots CH_4$) is about 9 kJ/mol. The Ar ⋯ Ar interactive force is approximately 1 kJ/mol.

Ionic forces are probably the easiest of the intermolecular forces to understand. Fig. 1.2.2.2 illustrates a unit cell of a sodium chloride crystal. The + and – charges are arrayed to achieve the closest interaction of opposite charges and the furthest separation of similar charges. This unit cell can be repeated over and over in space, and the forces that hold it together are the electrostatic interaction of a permanent + charge and a permanent – charge. Typical ionic bond strengths (for example, NaCl) are about 770 kJ/mol.

Hydrogen bonding interactions are also straightforward to appreciate as electrostatic interactions. An electronegative element such as oxygen (it demands electrons) can distort the binding electron cloud from the hydrogen nucleus leaving the hydrogen (just a proton and electron) with less electron and thus more plus-charged proton.



• **Figure 1.2.2.3** A hydrogen bond between two water molecules.



• **Figure 1.2.2.5** Covalent bonding along a section of polyethylene chain. Carbons share pairs of electrons with each other, and each hydrogen shares an electron pair with carbon.

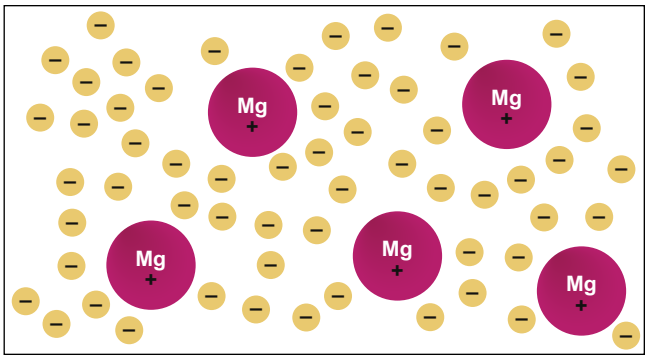
This somewhat positive charge will, in turn, then interact with an electronegative oxygen (Fig. 1.2.2.3). Typical hydrogen bond strengths (for example, O–H ⋯ H) are about 20 kJ/mol.

Metallic bonding is explained by a delocalized "sea" of valence electrons with positively charged nuclear cores dispersed within it (Fig. 1.2.2.4). A single metallic bond is rarely discussed. The total interactive strength is realized through the multiplicity of the plus–minus interactions. The strength of this interaction can be expressed by heats of sublimation. For example, at 25°C, aluminum will have a heat of sublimation of 325 kJ/mol, while titanium will be about 475 kJ/mol.

Covalent bonds are relatively strong bonds associated with the sharing of pairs of electrons between atoms (Fig. 1.2.2.5). Typical covalent bond strengths (for example, C–C) are about 350 kJ/mol.

Molecular Assemblies

Atoms can combine in defined ratios to form molecules (usually they combine with covalent bonds), or they can form cohesive assemblies of atoms (think of gold and metallic interactive forces, for example). Thus materials can be made of atoms or of molecules (i.e., covalently joined atoms). The difference between the dense, lubricious plastics used in orthopedics, the soft, elastic materials of catheters, and the hard, strong metals of a hip joint is associated with how those atoms and molecules are organized (due to attractive and interactive forces) in materials. Metals used in biomaterials applications can be strong, rigid, and brittle, or flexible and ductile. Again, the difference is largely how the atoms making up the metal are organized, and how strongly their atoms interact.



• **Figure 1.2.2.4** Metallic bonding in magnesium. The 12 electrons from each Mg atom are shared among positively charged nuclear cores (the single + charge on each magnesium atom in the figure is simply intended to indicate there is some degree of positive charge on each magnesium nuclear core).

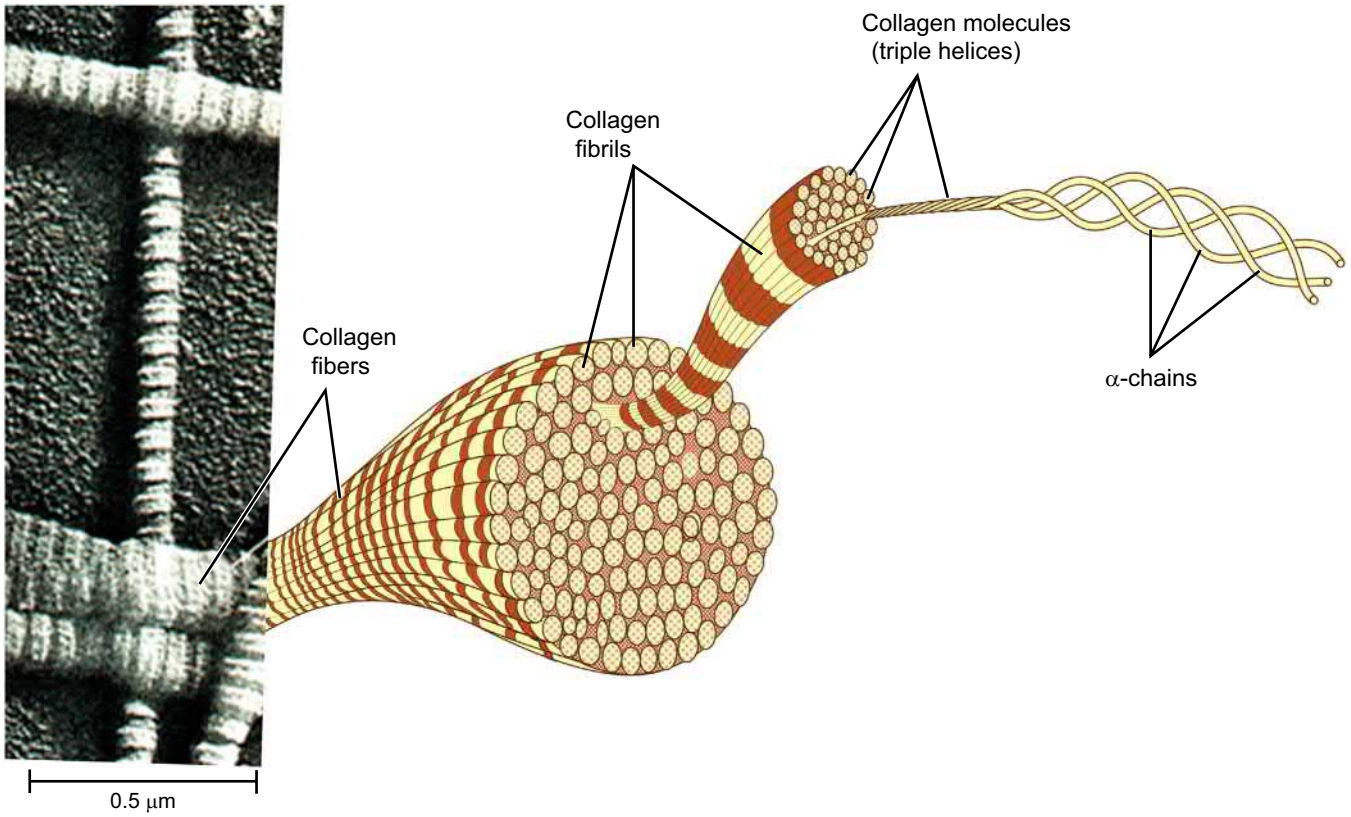
Molecules also organize or assemble. The widely varying properties of polymers are due to molecular organization. The assembly of lipid molecules to make a cell membrane or a microparticulate for drug delivery is another example of this organization.

A key concept in appreciating the properties of materials is hierarchical structures. The smallest size scale that we need consider here in materials is atoms, typically about 0.2 nm in diameter. Atoms combine to form molecules with dimensions ranging from 1 to 100 nm (some large macromolecules). Molecules may assemble or order to form supramolecular structures with dimensions up to 1000 nm or more. These supramolecular structures may themselves organize in bundles, fibers, or larger assemblies with dimensions reaching into the range visible to the human eye. This concept of hierarchical structure is illustrated in Fig. 1.2.2.6, using collagen protein as the example.

The single α-chains comprising the collagen triple helix would break under tension with an application of nanograms of force. On the other hand, the collagen fibers in a hierarchical structure such as a tendon can support many kilograms of force. Such hierarchical structures are noted frequently in both materials science and in biology.

Surfaces

As assemblies of atoms and/or molecules form, within the bulk of the material, each unit is uniformly "bathed" in a field of attractive forces of the types described in Table 1.2.2.1. However, those structural units that are at the surface are pulled upon asymmetrically by just the units beneath them. This asymmetric attraction distorts the electron distributions of the surface atoms or molecules, and gives rise to the phenomenon of surface energy, an excess energy associated with this imbalance. For this reason, surfaces always have unique reactivities and properties. This idea will be expanded upon in Chapter 1.2.4.



• **Figure 1.2.2.6** Collagen fibers make up many structures in the body (tendons, for example). Such anatomical structures as tendons are comprised of collagen fibrils, formed of aligned bundles of collagen triple helices that are themselves made up of single collagen protein chains (α-chains). The α-chains are constructed of joined amino acid units, and the amino acids are molecules of carbon, oxygen, nitrogen, and hydrogen atoms in defined ratios and orders. (Illustration from Becker, W., 2002. The World of the Cell. Reprinted with permission of Pearson Education, Inc.)

Conclusion

In this section we reviewed the transition from chemistry to matter. Interacting assemblies of atoms and molecules comprise matter. Without matter, we cannot have biomaterials. Matter exists because of electrostatic forces—positive and negative charges, in all cases, hold atoms together. The strength of those interactions, associated with the magnitude of the charge on each atom, and the environment the atoms are in (water, air, etc.) ultimately dictate the properties of matter (a soft gel, a hard metal, etc.). Now that we have a general idea what "matter" is, we can take these concepts from physics and chemistry and bring them to a consideration of the mechanical properties of materials, the surface properties of materials, and then into the specifics of polymers, metals, ceramics, and other types of materials.

1.2.3

Bulk Properties of Materials

GUIGEN ZHANG[1], CHRISTOPHER VINEY[2]

[1]F Joseph Halcomb III, M.D. Department of Biomedical Engineering, University of Kentucky, Lexington, KY, United States

[2]School of Engineering, University of California at Merced, Merced, CA, United States

Introduction

When describing a material, the term "bulk properties" is often used to differentiate, either intentionally or unintentionally, from the term "surface properties." The importance of surfaces for biomaterials science is highlighted briefly in Chapter 1.2.2 and in great detail in Chapter 1.2.4. While it is important to know that the success or failure of many biomaterials depends on the physical and chemical characteristics of their surface because the surface properties dictate interactions between a material and its environment (thereby determining whether a permanently implanted material will be tolerated or rejected), it does not suggest that bulk properties of biomaterials are any less important. In fact, for almost all biomedical applications, either as short-term degradable applications or long-term structural or load-bearing applications, the bulk properties must meet the physical and/or mechanical demands of these applications over the desired time period, even if the surface properties are deemed to facilitate biocompatible material–tissue interactions. The requirements for biomaterials to exhibit certain *bulk* characteristics are multifaceted, including maintaining physical shapes, carrying mechanical loads, and possessing certain desirable electrochemical behavior, optic index, and/or thermal characteristics, among others.

As discussed in Chapter 1.2.2, the differences in bulk properties of many materials such as metals, polymers, and ceramics are the results of different types of interatomic or intermolecular forces that hold atoms and molecules together. For example, metals and alloys are typically characterized by metallic bonds, ceramics are held together by ionic bonds, and polymers are predominately formed by covalent bonds. The differences in these bonding mechanisms and energies dictate the different bulk properties of these materials. This chapter provides an overview of some of the useful concepts related to the bulk properties of these materials, with an emphasis on mechanical properties. For more in-depth information, the reader is encouraged to consult books on materials science and strength of materials.

Mechanical Variables and Mechanical Properties

The mechanical properties of a material refer to the characteristic values of a material under various mechanical loading conditions. By characteristic values, we refer to quantitative measures of mechanical variables at which certain transitions in the material would occur. For example, stress and strain are two mechanical variables that are commonly referred to for a material, but they are not properties of the material. Only the stresses that cause certain structural changes, such as yielding or breaking, etc. will be regarded as properties. This can be likened to the fact that the temperature of water is a physical variable, but we do consider certain temperatures, at which transitions occur in the state of water, properties such as the freezing point or boiling point of water.

Taking a cylindrical rod with uniform cross-section area (often called prismatic rod) as an example of a material structure, stress (σ) is defined as force per unit area, obtainable by dividing the applied force (F) by the cross-section area (A) of the rod, $\sigma = F/A$.

Stress determined this way is commonly regarded as the *nominal stress* because the actual value of the area (cross-section) to which the load is applied will change as the sample deforms in response to the load. Nominal stress is often synonymously referred to as *engineering stress*.

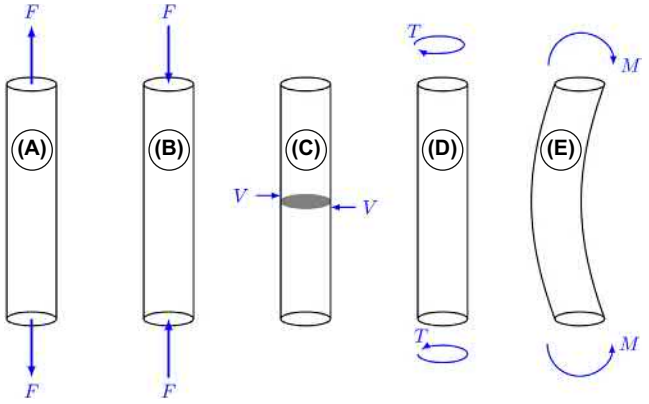
Strain (ε) is deformation per unit length, obtainable by dividing the deformation (δ) by the length of the rod (L), $\varepsilon = \delta/L$.

By the same argument, strain determined this way is regarded as the *nominal strains or engineering strain* because the actual value of the length will change as the sample deforms in response to the load. Stresses and strains determined with reference to the actual cross-section area (A) and length (L) are initially known as true stresses and true strains, respectively. Unfortunately, because A and L change continuously during the course of a mechanical test, true stresses and strains can be difficult to measure in practice. Therefore, nominal stress and strain are commonly used instead of true stress and strain.

Stress (or strain) can be either normal or shear stress (or strain). Normal stress is determined by considering only the normal component of an arbitrary applied force, and shear stress by considering the tangent component of the force. The SI units of stress are newtons per square meter (N/m^2) or pascals (Pa), and strain is dimensionless.

Five Types of Mechanical Loading

A mechanical loading situation in a structure can be represented by a combination of several mechanical loads. In general, there are five basic types of loads as illustrated in Fig. 1.2.3.1 (Beer et al., 2014). When a pair of forces (F–F) with opposite directions is applied to a cylindrical rod along its axial direction, the situation is called axial loading. Under axial loading, we are more concerned with the deformations along the axial direction. If the axial load is making the rod longer, it is regarded as tensile loading, and if the axial load is making the rod shorter, it is compressive loading. When a pair of shear forces (V–V) with opposite directions is applied to the rod in a transverse direction, the loading condition is regarded as shearing loading with which we are mainly concerned about the transverse shear stress, strain, and deformation. When a pair of torques (T–T) with opposite directions is applied to the rod with respect to its axial orientation, the rod is regarded as under torsion loading in which we are concerned with twisting stress, strain, and angle. Finally, when a pair of moments (M–M) with opposite directions is applied to the rod, it is regarded as under bending. In a bending situation, we are more concerned about bending-induced tensile, compressive, and shear stresses and strains, as well as flexure deformation. Note that the term load is used here to represent all these forces, torques, and moments. Because of that, these loads will have different units, for instance, tensile, compressive, and shearing forces carry the units of newtons (N), and torque and moment have the units of newtons × meter (Nm).

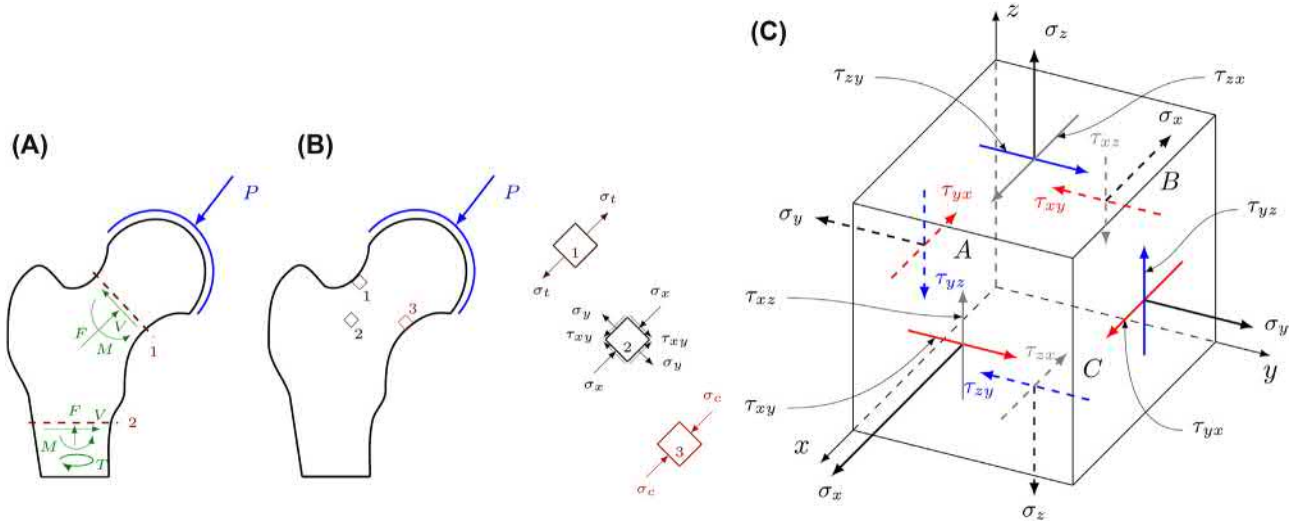


• **Figure 1.2.3.1** Five basic types of mechanical loading situations: (A) tension, (B) compression, (C) shearing, (D) torsion, and (E) bending.

An actual structure is likely subjected to a combined loading situation consisting of several or all of these five types of basic loading. Very often, we impose certain mechanical constraints to the structure such that we can focus on stresses, strains, and deformations under the mechanical load and ignore other mechanical consequences such as translation and rotation, motion (linear and rotational velocity) and acceleration, among others.

From External Loads to Internal Loads and Stresses

In analyzing the mechanical properties of a material structure, the external loading condition (P) is first considered to determine the equivalent forces, torques, and moments at selected internal section planes. In a simplified two-dimensional (2D) view for example, in section plane 1 (Fig. 1.2.3.2A), the equivalent forces may consist of a compressive force (F), a shear force (V), and a bending moment



• **Figure 1.2.3.2** Two-dimensional illustration of how external mechanical loads are converted to equivalent internal forces, torques, and moments on different section planes (A), and internal stresses in a 2D (B) and 3D sense (C).

(M), but in section plane 2, an additional torque will have to be considered aside from the compressive and shear forces and moment. With these sectional forces, moments, and torques, the resulting internal stresses and strains as well as deformations can be obtained. As depicted by the three 2D stress elements shown in Fig. 1.2.3.2B, stress elements 1 and 3 are taken at the upper and lower surfaces of the neck region, where only tensile stress exists on stress element 1 and compressive stress on stress element 3. On a stress element isolated from an interior location (e.g., stress element 2), however, a much more complex stress state could exist. In a three-dimensional (3D) sense, we will have to deal with stress cubes on which six stress components would exist including σ_x, σ_y, σ_z, τ_{xy}, τ_{yz}, and τ_{xz}.

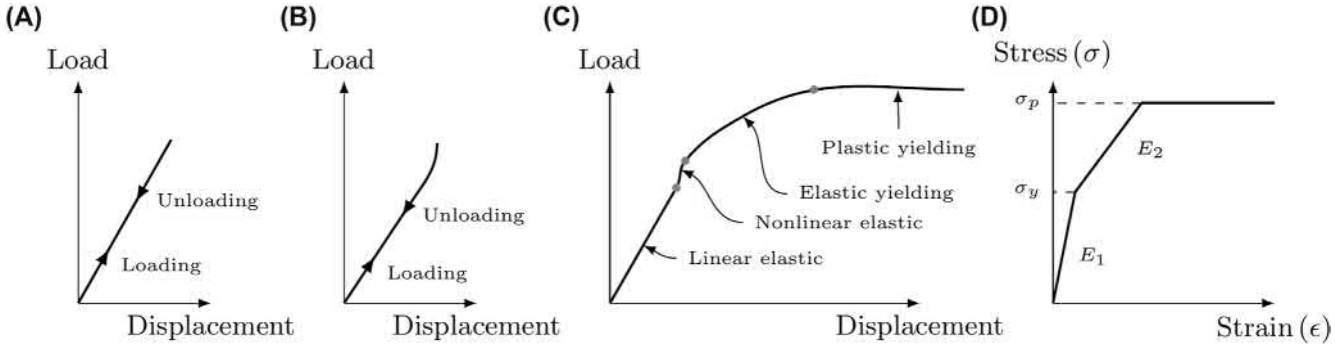
Linear and Nonlinear Relationship, Elastic and Plastic Behavior

In dealing with materials' mechanical properties, we always encounter terms like linear and nonlinear relationship, and elastic and plastic behavior, and very often we tend to (wrongly) associate a linear relationship with elastic behavior and a nonlinear relationship with plastic behavior. The terms "linear" and "nonlinear" are often used to refer to a relationship between two variables such as in a load–displacement curve or in a stress–strain curve. When these relationships are straight lines, we call them linear, and when they are curved lines, we call them nonlinear. The terms "elastic" and "plastic," however, refer to a material's deformational behavior, specifically the ability (or inability) to regain the original shape after the removal of loads. When a material structure regains its original shape (all deformations vanish) after the removal of loads, we consider it deforming with elastic behavior, and when it does not regain its original shape, we call it deforming with plastic behavior.

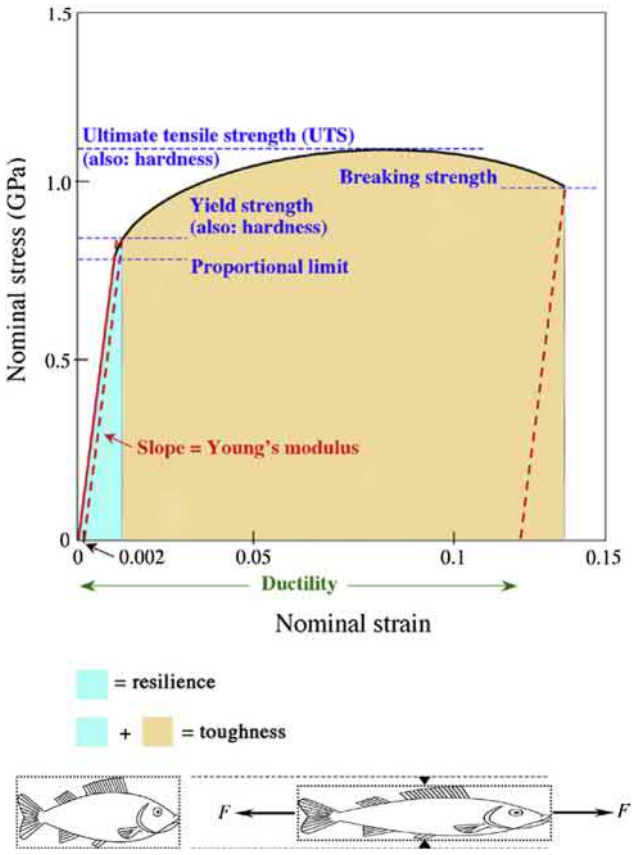
A linear relationship is not necessarily always associated with elastic behavior and a nonlinear relationship plastic behavior. In fact, these terms are often used in combinations to describe a certain mechanical property or behavior (Zhang, 2017). For example, a material structure can exhibit elastic behavior with either linear or nonlinear relationship between load and displacement. As illustrated in Fig. 1.2.3.3, linear elastic behavior (Fig. 1.2.3.3A) is one in which the load–displacement curve is a straight line (hence linear) and the loading and unloading curves follow the same trace such that the displacement will vanish (hence elastic) when the applied load is removed. Nonlinear elastic behavior (Fig. 1.2.3.3B) describes a curved load–displacement relationship, but the displacement induced by loading will vanish after the removal of the load.

As illustrated in Fig. 1.2.3.3C, the linear elastic behavior of a material typically occurs at the beginning of the loading stage when the induced displacement is extremely small. When the displacement increases slightly, the material may exhibit nonlinear but elastic behavior. This behavior is sometimes referred to as geometric nonlinearity. When the displacement increases further, the material will reach an elastic yielding zone where it still exhibits elastic behavior but with reduced rigidity. As the displacement continues to increase the material will enter a plastic yielding zone in which the displacement or deformation will keep increasing without needing any further increase in loads.

Fig. 1.2.3.3D shows the corresponding stress–strain curve derived conceptually from the load–displacement curve shown in Fig. 1.2.3.3C by dividing the load by the cross-section area and the displacement by the length. It presents a different look at the mechanical properties from a pure material's perspective by minimizing geometric-related influences. By convention, the stress is plotted vertically and the strain is plotted horizontally. When the material behaves elastically, in both a linear and nonlinear manner, the stress–strain curve typically exhibits a straight-line relationship with a constant slope E_1 (which is commonly known as the modulus of elasticity or Young's modulus; more discussion in the next section). When the stress in the material reaches its elastic yielding point σ_y it will start to exhibit reduced elastic property with decreased slope E_2, where $E_2 < E_1$. As the strain in the material further increases, the material will reach its plastic yielding point σ_p after which full plastic deformation (i.e., deformation that keeps increasing without the need of increasing the applied loads) will occur and the stress in the material will remain the same until the material breaks.



• **Figure 1.2.3.3** Sketches of linear elastic (A) and nonlinear elastic (B) load–displacement curves. Sketches of a single load–displacement curve containing linear elastic, nonlinear elastic, elastic yielding, and plastic yielding behavior (C) and its corresponding stress–strain curve (D).



• **Figure 1.2.3.4** Schematic stress versus strain curve for a ductile metal, emphasizing the features that relate to specific mechanical properties and illustration of the Poisson ratio effect $\nu = -\frac{\varepsilon_{\text{transverse}}}{\varepsilon_{\text{longitudinal}}}$.

Pseudoelastic, Hyperelastic, and Viscoelastic Materials

Some materials, like shape memory alloys (SMAs), will undergo phase transition due to temperature changes, thereby exhibiting recoverable or reversible deformation behavior (hence elastic) as temperature changes back and forth. This type of "elastic" behavior is sometimes called pseudoelastic or superelastic. Superelasticity is an isotherm process in which phase transformation typically occurs from the austenite to martensite phase under an external load. Because the martensite phase is unstable, after removal of the external load the material will transform again to the austenite phase.

Other materials, like many polymeric materials and biological tissues, will undergo polymer-chain or collagen-fiber reorientation under stretching, leading to stiffening of the materials (i.e., an increase in the slope of the load–displacement curve). When the material is in its elastic nature, the observed nonlinear stiffening behavior is called hyperelastic.

Viscoelasticity is a term used to describe a material that possesses time- (or rate-) dependent behavior, meaning that the material may exhibit a different load–displacement or stress–strain curve when the loading rate is different. The main reason for this behavior is that viscoelastic materials are regarded as made of solid components that follow Hooke's law and fluidic components that follow Newton's law. For viscoelastic materials, a combined Hookean and Newtonian method is often used to evaluate these combined solid/fluid-like characteristics with equivalent models made of springs (representing the elastic part) and dashpots (representing the viscous part). Load–displacement or stress–strain relationships of viscoelastic materials are always nonlinear with loading and unloading curves following two different paths, known as hysteresis. But after the removal of all loads, deformations in the material will vanish (hence elastic), albeit slowly, due to the viscous components. Common viscoelastic materials include paint, rubber, and many biological materials. For viscoelastic materials, the behavior stress relaxation (stress decays under a fixed constant strain condition) and creep (strain increases under a fixed constant stress condition) as well as the rate at which stress relaxes or strain creeps are common properties of interest.

Common Mechanical Properties of Isotropic Materials

Elastic Properties

Fig. 1.2.3.4 shows a typical stress–strain curve obtained from an isotropic ductile metallic slender rod subjected to tensile loading. An isotropic material is one that has properties considered to be independent of the direction one picks to examine the material. The linear segment of the curve reflects the simplified Hooke's law relationship in honor of Robert Hooke. The constant of proportionality (or slope) between stress and strain is known as the *Young's modulus*, E. The equivalent constant of proportionality in the case of a shear stress being applied is known as the *shear modulus*, G. The ratio of the resulting transverse strain (perpendicular to the direction of the applied load) and longitudinal strain (parallel to the direction of the applied load) is another elastic property of the material commonly known as the *Poisson's ratio*, which is defined as:

$$\nu = -\frac{\varepsilon_{\text{transverse}}}{\varepsilon_{\text{longitudinal}}}$$

The negative sign is used to obtain a convention in which the values of ν are positive for most materials. An illustration of such a Poisson ratio effect is given in Fig. 1.2.3.4, where a stretching force applied to a material causes it to become *narrower* as it gets longer. While most materials possess a positive Poisson ratio, a relatively small number of materials—known as auxetic materials—has a negative Poisson's ratio. Typically, these are low-density, cellular materials, with cell walls that are able to hinge or buckle when loads are applied. Pulling on a piece of auxetic material causes it to become *wider* as well as longer, while attempting to squash it will cause it to become thinner as well as shorter.

It can be shown that of the three elastic constants (E, G, ν) only two are independent, due to the following relationship among them:

$$G = \frac{E}{2(1+\nu)}.$$

Yield Strength and Ductility

As the stress on the material increases, a point may be reached where the response is no longer linear, generating a permanent (irreversible) deformation, commonly known as *plastic* deformation. This occurs commonly in ductile metals and polymers, and rarely in brittle materials such as ceramics.

The amount of plastic deformation associated with a given stress can be found by drawing a line from the point of interest on the stress–strain curve, parallel to the initial linear segment of the curve, and marking the point where this constructed line intersects the horizontal (strain) axis. The horizontal distance from the origin to the point of intersection is a measure of the plastic strain. The value of plastic strain required to break the material defines the *ductility* (Fig. 1.2.3.4). The stress at which departure from a linear stress–strain relationship occurs is known as the *proportional limit* (Fig. 1.2.3.4).

It is not always easy to ascertain the proportional limit accurately, and so a more practical determination of the condition for plastic deformation is provided by the *yield strength* (Fig. 1.2.3.4), which is the stress at which *noticeable* plastic strain occurs. In this context, "noticeable" is often taken to be a value of 0.002 (0.2%) for metals—although it may be chosen to be much higher in polymers, where elastic behavior persists to strains that may be 10 or even 100 times higher, and where the transition from elastic to plastic behavior may be difficult to pinpoint.

A marked *yield drop* is often displayed in the stress versus strain plot when the yield stress of a polymer is exceeded. The yield drop occurs because the polymer chains become partially aligned during initial deformation, allowing easier relative motion of chains and reducing the stress needed to further deform the material. The chains then straighten and extend as deformation continues, requiring little increase in stress. Eventually, the opportunities for relative motion of chains are exhausted, along with the capacity for additional chain extension, and the stress versus strain plot then rises sharply.

Strength and Failure

Failure of a loadbearing material occurs when the material ceases to perform its loadbearing function. Different interpretations of "failure" are in common use, and so it is important to be clear about the intended meaning when we speak of materials failure. For materials that must not undergo in situ permanent deformation, failure is synonymous with the yield stress being exceeded, and so the yield stress represents an estimate of the strength of the material in those cases.

For materials in which permanent deformation is acceptable, failure may be deemed to occur when a noticeable "neck" (constriction) develops in the material. The effect of the neck is to concentrate the load on a smaller area; therefore, the load that can be supported by the sample is decreased. On a nominal stress versus nominal strain plot, where stresses are referred to the *original* loadbearing areas of the sample, the stress required for additional deformation decreases. Therefore, the onset of necking corresponds to a maximum in the nominal stress versus nominal strain plot, defining the *ultimate tensile strength* (UTS) or simply the *tensile strength* of the material (Fig. 1.2.3.4). There is no corresponding maximum on a true stress versus true strain plot, because the stress continues to rise past the onset of necking as values of stress are obtained by dividing the applied load by the actual (small) cross-section of the neck.

On both nominal stress versus nominal strain and true stress versus true strain plots, a *breaking strength* can be defined at the point where the material actually breaks. However, to reach this point practically, at least in the case of most metals, the tensile strength of the material must first be reached, and it is tensile strength that represents the practically measurable maximum stress that a metal can survive. Ceramics, on the other hand, usually reach their breaking stress before they yield.

Thus, the perceived strength of a material depends in part on the definition of failure that is used (onset of plastic deformation, onset of necking, or actual occurrence of breaking). It also depends on the conditions that are used for testing. The *strain rate* used in a tensile test can affect the maximum stress that is reached, depending on the ability of the microstructure to undergo rearrangement to accommodate the imposed deformation.

Over long periods of time, even stresses that are below the conventionally measured yield strength of a material may be sufficient to cause gradual elongation and eventual failure via *creep*. Therefore, creep tests, in which a fixed load is applied while the strain is monitored until the sample breaks, are important for materials that are required to have a long projected service life—as is the case with many implants. Similarly, materials that will be subjected to cyclic loading patterns during service may undergo *fatigue* failure at loads that are smaller than those needed to trigger failure in a conventional stress versus strain test. Testing to determine the relationship between average load, maximum and minimum load, and the number of loading cycles that lead to failure is required in such cases. Finally, the catastrophic failure of a material can be triggered by preexisting flaws that locally concentrate the effect of an applied stress.

Hardness

The hardness of a material is measured by applying a known load to a small indenter of known geometry (typically pyramidal or spherical) in contact with the surface of the material, for a known period of time. The dimensions of the resulting indentation are measured, and this information, together with the experimental conditions, is used to rate the hardness of the material on a relative scale. Indents made in a soft material under a given set of conditions are larger than those made in a hard material. Therefore, hardness provides a measure of how successfully a material resists plastic deformation, which in turn is characterized by both yield strength and tensile strength. It is therefore possible to empirically develop calibration charts that can be used

to convert hardness measurements into both yield strength and tensile strength values. Hardness testing is popular for estimating the yield strength and tensile strength of materials because the equipment is relatively simple and inexpensive, and the tests are nondestructive.

Resilience

Resilience is a measure of the *elastic energy* that can be stored in a unit volume of stressed material. It corresponds to the area underneath a stress versus strain plot, extending from zero strain up to the strain at which the sample yields:

$$U_r = \int_0^{\varepsilon_y} \sigma d\varepsilon .$$

If the stress versus strain relationship is linear up to the yield strain (typical for ceramics, and approximate for many metals and polymers), the corresponding area under the stress versus strain plot is triangular, and the integral in the previous equation simplifies to:

$$U_r = \frac{1}{2}\sigma_y \varepsilon_y = \frac{\sigma_y^2}{2E} .$$

Resilience is an important consideration for materials that need to be "springy," i.e., that absorb and return significant amounts of energy. Examples include natural and replacement tendons and ligaments, and materials used in foot arch reconstruction or support.

Toughness

Toughness is a measure of the energy required to deform a unit volume of material to its breaking point. Therefore, the definition is similar to that used for resilience, except that we now take into account the entire area under the stress versus strain plot, extending from zero strain up to the strain at which the sample breaks:

$$U_{\text{break}} = \int_0^{\varepsilon_{\text{break}}} \sigma d\varepsilon .$$

Fracture Toughness and Fatigue Strength

Although fracture toughness and toughness sound superficially similar, they refer to quite different properties. Fracture toughness is a measure of the ability of a material to resist the propagation of a crack. It takes the form of critical stress intensity factor (K_{IC}) of a sharp crack where propagation of the crack suddenly becomes rapid and unlimited.

When a material is subjected to repetitive, or cyclic loading, a process of fracture may result from the initiation and propagation of a crack. The process of initiation and propagation of a crack in response to cyclic stresses is called fatigue. The stresses required to induce a failure by fatigue are typically known as the fatigue strength. Typically, the fatigue strength is well below the yield strength or ultimate strength of the material, but the ultimate fracture of the material would require millions of cycles of loading, during which localized damage accumulates, leading to the crack initiation and propagation.

Fatigue strength is often assessed by subjecting a sample to a cyclic loading test, counting the number of cycles applied until failure and plotting the stress (S) versus the log of the number (N) of cycles to failure in so-called S–N curves. Detailed discussions on facture toughness and fatigue strength of metallic materials can be found in Chapter 1.3.3.

Generalized Hooke's Law and Anisotropy of Materials

As discussed in "Common Mechanical Properties of Isotropic Materials," in the simplest form, the stress and strain relationship of an isotropic elastic material can be expressed as $\sigma = E\varepsilon$. While this equation captures well, conceptually, the stress–strain relationship governed by Hooke's Law, it is valid only for situations where uniaxial stress and strain in a one-dimensional structure are of concern. In a complex situation, one must deal with all six stress components (see "From External Loads to Internal Loads and Stresses"), in which case the generalized Hooke's law takes the following form:

$$\begin{Bmatrix} \sigma_x \\ \sigma_y \\ \sigma_z \\ \tau_{yz} \\ \tau_{xz} \\ \tau_{xy} \end{Bmatrix} = \begin{bmatrix} c_{11} & c_{12} & c_{13} & c_{14} & c_{15} & c_{16} \\ c_{12} & c_{22} & c_{23} & c_{24} & c_{25} & c_{26} \\ c_{13} & c_{23} & c_{33} & c_{34} & c_{35} & c_{36} \\ c_{14} & c_{24} & c_{34} & c_{44} & c_{45} & c_{46} \\ c_{15} & c_{25} & c_{35} & c_{45} & c_{55} & c_{56} \\ c_{16} & c_{26} & c_{36} & c_{46} & c_{56} & c_{66} \end{bmatrix} \begin{Bmatrix} \varepsilon_x \\ \varepsilon_y \\ \varepsilon_z \\ \gamma_{yz} \\ \gamma_{xz} \\ \gamma_{xy} \end{Bmatrix}$$

in which the 6×6 square [c] matrix is sometimes called the modulus matrix. Since the [c] matrix is symmetric square matrix, the highest number of independent constants for an anisotropic material is 21. However, the actual number of independent constants can be much less due to certain symmetry in materials of different isotropy.

For instance, as shown in Fig. 1.2.3.5A, for isotropic materials the [c] matrix has only two independent nonzero constants, c_{11} and c_{12}. These two constants are related to the three *E, G, ν* constants discussed earlier through the following relationships:

$$c_{11} = \frac{E(1-\nu)}{(1+\nu)(1-2\nu)} \text{ and } c_{12} = \frac{E\nu}{(1+\nu)(1-2\nu)}$$

$$\frac{c_{11} - c_{12}}{2} = \frac{E}{2(1+\nu)} = G$$

Note that , confirming that of the three constants (*E, G, ν*), only two are independent.

Moreover, as also illustrated in Fig. 1.2.3.5 (Zhang, 2020), materials with cubic (crystal) symmetry have three independent nonzero constants, c_{11}, c_{12}, and c_{44} (Fig. 1.2.3.5B); materials with hexagonal symmetry have five independent constants, c_{11}, c_{12}, c_{13}, c_{33}, and c_{44} (Fig. 1.2.3.5C); materials with tetragonal symmetry have seven independent constants, c_{11}, c_{12}, c_{13}, c_{16}, c_{33}, c_{44}, and c_{66} (Fig. 1.2.3.5D); materials with orthorhombic symmetry have nine independent constants, c_{11}, c_{12}, c_{13}, c_{22}, c_{23}, c_{33}, c_{44}, c_{55}, and c_{66} (Fig. 1.2.3.5E); and materials with monoclinic symmetry have 13 independent constants, c_{11}, c_{12}, c_{13}, c_{15}, c_{22}, c_{23}, c_{25}, c_{33}, c_{35}, c_{44}, c_{46}, c_{55}, and c_{66} (Fig. 1.2.3.5F). These

types of crystal symmetry are commonly found in metals and ceramics.

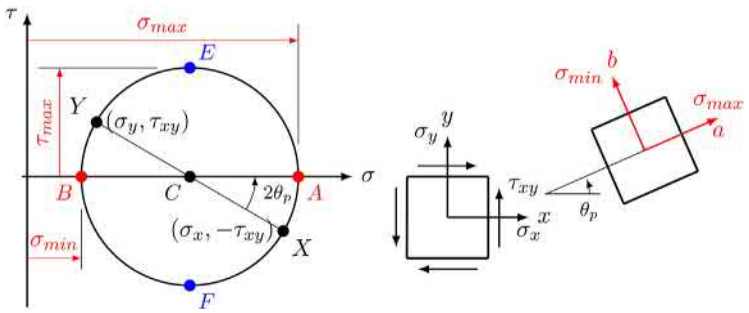
Loading Modes, Stress States, and Mohr's Circle

As we discussed in "From External Loads to Internal Loads and Stresses," external loads dictate the resulting internal stresses. However, the external loading mode does not always reflect directly the failure mode of the material tested. For example, let us look at the two images in Fig. 1.2.3.6, in which two cylindrical rods failed in two different modes under the same type of torsional loading. The rod on the left has a fracture surface that resembles a perpendicular cross-section cut and the rod on the right has a fracture surface of a helical shape. The fact that these two rods, having the same geometric shape and subjected to the same type of loading, fail in two different modes confirms that the failure mode of a material does not always reflect directly its loading mode. To better understand the failure modes, it is necessary to consider the actual stress state induced in the material and its causal relationship with the breakage of the atomic bonds within the materials.

If we look closely at the fracture surfaces, we will note that the textures of the two fracture surfaces are also different. The one on the left shows the sign of material yielding and the one on the right sign of tensile breakage. So then, why do yielding and breakage failure modes cause the two rods to fracture in two different fracture surfaces? To answer this question, we will need to know the stress states in these rods with the help of Mohr's circle.

Mohr's circle is a 2D graphical representation of the stress state of a given point in a material using a circle (for a 2D stress state; three circles will be needed for a 3D stress state) in a σ–τ coordinate system with a pair of opposite points on the circle representing the stress state of a stress element in a given direction. To visualize this, let us look at Fig. 1.2.3.7, where a Mohr's circle and two stress elements in a plane stress situation (see "Plane-Stress and Plane-Strain Simplification" for further discussion) are sketched. For the stress element shown in the middle, representing a viewing angle through the x–y orientation, we consider a normal stress σ_x and a shear stress τ_{xy} in the x-cut plane, and a normal stress σ_y and a shear stress τ_{xy} in the y-cut plane. By using these paired stress values as coordinates, we mark two points X (σ_x, τ_{xy}) and Y (σ_y, τ_{xy}) in the σ–τ coordinate system shown on the left with σ as the abscissa and τ as the ordinate. A sign convention is followed in this process in which tensile normal stresses (σ_x and σ_y) are considered positive and compressive normal stresses negative, and clockwise shear stresses (τ_{xy}) are positive and counterclockwise shear stresses negative. By linking the two points, X and Y, with a line we find an intersect with the abscissa at point C. Then using point C as the center point, we construct a circle passing through both points X and Y. This circle is the so-called Mohr's circle, honoring its creator Christian Otto Mohr.

On a Mohr's circle, any paired opposite points (with respect to the center point C), like the X–Y pair, represent



• **Figure 1.2.3.7** Mohr's circle and stress elements for depicting the stress state of a given point.

the stress state of the given point in a certain viewing orientation. This means that the stress state of the given point can be represented by countless different combinations of stress components depending on our viewing orientations. For the A–B pair, while still representing the same stress state of the point, because τ_{xy} is zero, it describes an orientation in which a stress element only has normal stresses acting on it. This orientation is called the principal directions and the corresponding stresses are called principal stresses.

From the Mohr's circle, we can see that a counterclockwise rotation by an angle of 2θ will transform the X–Y pair to the A–B pair. For the stress element, a counterclockwise rotation by θ (half of the rotation in the Mohr's circle) will transform the element in the x–y orientation to the one in the principal a–b orientation, as shown on the right in Fig. 1.2.3.7. With a further 90° counterclockwise rotation from the A–B orientation we will reach the E–F orientation where the shear stress reaches its maximum, τ_{max}. This means that a 45° counterclockwise rotation from the a–b stress element will obtain a stress element having maximum shear stresses.

Let us now return to the two torsional rods discussed earlier and analyze the cause for fracture by examining the stress states in them. Fig. 1.2.3.6 also shows the Mohr's circle for a surface point on a cylindrical rod undergoing pure torsional loading. From this Mohr's circle, we can see that in the x–y orientation (corresponding to the X,Y points on the circle) the stress element has only shear stresses acting on it with no normal stresses. This means that the x–y stress element experiences the maximum shear stresses. On the other hand, the principal stress element, the a–b stress element (corresponding to the A,B points on the circle), is a 45° counterclockwise rotation away, because the X–Y and A–B lines are 90° apart in the Mohr's circle. In the principal stress element, the maximum principal is maximum tension and the minimum principal stress is maximum compression. Taken together, when the two rods undergo a torsion loading test, the x-cut plane (as well as the y-cut plane) endures maximum shearing, the 45°-cut plane experiences the maximum tension and the 135°-cut plane the maximum compression.

Keep in mind that a ductile material tends to fail due to shear-induced material yielding and a brittle material due to tension-induced breakage. It becomes clear that the rod on the left failed in a shear mode due to its ductile material nature and the highest shear stress existing in the x-cut plane (incidentally this cut plane has the smallest cross-section area). For the rod on the right, it failed in a tension mode due to its brittle nature and the highest tensile stress existing along a plane oriented at 45°. It is thus not surprising that the fracture surface caused by tension-induced breakage is oriented at a 135° angle from the x-cut plane, perpendicular to the direction of the maximum tension.

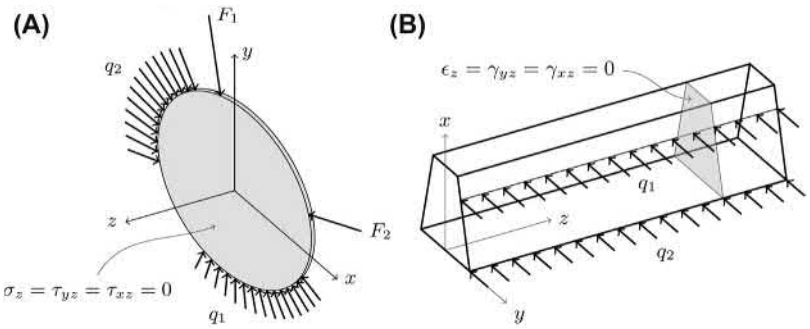
In short, the failure mode of a material is not determined by the loading mode but by the induced stress state (i.e., the maximum stresses and their orientations) and the type of materials. If the material is of the ductile type, shearing-induced yielding failure should be of concern and if the material is of the brittle type, tension-induced breakage should be avoided. To put this knowledge to use, the reader is encouraged to refer to Chapter 3.1.9 for case studies of some failure modes of various implant devices based on the observations made from implant retrieval analyses.

Plane-Stress and Plane-Strain Simplification

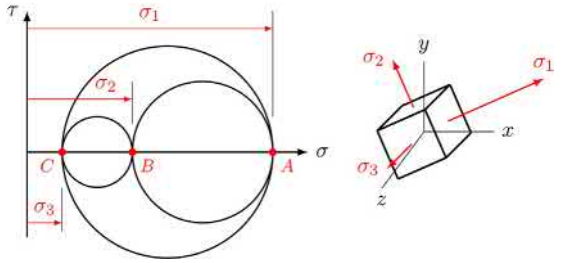
In real life we always encounter three-dimensional (3D) objects, yet we often use the terms two-dimensional (2D) and one-dimensional (1D) problems. Technically speaking, all problems are 3D in a geometry sense, but in certain circumstances they can be simplified through approximation into 2D and 1D problems. Due to the approximation nature, the conditions for making the simplification should be considered carefully. For example, when a material is thin in its third dimension (say, along the z axis) compared with the other two dimensions, and if the loading and deformations in the material occur only within the thin plane, the stresses in the third dimension, as illustrated in Fig. 1.2.3.8A, σ_z, τ_{yz}, and τ_{xz} are negligible. In this case, we can simplify the 3D problem into a 2D plane-stress problem. Another situation is when the material is very long in its longitudinal z direction as compared with the x, y dimensions and the loading, deformations, and cross-section area remain unchanged over the entire longitudinal length, as depicted in Fig. 1.2.3.8B. In this case, the strains in the third dimension, ε_z, γ_{yz}, and γ_{xz} are negligible, and we can simplify the 3D problem into a 2D plane-strain problem.

Trajectories of Tensile and Compressive Stress Lines

At any given point in a structure under mechanical loading we can identify the principal stresses and their directions by



• **Figure 1.2.3.8** 2D simplification of 3D solid mechanical problems: (A) plane-stress situation, and (B) plane-strain situation.



• **Figure 1.2.3.9** 3D Mohr's circles and the first, second, and third principal stresses.

constructing Mohr's circles and determining the orientation of the stress element that corresponds to the pairs of extrema with zero shear stresses, i.e., the A–B, B–C, or A–C pairs on the Mohr's circles in Fig. 1.2.3.9.

Let us now consider a plane stress situation. Referring to Fig. 1.2.3.10, we assume that the first principal stress (σ_1) is positive (tensile), the second one (σ_2) zero, and the third one (σ_3) negative (compressive). After identifying the directions of the first (tension) and third (compression) principal stresses at randomly selected points across the plane structure, we mark the two directions using perpendicular crosses at these points (note that these two principal stresses are always perpendicular to each other). To distinguish the two stresses, we use red to represent the tensile direction and blue the compressive direction. By connecting the red and blue lines together, respectively, we obtain two sets of lines representing the directions of maximum tensile stress (red lines) and maximum compressive stress (blue lines), which sometimes are also referred to as the stress trajectories. Fig. 1.2.3.10 shows the trajectories of tension and compression lines in a rectangular beam structure subjected to three-point bending. With a close inspection, we note that these two sets of lines are indeed orthogonal, indicating that, at each intersect, a red line is perpendicular to a blue line, as expected.

Assuming the beam structure is made of concrete, we should expect tension-induced breakage as the failure mode. Referring to the principal stress element shown in the figure, a fracture surface caused by tensile stresses should be perpendicular to the tensile stress, meaning that the breaking surface in the concrete should coincide with the compression lines. By examining the images of the actual fracture lines near the corner and at the bottom of the beam shown in Fig. 1.2.3.10, one can see that these fracture lines follow exactly the compression lines in these regions.

Knowing the stress trajectories provides us with crucial insight into how to strengthen certain structural design. The structure of the human femoral head is an example that our body knows how to strengthen bone structure according to the stress trajectories as a result of constant bone remodeling. The architecture of the spongy bone is likely the result of the bone remodeling process with the purpose of meeting the strengthening needs of human growth and daily activities, guided by the stress trajectories inside the femoral head.

Other Bulk Properties

The bulk properties of a material are of course not limited to performance in mechanical tests. Other types of bulk properties that may have to be taken into account during the selection of a biomaterial include: thermal properties; optical properties; electrical properties; and magnetic properties. Even cost—financial and environmental—can be considered to be a bulk property, given the dependence of cost on: (1) the type and volume of material that is used; and (2) the complexity of microstructural rearrangement during processing.

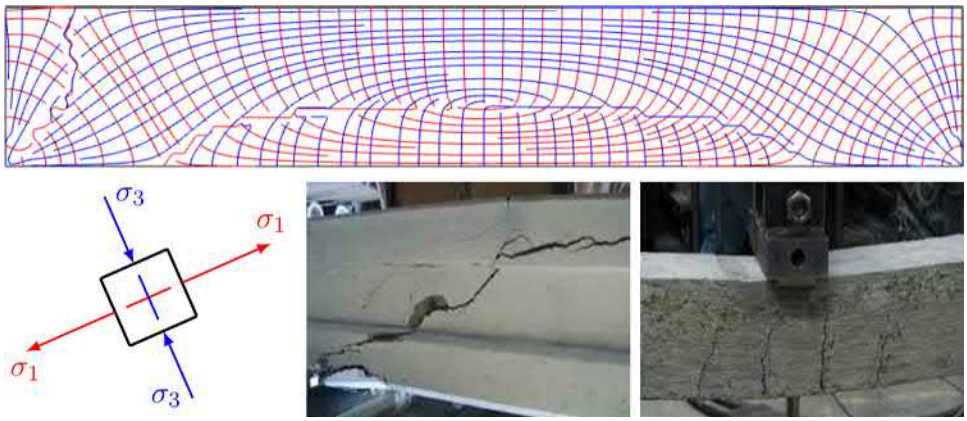
Thermal Properties

Thermal conductivity becomes a significant consideration if an implanted material contributes to an unnatural flow of heat through the surrounding tissue. For example, metal rods selected for their combination of stiffness, strength, fracture toughness, and biocompatibility can promote heat loss and cause the patient to feel colder than normal. Heat conduction through a metal dental filling can also be a source of discomfort and may therefore play a role in the choice between a metal or nonmetal filling.

Thermal expansion is a (nominal) strain that occurs when the temperature of a material is changed:

$$\varepsilon_{\text{thermal}} = \alpha \left(T_{\text{final}} - T_{\text{initial}} \right)$$

where α is the thermal expansion coefficient; its units are $(\text{degrees})^{-1}$, with "degrees" measured on whatever standard scale is used to measure temperature T.



• **Figure 1.2.3.10** Trajectories of tension (*red*) and compression (*blue*) *lines* in a beam structure subjected to three-point bending along with a principal stress element and two images of *fracture lines* in concrete beams under the same type of loading.

Attempts to match the properties of a dental filling to those of the surrounding tissue must therefore extend beyond achieving compatible elastic constants to include consideration of thermal expansion, to avoid premature failure of the interface.

Optical Properties

In the context of biomaterials, the most significant bulk optical properties are color, refractive index, and transparency; all three are important in the selection of materials for intraocular lenses or fluids. The color of a transparent material is controlled by composition, and therefore demands a high degree of quality control to avoid impurities that could adversely affect color. Long-term stability of material composition is also important: components should not selectively diffuse into the surrounding tissue, and no chemical changes should occur—either by reactions between the components or in response to light.

The *refractive index n* of a material is defined as:

$$n = \frac{C_{\text{vacuum}}}{C_{\text{material}}}$$

where c denotes the speed of light in the subscripted medium. When light crosses the interface between two media (materials), it is deviated from its original path by an angle that is an increasing function of the difference between the refractive indices of the media. Therefore, the effectiveness of a material as a lens is directly related to its refractive index. Refractive index increases along with the content of electron-rich atoms, which is why lead "crystal" is so useful in both lenses and decorative glassware.

Transparency is a qualitative term that describes the ability of a material to transmit light without attenuating (absorbing or scattering) it. To minimize absorption, the primary bonds in the material must be strongly covalent or ionic (and definitely not metallic). Scattering is minimized if the material is free of internal interfaces (which could reflect light) and compositional differences (which would be associated with refractive index differences that could deviate light from an uninterrupted path through the material). Thus, an optimally transparent material will either be a homogeneous single crystal or it will be completely and homogeneously amorphous.

There is no commonly accepted quantitative definition of transparency. Instead, it is usual to consider the complementary property, *opacity*. This is itself a colloquial term, but it lends itself to a more formal description by way of the *mass attenuation coefficient*. If light of a given frequency (color) and initial intensity I_0 travels a distance x through a material, then the intensity is decreased to:

$$I(x) = I_0 \exp(-\mu\rho x)$$

where μ is the mass attenuation coefficient of the material, and ϱ is the density.

Piezoelectric Properties

Piezoelectricity deals with the coupled mechanical and electrical properties of a material that becomes electrically polarized when it is mechanically strained. There are two forms of piezoelectric effect. Direct piezoelectric effort describes the generation of electric dipoles and polarization as a result of displaced atoms and the associated redistribution of electrons inside a solid when it is mechanically strained. This polarization in turn generates an electric field. By contrast, reverse piezoelectric effect is a phenomenon in which a solid becomes strained when placed in an electric field. Piezoelectric effect was first discovered and demonstrated in its direct form by the brothers Pierre and Jacques Curie in 1880. Since then, the science of piezoelectricity has slowly moved from research laboratories to real-world applications such as sonars, devices for the production and detection of sound and for mechanical actuation, sensors for thickness and temperature measurements, even biosensors, among others. The theory of piezoelectricity allows us to deal with relationships between the generated electrical field and applied strains, or vice versa, within the material's elastic deformation limit.

Weibull Modulus and Nonbrittle Materials

The Weibull distribution of fracture probability for materials provides a statistical measure of brittleness, via the specification of a Weibull modulus m (Derby et al., 1992). The value of m can in theory range from zero (totally random fracture behavior, where the failure probability is the same at all stresses, equivalent to an ideally brittle material) to infinity (representing a precisely unique, reproducible fracture stress, equivalent to an ideally nonbrittle material).

This quantitative approach to defining nonbrittleness is more robust than a qualitative description, since there is no single antonym of "brittle." Both "tough" and "ductile" are in particular senses the opposite of "brittle," but we have seen that "tough" and "ductile" are not interchangeable, and their corresponding nouns are associated with very different features on a stress–strain curve (Fig. 1.2.3.4).

Weibull statistics were initially adopted to quantify failure in classically brittle materials (Kelly and Macmillan, 1986), where tensile strength is dominated by the size distribution of preexisting flaws, and the use of this method is rarely extended to materials that are regarded as nonbrittle. However, there is no a priori reason to restrict Weibull statistics to the analysis of failure in classically brittle materials. For example, although natural silks exhibit large extensions to failure, and many of them behave like an elastomer at least during the initial stages of deformation, Weibull analysis has proved to be useful for characterizing and contextualizing the failure strength variability of these materials (Pérez-Rigueiro et al., 1998, 2001).

Why *is* a Weibull analysis appropriate for nonbrittle materials? A justification can be formulated simply on phenomenological grounds: after significant deformation, silk *develops* the statistical failure *characteristics* of a brittle material, even though it initially deserves classification as an elastomer. While the existence of strength-limiting defects can be inferred from this description, their nature has yet to be confirmed; it is not clear whether they are present in as-spun material, or whether they begin to develop during the earlier stages of deformation.

The appropriateness of Weibull analysis for a nonbrittle material can also be justified fundamentally (Viney, 2002), given the equation that is used as the basis for measuring m (see "Statistical Aspects of Failure"):

$$1 - F = \exp\left(-\frac{\sigma}{\sigma_0}\right)^m$$

If F is to be independent of σ, which is the hallmark of an ideally brittle material, this equation requires m to be equal to zero. However, practical Weibull analysis necessarily admits to nonzero values of m, so it is implicit that ductile contributions to failure can also be accommodated.

Under the conditions of constant stress and constant strain, the constitutive relation governing piezoelectricity can be expressed as

$$D = \varepsilon E^e + dT \text{ and } D = \varepsilon E^e + eS$$

respectively, where D is electric displacement vector, E^e electric field, T stress vector, S strain vector, ε permittivity constants, d piezoelectric strain constants, and e piezoelectric stress constants (Zhang, 2020). Of these seven terms, D, E^e, T, and S are physical variables, and d, e, and ε are piezoelectric properties. For an anisotropic piezoelectric material in a 3D space, D and E^e are 3×1 vectors, T and S are 6×1 vectors, d and e are 3×6 matrices, and ε is a 3×3 matrix. Very often, due to structural symmetry in the material, the actual numbers of constants in these matrices is much lower. For example, a cubic crystal with class 23 symmetry has only one independent nonzero constant in d, e, and ε matrices, respectively.

Electrochemical Properties

The electrochemical properties of a biomaterial (typically of metals and alloys) are the material's characteristics in an electrochemically corrosive environment, including electrochemical potentials, reaction constants, etc. These properties dictate the responses of such metallic biomaterials governed by corrosive oxidation and reduction reactions, where the oxidation processes take metal (zero valence) and increase its valence to make ions (cations) or oxides (or other solid oxidation products). On the reduction side, processes may include water and oxygen reduction to form hydroxide ions and/or reactive oxygen intermediates, aside from many other biologically based molecules that are susceptible to redox processes. The oxidation and reduction reactions are electrically connected through the metal and complete the circuit through the solution (commonly known as the two half-cell reactions), resulting in currents (electronic and ionic) through both phases. All metallic biomaterials exhibit some form of corrosion process, whether passive dissolution of ions through the passive film, to more aggressive process caused by wear or crevice geometries. Fortunately, the common implantable metals and alloys (with the exception of noble metals such as gold or platinum) have protective oxide films to control corrosion of the material to acceptable levels. These oxides are commonly referred to as passive films, typically of only a few nanometers in thickness, and will limit transport of metallic ions to the implant surface. More detailed discussions on the electrochemical properties of many metallic biomaterials are given in Chapters 1.3.3 and 2.4.3.

Chapter Questions

1. A stainless-steel rod with a circular cross-section has a length of 100 mm and a diameter of 2.0 mm. It is deformed elastically in compression by a force of 500 N applied parallel to its length. The material has a Young's modulus of 200 GPa, a shear modulus of 77 GPa, and a yield strength of 0.3 GPa. Calculate (A) the amount by which the rod will decrease in length; and (B) the amount by which the rod will increase in diameter.

Solution:

(A) Before we solve the problems, it is helpful to convert all units to the SI units. Doing so, we have the length of the rod L = 0.1 m and diameter d = 0.002 m. By the definition of stress, $\sigma = F/A$, we calculate the compressive stress as

$$\sigma = \frac{F}{A} = \frac{-500\ (\mathrm{N})}{\frac{\pi}{4}(0.002\ \mathrm{m})^2} = -0.159\ (\mathrm{GPa})$$

Since the induced compressive stress is below the yield strength of 0.3 GPa, the rod is deforming elastically. Moreover, because we are dealing with a rod under uniaxial loading, we can use the simplified Hooke's Law to capture the linear relationship between stress and strain with:

$$\sigma = E\varepsilon$$

and find the induced strain in the rod

$$\varepsilon = \frac{\sigma}{E} = \frac{-0.159\ (\mathrm{GPa})}{200\ (\mathrm{GPa})} = -7.962 \times 10^{-4}$$

Knowing the strain value, the change in length of the rod can be determined by

$$\delta = L\varepsilon = 0.1\ (\mathrm{m}) \times (-7.962) \times 10^{-4} = -7.962 \times 10^{-5}\,(\mathrm{m}) = -7.962 \times 10^{-2}\,(\mathrm{mm})$$

The negative value suggests that the length of the rod is getting shorter due to a compressive force.

(B) To determine the change in diameter, we will need to know the Poisson's ratio. From the known relationship between Yong's modulus (E) and shear modulus (G), namely,

$$G = \frac{E}{2(1+\nu)}$$

we have

$$\nu = \frac{E}{2G} - 1 = \frac{200\ (\mathrm{GPa})}{2 \times 77\ (\mathrm{GPa})} - 1 = 0.299$$

From the definition of the Poisson's ratio

$$\nu = -\frac{\varepsilon_{transverse}}{\varepsilon_{longitudinal}}$$

and with the longitudinal strain determined earlier, we calculate

$$\varepsilon_{transverse} = -\nu\varepsilon_{longitudinal} = -0.299 \times (-7.962) \times 10^{-4} = 2.378 \times 10^{-4}$$

With this, the change in diameter can be determined as

$$\delta = d\varepsilon_{transverse} = 0.002\ (\mathrm{m}) \times 2.378 \times 10^{-4} = 4.757 \times 10^{-7}\ (\mathrm{m})$$

The positive value suggests that the diameter of the rod is becoming wider due to a compressive force.

2. Use a stress-strain curve to depict the determination of the followings: (A) strain energy, (B) resilience, and (C) toughness.

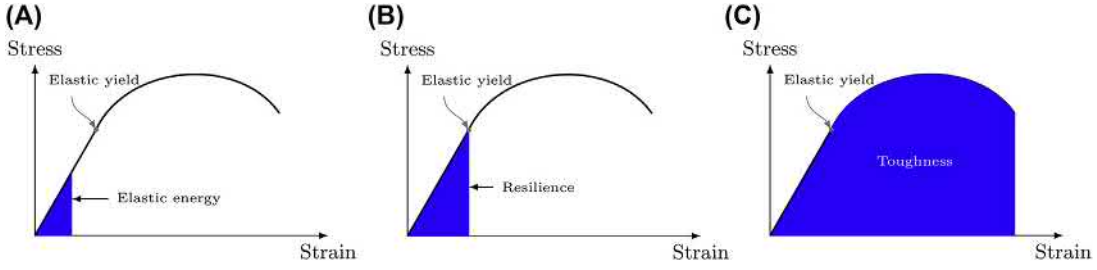
Solution:

Using the stress-strain curve of a typical metallic material, we can sketch the followings.

(A) Strain energy is typically obtained by the area under the stress-strain curve at a given stress which is below the elastic yield point.

(B) Resilience is determined by the area under the stress-strain curve up to the point where stress reaches the elastic yield point.

(C) Toughness is determined by the area under the stress-strain curve up to the point where stress reaches the breaking point.



3. Referring to the generalized Hooke's Law relation and the [c] matric given in Fig. 1.2.3.5A for an isotropic material, derive the reduced stress-strain relation for a 2D plane-strain and plane-stress situation.

Solution:

With the [c] matrix for an isotropic material given in Fig. 1.2.3.5A, we can write its stress and strain relations according to the generalized Hooke's Law as,

$$\begin{Bmatrix}\sigma_x\\ \sigma_y\\ \sigma_z\\ \tau_{yz}\\ \tau_{xz}\\ \tau_{xy}\end{Bmatrix} = \begin{bmatrix} c_{11} & c_{12} & c_{12} & 0 & 0 & 0\\ c_{12} & c_{11} & c_{12} & 0 & 0 & 0\\ c_{12} & c_{12} & c_{11} & 0 & 0 & 0\\ 0 & 0 & 0 & \frac{c_{11}-c_{12}}{2} & 0 & 0\\ 0 & 0 & 0 & 0 & \frac{c_{11}-c_{12}}{2} & 0\\ 0 & 0 & 0 & 0 & 0 & \frac{c_{11}-c_{12}}{2} \end{bmatrix} \begin{Bmatrix}\epsilon_x\\ \epsilon_y\\ \epsilon_z\\ \gamma_{yz}\\ \gamma_{xz}\\ \gamma_{xy}\end{Bmatrix}$$

By substituting the given expressions in this chapter for c_{11} and c_{12}, we have

$$\begin{Bmatrix}\sigma_x\\ \sigma_y\\ \sigma_z\\ \tau_{yz}\\ \tau_{xz}\\ \tau_{xy}\end{Bmatrix} = \frac{E}{(1+\nu)(1-2\nu)} \begin{bmatrix} 1-\nu & \nu & \nu & 0 & 0 & 0\\ \nu & 1-\nu & \nu & 0 & 0 & 0\\ \nu & \nu & 1-\nu & 0 & 0 & 0\\ 0 & 0 & 0 & 0.5-\nu & 0 & 0\\ 0 & 0 & 0 & 0 & 0.5-\nu & 0\\ 0 & 0 & 0 & 0 & 0 & 0.5-\nu \end{bmatrix} \begin{Bmatrix}\epsilon_x\\ \epsilon_y\\ \epsilon_z\\ \gamma_{yz}\\ \gamma_{xz}\\ \gamma_{xy}\end{Bmatrix}$$

For a plane-strain situation, by referring to Fig. 1.2.3.8B the following three strain components are zero: $\epsilon_z = \gamma_{yz} = \gamma_{xz}$. Plugging in these zero components into the above matrix equation we have

$$\begin{Bmatrix}\sigma_x\\ \sigma_y\\ \sigma_z\\ \tau_{yz}\\ \tau_{xz}\\ \tau_{xy}\end{Bmatrix} = \frac{E}{(1+\nu)(1-2\nu)} \begin{bmatrix} 1-\nu & \nu & \nu & 0 & 0 & 0\\ \nu & 1-\nu & \nu & 0 & 0 & 0\\ \nu & \nu & 1-\nu & 0 & 0 & 0\\ 0 & 0 & 0 & 0.5-\nu & 0 & 0\\ 0 & 0 & 0 & 0 & 0.5-\nu & 0\\ 0 & 0 & 0 & 0 & 0 & 0.5-\nu \end{bmatrix} \begin{Bmatrix}\epsilon_x\\ \epsilon_y\\ 0\\ 0\\ 0\\ \gamma_{xy}\end{Bmatrix}$$

With simplification, we obtain the following reduced stress-strain relation for a 2D plane-strain situation:

$$\begin{Bmatrix}\sigma_x\\ \sigma_y\\ \tau_{xy}\end{Bmatrix} = \frac{E}{(1+\nu)(1-2\nu)} \begin{bmatrix} 1-\nu & \nu & 0\\ \nu & 1-\nu & 0\\ 0 & 0 & 0.5-\nu \end{bmatrix} \begin{Bmatrix}\epsilon_x\\ \epsilon_y\\ \gamma_{xy}\end{Bmatrix}$$

along with

$$\sigma_z = E\nu(\epsilon_x+\epsilon_y)/[(1+\nu)(1-2\nu), \quad \tau_{yz}=\tau_{xz}=0$$

For a plane-stress situation, we first express the above generalized stress-strain relations in strain-stress relations by taking the inverse of the generalized Hooke's Law matrix equation as

$$\begin{Bmatrix}\epsilon_x\\ \epsilon_y\\ \epsilon_z\\ \gamma_{yz}\\ \gamma_{xz}\\ \gamma_{xy}\end{Bmatrix} = \frac{1}{E} \begin{bmatrix} 1 & -\nu & -\nu & 0 & 0 & 0\\ -\nu & 1 & -\nu & 0 & 0 & 0\\ -\nu & -\nu & 1 & 0 & 0 & 0\\ 0 & 0 & 0 & 2(1+\nu) & 0 & 0\\ 0 & 0 & 0 & 0 & 2(1+\nu) & 0\\ 0 & 0 & 0 & 0 & 0 & 2(1+\nu) \end{bmatrix} \begin{Bmatrix}\sigma_x\\ \sigma_y\\ \sigma_z\\ \tau_{yz}\\ \tau_{xz}\\ \tau_{xy}\end{Bmatrix}$$

Referring to Fig. 1.2.3.8A, we have the three zero stress components: $\sigma_z = \tau_{yz} = \tau_{xz}$ for a plane-stress situation. Plugging in these zero components into this equation we have

$$\begin{Bmatrix}\epsilon_x\\ \epsilon_y\\ \epsilon_z\\ \gamma_{yz}\\ \gamma_{xz}\\ \gamma_{xy}\end{Bmatrix} = \frac{1}{E} \begin{bmatrix} 1 & -\nu & -\nu & 0 & 0 & 0\\ -\nu & 1 & -\nu & 0 & 0 & 0\\ -\nu & -\nu & 1 & 0 & 0 & 0\\ 0 & 0 & 0 & 2(1+\nu) & 0 & 0\\ 0 & 0 & 0 & 0 & 2(1+\nu) & 0\\ 0 & 0 & 0 & 0 & 0 & 2(1+\nu) \end{bmatrix} \begin{Bmatrix}\sigma_x\\ \sigma_y\\ 0\\ 0\\ 0\\ \tau_{xy}\end{Bmatrix}$$

With simplification, we obtain the reduced strain-stress relation for a 2D plane-stress situation:

$$\begin{Bmatrix}\epsilon_x\\ \epsilon_y\\ \gamma_{xy}\end{Bmatrix} = \frac{1}{E} \begin{bmatrix} 1 & -\nu & 0\\ -\nu & 1 & 0\\ 0 & 0 & 2(1+\nu) \end{bmatrix} \begin{Bmatrix}\sigma_x\\ \sigma_y\\ \tau_{xy}\end{Bmatrix}$$

or its inverse stress-strain relation

$$\begin{Bmatrix}\sigma_x\\ \sigma_y\\ \tau_{xy}\end{Bmatrix} = \frac{E}{(1-\nu^2)} \begin{bmatrix} 1 & \nu & 0\\ \nu & 1 & 0\\ 0 & 0 & (1-\nu)/2 \end{bmatrix} \begin{Bmatrix}\epsilon_x\\ \epsilon_y\\ \gamma_{xy}\end{Bmatrix}$$

along with

$$\epsilon_z = -\nu(\sigma_x+\sigma_y)/E, \quad \gamma_{yz}=\gamma_{xz}=0$$

4. For an isotropic elastic material having Young's modulus of E =210 GPa and Poisson's ratio of ν =0.33, find the [c] matrix for 2D simplified plane-stress and plane-strain situations.

Solution:

For a plane-strain situation, by plugging the given values for E and ν into the reduced stress-strain relations found in Question 3, we have

$$[c] = 10^{11} \times \begin{bmatrix} 3.110 & 1.530 & 0\\ 1.530 & 3.110 & 0\\ 0 & 0 & 0.789 \end{bmatrix}$$

For a plane-stress situation, by plugging the given values for E and ν into the reduced stress-strain relations found in Question 3, we get

$$[c] = 10^{11} \times \begin{bmatrix} 2.360 & 0.778 & 0 \\ 0.778 & 2.360 & 0 \\ 0 & 0 & 0.789 \end{bmatrix}$$

Apparently, the two [c] matrices are not the same. The [c] matrix of the plane-strain situation is stiffened as compared with that of the plane-stress situation. The two terms in the first row are 3.110×10^{11} GPa and 1.530×10^{11} GPa for the plane-strain situation, which are approximately 1.32 and 1.97 times higher than the respective terms in the plane-stress situation (i.e, 2.360×10^{11} GPa and 0.778×10^{11} GPa). This suggests that treating a plane-stress problem by mistake as a plane-strain problem would lead to stiffening the material significantly. On the contrary, treating a plane-strain problem as a plane-stress one would lead to softening the material.

5. The constitutive relations between strains and stresses for a 2D plane-stress simplified problem can be expressed in a reduced 3×3 matrix equation as follows

$$\begin{Bmatrix} \epsilon_x \\ \epsilon_y \\ \gamma_{xy} \end{Bmatrix} = \frac{1}{E} \begin{bmatrix} 1 & -\nu & 0 \\ -\nu & 1 & 0 \\ 0 & 0 & 2(1+\nu) \end{bmatrix} \begin{Bmatrix} \sigma_x \\ \sigma_y \\ \tau_{xy} \end{Bmatrix}$$

Show that when the situation can be further simplified to a 1D problem, a simple relationship between stress and strain as

$$\sigma_x = E\varepsilon_x$$

Will govern the constitutive relation.

Solution:

For a 1D situation, we can further assume $\sigma_y = \tau_{xy} = 0$. By plugging these two zero terms into the given relations, we have

$$\begin{Bmatrix} \epsilon_x \\ \epsilon_y \\ \gamma_{xy} \end{Bmatrix} = \frac{1}{E} \begin{bmatrix} 1 & -\nu & 0 \\ -\nu & 1 & 0 \\ 0 & 0 & 2(1+\nu) \end{bmatrix} \begin{Bmatrix} \sigma_x \\ 0 \\ 0 \end{Bmatrix}$$

With simplification, we obtain

$\sigma_x = E\varepsilon_x$ along with $\varepsilon_y = -\dfrac{\nu\sigma_x}{E}$ and $\gamma_{xy} = 0$

The first equation is the 1D Hooke's Law governed constitutive relation, and the first two equations will lead to the Poisson's ratio equation

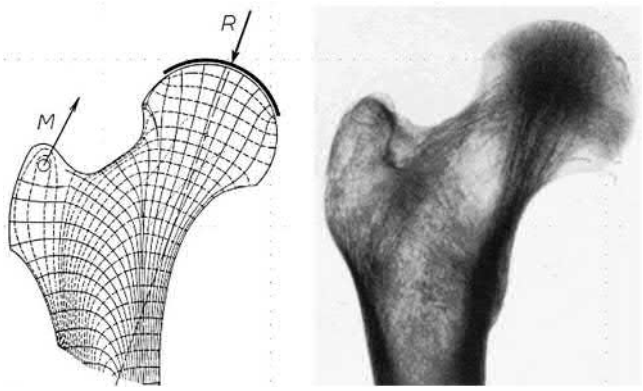
$$-\frac{\varepsilon_y}{\varepsilon_x} = -\frac{-\dfrac{\nu\sigma_x}{E}}{\dfrac{\sigma_x}{E}} = \nu$$

6. The image given below shows a helical fracture in a femur bone. Explain your observation.

Solution:

A helical fracture line is surely the result of torsional loading. Referring to the Mohr's circle and stress elements shown in Fig. 1.2.3.6, it is known that under a torsional load, the femur could break either in a shear failure mode or a tensile failure mode. If in a shear-failure mode, the fracture surface should be in a cross-cutting plane perpendicular to the shaft of the femur because the this plane is where the maximum shear stress lies, and if in tensile-failure mode, the fracture surface will follow a helical line due to the existence of the maximum tensile stress following a helical pattern. From the fracture shown, it is believed that the bone fractured under a torsional load. However, the load was applied very likely at a relatively high speed such that the bone behaves more like a brittle material. In this situation, the tensile strength of the bone becomes the weakest link because it will not be able to resist the highest tensile stress generated in the bone, thereby leading to a tensile-stress induced helical fracture due to the high-speed torsional load. This example highlights the fact that regardless the external loading situations, the actual fracture mode in a material is always dictated by the internal stress state and the nature of material, as well as the loading speed in the case of materials of viscoelastic nature.

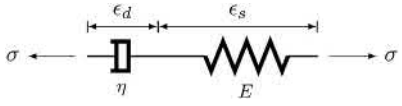
7. Of the two images given below, one showing the stress trajectories obtained from a finite element analysis of a 2D femoral-head-like structure, and the other showing the X-ray microarchitectures in a femoral head. Explain your observations.



Solution:

Inside the thin layer of strong cortical (or compact) bone of a femoral head is coarsely structured trabecular (or cancellous, spongy) bony structure. The microarchitecture of the spongy bony structure is not random, instead it appears to follow the stress trajectories inside the femoral head. According to Wolff's Law, living bones will remodel in adaptation to the external loads they experience. The microarchitecture of the spongy bone is likely the result of the bone remodeling process in meeting the strengthening needs of human/animal growth and daily activities, guided by the stress trajectories dictated by the internal stress state.

8. A viscoelastic material represented by a spring (with modulus of E) and a dashpot (with viscosity of η) connected in series is illustrated below. The spring is regarded as governed by Hooke's Law and the dashpot by Newton's Law. Derive the governing differential equation for the material and find the time-dependent stress function in response to a step function of strain.



Solution:

Since the spring and dashpot are connected in series, the stress in the material (σ) will be experienced by the spring ($\sigma_s = \sigma$) and the dashpot ($\sigma_d = \sigma$), and the strain in the material will be shared by the spring and dashpot in the following relationship:

$$\varepsilon = \varepsilon_s + \varepsilon_d$$

By applying Hooke's Law to the spring, we have:

$$\varepsilon_s = \frac{\sigma}{E}$$

and by applying the Newton's Law to the dashpot, we have:

$$\frac{d\varepsilon_d}{dt} = \frac{\sigma}{\eta}$$

Taking the time derivative of the first two equations, we obtain

$$\frac{d\varepsilon}{dt} = \frac{d\varepsilon_s}{dt} + \frac{d\varepsilon_d}{dt} \text{ and } \frac{d\varepsilon_s}{dt} = \frac{1}{E}\frac{d\sigma}{dt}$$

With the three derivative expressions, we can eliminate the ε_s and ε_d terms, and arrive at the following governing differential equation in time domain for the viscoelastic material:

$$\frac{d\varepsilon}{dt} = \frac{1}{E}\frac{d\sigma}{dt} + \frac{\sigma}{\eta}$$

To find the time-dependent stress function in response to a step function of strain, we first multiply the above differential equation by E and rearrange it to

$$\frac{d\sigma}{dt} + \frac{E}{\eta}\sigma = E\frac{d\varepsilon}{dt}$$

Then by taking the Laplace transformation of the above equation, we arrive at the following frequency-domain differential equation

$$\sigma(s)\left(s + \frac{E}{\eta}\right) = E\varepsilon(s)s$$

in which $\sigma(s)$ and $\varepsilon(s)$ are stress and strain in frequency domain, corresponding to the $\sigma(t)$ and $\varepsilon(t)$ in time domain, respectively, and s is the Laplace variable.

Let a step function of strain take the following form

$$\varepsilon(t) = \begin{matrix} \varepsilon_0, & t \geq 0 \\ 0, & t < 0 \end{matrix}$$

then its Laplace transformed function will be

$$\varepsilon(s) = \frac{\varepsilon_0}{s}$$

Substituting this expression into the frequency-domain differential equation with some rearrangement, we obtain the stress response function in frequency-domain as

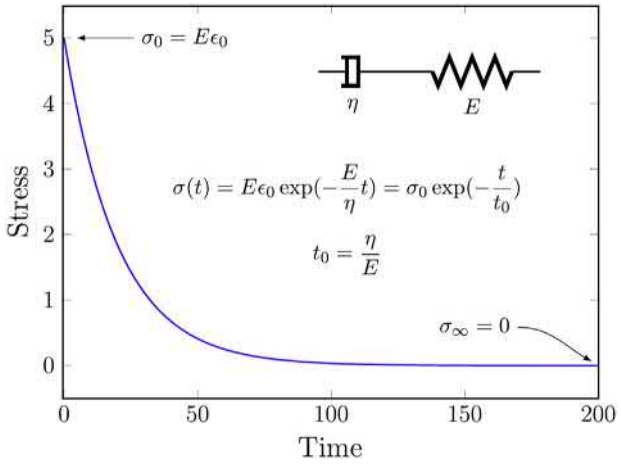
$$\sigma(s) = \frac{E\varepsilon_0}{\left(s + \frac{E}{\eta}\right)}$$

To find the time-dependent stress function, we will just take the inverse Laplace transformation. Do so leads us to the following stress response function in time domain:

$$\sigma(t) = E\varepsilon_0 \exp\left(-\frac{E}{\eta}t\right)$$

Clearly, the time-dependent stress function in response to a step function of strain is an exponential delaying function. This behavior is commonly referred to as the stress

relaxation behavior of viscoelastic materials. Obviously, the stress decays exponentially from $E\varepsilon_0$ at $t = 0$ to zero as $t \to \infty$,



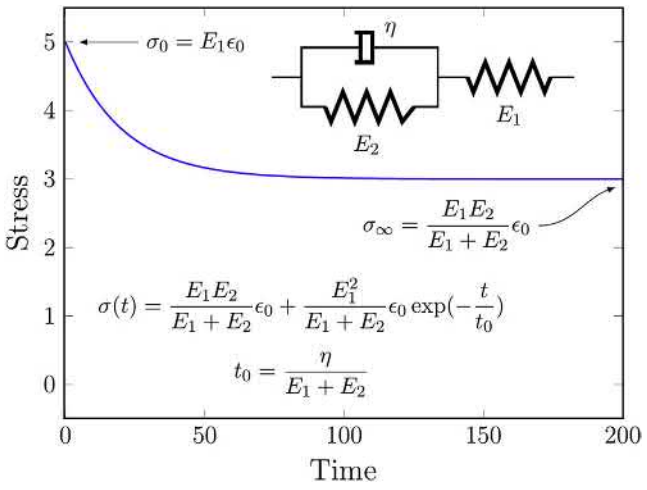
as illustrated in the plot given below.

9. For a viscoelastic material represented by two springs and a dashpot as illustrated in the given figure, show its governing differential equation as

$$\frac{d\sigma}{dt} + \frac{E_1 + E_2}{\eta}\sigma = E_1\frac{d\varepsilon}{dt} + \frac{E_1E_2}{\eta}\varepsilon$$

and its time-dependent stress function in response to a step function of strain as

$$\varepsilon(t) = \varepsilon_0,\ \sigma(t) = \frac{E_1E_2}{E_1+E_2}\varepsilon_0 + \frac{E_1^2}{E_1+E_2}\varepsilon_0 \exp(-t/t_0)\eta$$



Solution:

Since spring 2 (E_2) is connected in parallel with the dashpot (η), they will experience the same strain, $\varepsilon_d = \varepsilon_{2s} = \varepsilon_2$. Moreover, because spring 1 (E_1) is in series with the parallel combo of spring 2 and the dashpot, the stress in the material (σ) will be experienced by spring 1 ($\sigma_{1s} = \sigma$) and by the combined spring 2 and dashpot ($\sigma_d + \sigma_{2s} = \sigma$), and the strain in the material will be shared by spring 1 and the combo of spring 2 and dashpot in the following relationship:

$$\varepsilon = \varepsilon_{1s} + \varepsilon_2$$

By applying Hooke's Law to the springs, we have:

$$\sigma = \sigma_{1s} = E_1\varepsilon_{1s}$$

and

$$\sigma_{2s} = E_2\varepsilon_{2s} = E_2\varepsilon_2$$

and by applying the Newton's Law to the dashpot, we have:

$$\sigma_d = \eta\frac{d\varepsilon_d}{dt} = \eta\frac{d\varepsilon_2}{dt}$$

Substituting the last two expressions into $\sigma_d + \sigma_{2s} = \sigma$, we have

$$\sigma = \eta\frac{d\varepsilon_2}{dt} + E_2\varepsilon_2$$

With further substitution using $\varepsilon = \varepsilon_{1s} + \varepsilon_2$, $\sigma = E_1\varepsilon_{1s}$ and $\frac{d\sigma}{dt} = E_1\frac{d\varepsilon_{1s}}{dt}$, we obtain

$$\sigma = \eta\frac{d\varepsilon_2}{dt} + E_2\varepsilon_2 = \eta\frac{d\varepsilon - d\varepsilon_{1s}}{dt} + E_2(\varepsilon - \varepsilon_{1s}) = \eta\left(\frac{d\varepsilon}{dt} - \frac{d\sigma}{E_1dt}\right) + E_2\left(\varepsilon - \frac{\sigma}{E_1}\right)$$

After rearranging it, we obtain the following time-domain governing differential equation for the viscoelastic material as

$$\sigma\left(1 + \frac{E_2}{E_1}\right) + \frac{\eta}{E_1}\frac{d\sigma}{dt} = E_2\varepsilon + \eta\frac{d\varepsilon}{dt}$$

Or in the following form after some further rearrangement,

$$\sigma + \frac{\eta}{E_1+E_2}\frac{d\sigma}{dt} = \frac{E_1E_2}{E_1+E_2}\varepsilon + \frac{E_1\eta}{E_1+E_2}\frac{d\varepsilon}{dt}$$

This is the governing differential equation for the viscoelastic material represented by the given model. This equation, with some rearrangement, is exactly the same as that given in the question.

To find the time-dependent stress function in response to a step function of strain, we take the Laplace transformation of the above equation, and arrive at the following frequency domain differential equation

$$\sigma(s)\left(1 + \frac{\eta s}{E_1+E_2}\right) = \varepsilon(s)\left(\frac{E_1E_2}{E_1+E_2} + \frac{E_1\eta s}{E_1+E_2}\right)$$

in which $\sigma(s)$ and $\varepsilon(s)$ are stress and strain in the frequency domain, corresponding to the $\sigma(t)$ and $\varepsilon(t)$ in the time domain, respectively, and s is the Laplace variable.

Let a step function of strain take the following form

$$\varepsilon(t) = \begin{matrix} \varepsilon_0, & t \geq 0 \\ 0, & t < 0 \end{matrix}$$

then its Laplace transformed function is

$$\varepsilon(s) = \frac{\varepsilon_0}{s}$$

Substituting this expression into the frequency-domain differential equation along with some rearrangement, we obtain

$$\sigma(s) = \frac{\frac{\varepsilon_0}{s}\left(\frac{E_1E_2}{E_1+E_2} + \frac{E_1\eta s}{E_1+E_2}\right)}{1+\frac{\eta s}{E_1+E_2}} = \frac{\varepsilon_0\left(\frac{E_1E_2}{\eta} + E_1 s\right)}{s\left(s+\frac{E_1+E_2}{\eta}\right)}$$

This equation can be further expressed by the partial-fraction decomposition method as

$$\sigma(s) = \varepsilon_0 \frac{\left(\frac{E_1E_2}{\eta} + E_1 s\right)}{s\left(s+\frac{E_1+E_2}{\eta}\right)} = \varepsilon_0\left(\frac{A}{s} + \frac{B}{s+\frac{E_1+E_2}{\eta}}\right) = \varepsilon_0\left(\frac{\frac{E_1E_2}{E_1+E_2}}{s} + \frac{\frac{E_1^2}{E_1+E_2}}{s+\frac{E_1+E_2}{\eta}}\right)$$

with $A = \frac{E_1E_2}{E_1+E_2}$ and $B = \frac{E_1^2}{E_1+E_2}$.

Taking the inverse Laplace transformation of the above equation, we obtain the following stress response function in time domain:

$$\sigma(t) = \frac{E_1E_2}{E_1+E_2}\varepsilon_0 + \frac{E_1^2}{E_1+E_2}\varepsilon_0 \exp\left(-\frac{E_1+E_2}{\eta}t\right)$$

Apparently, the time-dependent stress function in response to a step function of strain for this viscoelastic material is still an exponential relaxation function. In this case, the stress decays exponentially from $E_1\varepsilon_0$ at $t = 0$ to $\frac{E_1E_2}{E_1+E_2}\varepsilon_0$, not zero, as $t \to \infty$.

1.2.4

Surface Properties and Surface Characterization of Biomaterials

BUDDY D. RATNER[1], DAVID G. CASTNER[2]

[1]Bioengineering and Chemical Engineering, Director of University of Washington Engineered Biomaterials (UWEB), Seattle, WA, United States

[2]University of Washington, Seattle, WA, United States

Introduction

Nothing is rich but the inexhaustible wealth of nature. She shows us only surfaces, but she is a million fathoms deep.

Ralph Waldo Emerson.

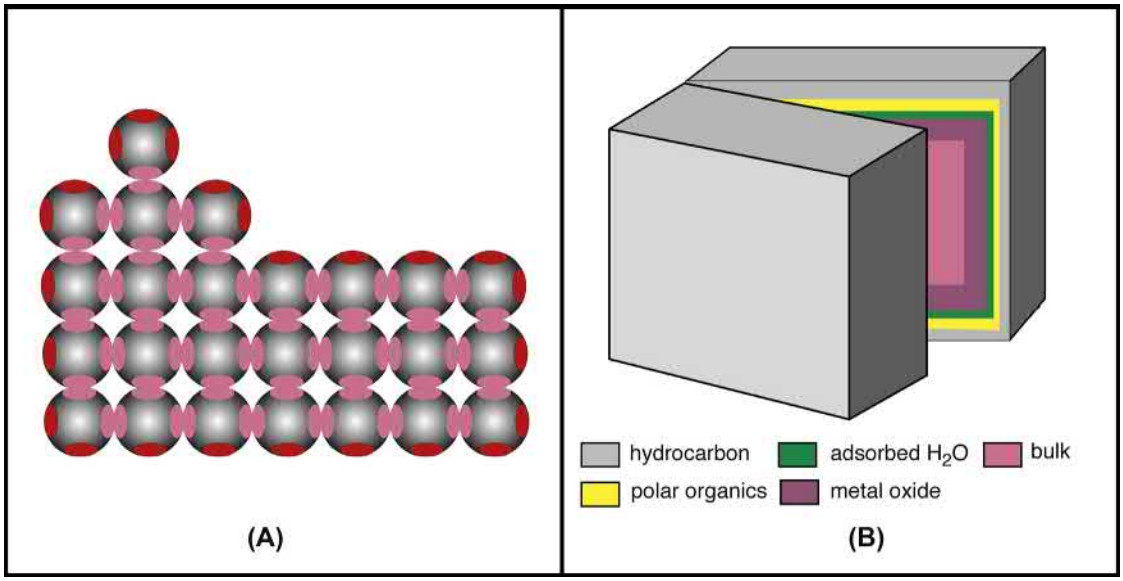
Biomaterials "show" to the world (and the biological environment) only surfaces. Atoms and molecules make up the outermost surface of a biomaterial (the interface between the material and the world). As we shall discuss in this section, these atoms and molecules that reside at the surface have a special organization and reactivity. They require special methods to characterize them, novel methods to tailor them, and they drive many of the biological reactions that occur in response to the biomaterial (protein adsorption, cell adhesion, cell growth, blood compatibility, etc.). The importance of surfaces for biomaterials science has been appreciated since the 1960s. Almost every biomaterials meeting will have sessions addressing surfaces and interfaces. In this chapter we focus on the special properties of surfaces, definitions of terms, methods to characterize surfaces, and some implications of surfaces as the drivers of bioreactions to biomaterials.

Atoms and molecules that reside at the surface of a biomaterial have special reactivity and a direct biological response.

During the development of biomedical implant devices and materials, we are concerned with physical properties, durability, and biocompatibility. The understanding of physical properties (e.g., mechanical strength, permeability, elasticity) has evolved over hundreds of years and is relatively well understood— the standard tools of engineers and materials scientists are appropriate to characterize and study physical properties (see Chapters 1.2.2 and 1.2.3). Durability, particularly in the biological environment, is less well understood. Still, the tests we need to evaluate durability are clear (see Chapters 1.2.2, 2.4.3, and 2.4.4). Biocompatibility represents a frontier of knowledge in this field, and its study is often assigned to the biochemist, biologist, and physician (see Chapters 2.3.2, 2.3.3, and 2.3.4). However, an important question in biocompatibility is how the device or material "transduces" its structural makeup to direct or influence the response of proteins, cells, and the organism to that material. For devices and materials that do not leach undesirable substances (i.e., that have passed routine toxicological evaluation; see Chapter 2.3.3), this transduction occurs through the surface structure. The body "reads" the surface structure and responds to the particular chemistry and organization. For this reason we must understand the surface structure of biomaterials, and thus there is an important role for the physical scientist in understanding surface-driven biointeractions. Chapter 3.1.9 elaborates on the biological implications of this idea.

General Surface Considerations and Definitions

This is the appropriate point to highlight general ideas about surfaces, especially solid surfaces. First, the surface region of a material is known to be of unique reactivity (Fig. 1.2.4.1A). Catalysis (for example, as used in petrochemical processing) and microelectronics both capitalize on special *surface* organization and reactivity—biology also exploits this enhanced surface reactivity to do its work. Second, the surface of a material is inevitably different from the bulk. The traditional techniques used to analyze the bulk structure of materials are not suitable for surface determination because they typically do not have the sensitivity to observe the small amount of material comprising the unique surface chemistry/structure. Third, there is not much total mass of material at a surface. An example may help us to appreciate



• **Figure 1.2.4.1** (A) A two-dimensional representation of a crystal lattice suggesting bonding orbitals (red or pink ovals). For atoms in the center (bulk) of the crystal (pink ovals), all binding sites have associations with those of other atoms (sharing electrons). At planar exterior surfaces, one of the bonding sites is unfulfilled (red oval). At corners, two bonding sites are unfulfilled. The single atom on top of the crystal (an adatom) has three unfulfilled valencies. Energy is minimized where more of these unfulfilled valencies can interact. Where interactions do not satisfy all binding orbitals, there is an asymmetric electrical field driving a surface dipole. (B) In a "real-world" material (a block of metal from an orthopedic device, for example), if we cleave the block (under ultrahigh vacuum to prevent recontamination), we should find hydrocarbon on the outermost layer (perhaps 3 nm, surface energy ~22 ergs/cm^2), polar organic molecules (>1 nm, surface energy ~45 ergs/cm^2), adsorbed water (<1 nm, surface energy ~72 ergs/cm^2), metal oxide (approximately 5 nm, surface energy ~200 ergs/cm^2), and finally, the uniform bulk interior (surface energy ~1000 ergs/cm^2). The interface between air and material has the lowest interfacial energy (~22 ergs/cm^2). The layers are not drawn to scale.

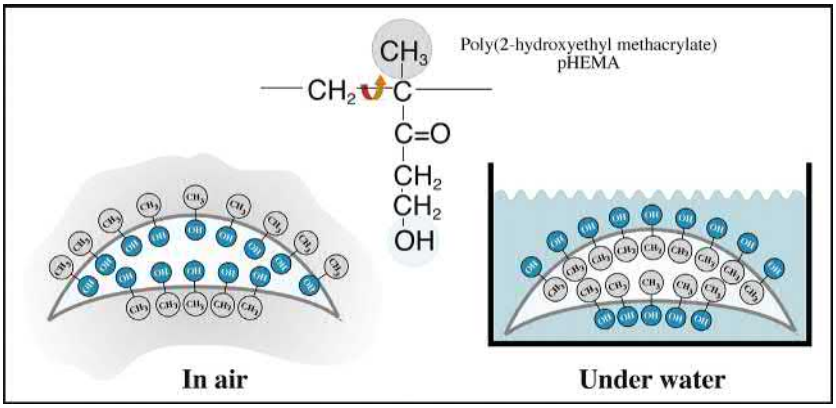
this—on a 1 cm^3 cube of titanium, the 100Å oxide surrounding the cube is in the same proportion as a 5 m-wide beach on each coast of the United States is to the roughly 5,000,000 m distance from coast to coast. Fourth, surfaces readily contaminate with components from the vapor phase (some common examples are hydrocarbons, silicones, sulfur compounds, iodine). Under ultrahigh vacuum conditions (pressures <10^{-7} Pa) we can retard this contamination. However, in view of the atmospheric pressure conditions under which all biomedical devices are used, we must learn to live with some contamination. The key questions here are whether we can make devices with controlled and acceptable levels of contamination and also avoid undesirable contaminants. This is critical so that a laboratory experiment on a biomaterial generates the same results when repeated after 1 day, 1 week, or 1 year, and so that the biomedical device is dependable and has a reasonable shelf-life. Finally, the surface structure of a material is often mobile. A modern view of what might be seen at the surface of a real-world material is illustrated in Fig. 1.2.4.1B.

Five points about surfaces include:
1. Surfaces have unique reactivity.
2. The surface is inevitably different from the bulk.
3. The mass of material that makes up the surface zone is very small.
4. Surfaces readily contaminate.
5. Surface molecules can exhibit considerable mobility.

The movement of atoms and molecules near the surface in response to the outside environment is often highly significant. In response to a hydrophobic environment (e.g., air), more hydrophobic (lower energy) components may migrate to the surface of a material—a process that reduces interfacial energy (Fig. 1.2.4.1B). Responding to an aqueous environment, the surface may reverse its structure and point polar (hydrophilic) groups outward to interact with the polar water molecules. Again, energy minimization drives this process. An example of this is schematically illustrated in Fig. 1.2.4.2. For metal alloys, one metal tends to dominate the surface, for example, silver in a silver–gold alloy or chromium in stainless steel.

The nature of surfaces is complex and the subject of much independent investigation. The reader is referred to one of many excellent monographs on this important subject for a complete and rigorous introduction (see Somorjai, 1981; Somorjai and Li, 2010; Adamson and Gast, 1997; Andrade, 1985; Garbassi et al., 1998). Biosurfaces, with particular relevance for biomaterials, are overviewed in articles and books (Castner and Ratner, 2002; Kasemo, 2002; Tirrell et al., 2002; Ratner, 1988; Castner, 2017).

When we say "surface," a question that immediately comes to mind is, "how deep into the material does it extend?" Although formal definitions are available, for all practical purposes, the surface is the zone where the structure and composition, influenced by the interface, differ from the average (bulk) composition and structure. This value often



• **Figure 1.2.4.2** Many materials can undergo a reversal of surface structure when transferred from air into a water environment. In this schematic illustration, a hydroxylated polymer (for example, a pHEMA contact lens) exhibits a surface rich in methyl groups (from the polymer chain backbone) in air, and a surface rich in hydroxyl groups under water. This has been observed experimentally [Ratner et al., J. Appl. Polym. Sci., 1978; 22, 643; Chen et al., J. Am. Chem. Soc., 1999; 121 (2); 446].

scales with the size of the molecules making up the surface. For an "atomic" material, for example gold, after penetration of about five atomic layers (0.5–1 nm), the composition becomes uniform from layer to layer (i.e., you are seeing the bulk structure). At the outermost atomic layer, the organization of the gold atoms at the surface (and their reactivity) can be substantially different from the organization in the averaged bulk (Barth et al., 1990), but it is not the atomic/molecular rearrangements we are discussing here. The gold surface, in air, will always have a contaminant overlayer, largely hydrocarbon, that may be roughly 2 nm thick. This results in a difference in composition between bulk and surface. For a polymer, the unique surface zone may extend from 10 to 100 nm (depending on the polymeric system and the chain molecular weight). Fig. 1.2.4.1B addresses some of these issues about surface definitions. Two more definitions must be considered. An interface is the transition between two phases, in principle an infinitely thin separation plane. An interphase is the unique compositional zone between two phases. For the example, for gold, we might say that the interphase between gold and air is 3 nm thick (the structurally rearranged gold atoms + the contaminant layer).

What Surface Properties Are We Interested in?

A surface is fully described by many parameters (Fig. 1.2.4.3). The more of these parameters we measure, the more we can piece together a complete description of the surface. A complete characterization requires a cadre of techniques to examine the many facets that contribute to the surface properties. Unfortunately, we cannot yet specify which parameters are most important for understanding specific biological responses to surfaces. Studies have been published on the importance of roughness, patterns, wettability, surface mobility, chemical composition, electrical charge, crystallinity, modulus, and heterogeneity to biological reaction. Since we cannot be certain which surface factors are predominant in each situation, the controlling variable or variables must be independently measured and correlated. We use surface analysis techniques to measure these surface properties.

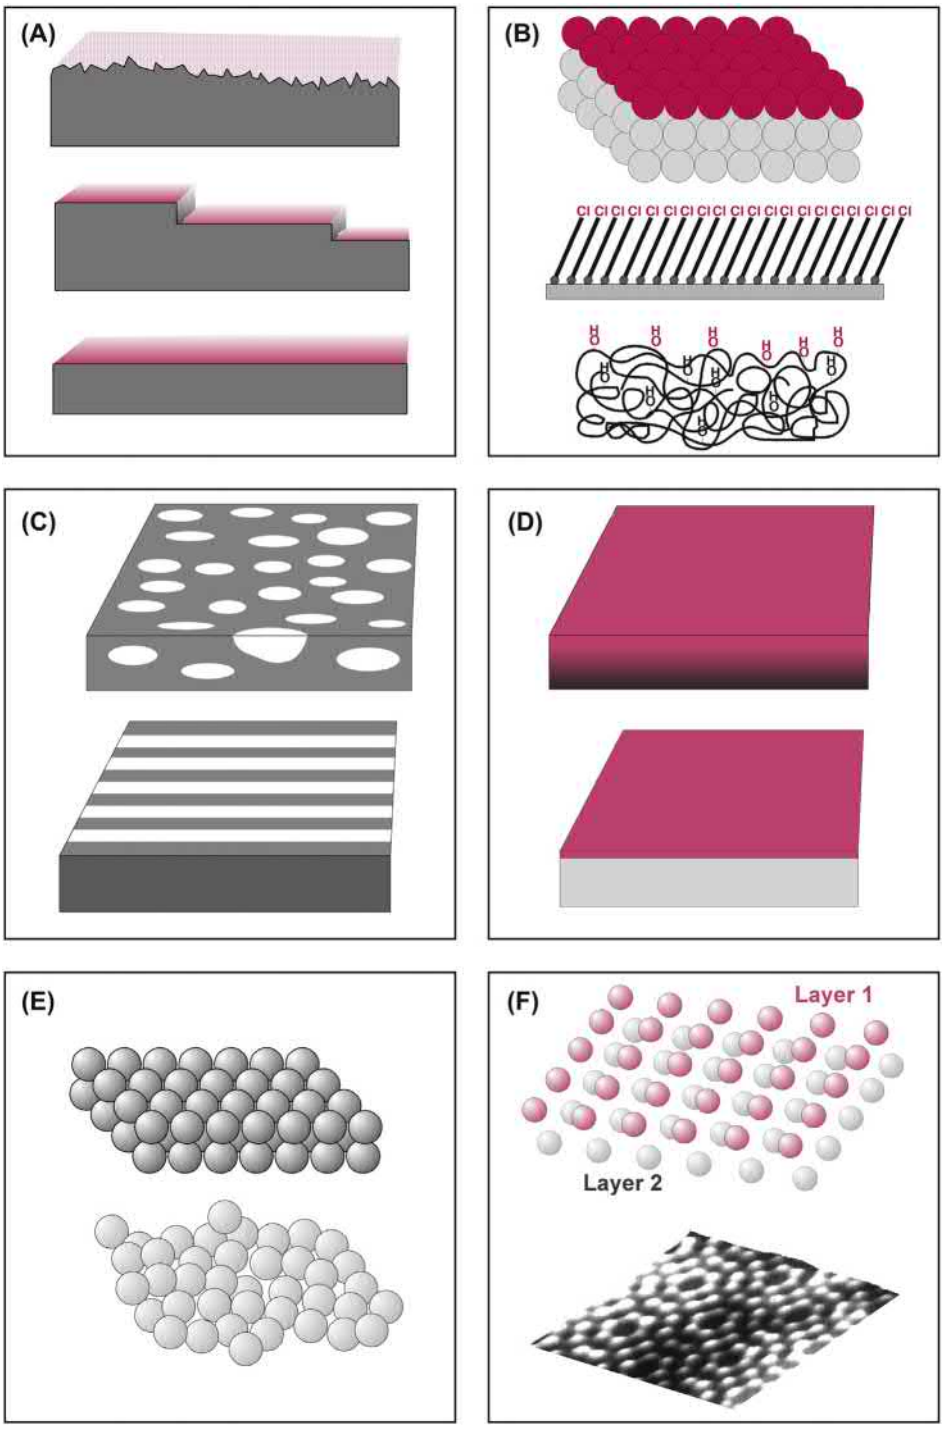
Surface Analysis Techniques: Principles and Methods

Sample Preparation

A guiding principle of surface analysis sample preparation is that the sample should resemble, as closely as possible, the material or device in the form that it is used for biological testing or implantation. Needless to say, fingerprints on the surface of the sample will obscure surface properties of interest. If the sample is placed in a package for shipping or storage prior to surface analysis, it is critical to know whether the packaging material can deliver surface contamination. Plain paper in contact with most specimens will transfer contaminants (often metal ions) to the surface of the material. Many plastics are processed with silicone oils or other additives that can migrate to the specimen. The packaging material used should be examined by surface analysis methods to ascertain its purity. Samples can be surface analyzed prior to and after storage in containers to ensure that the surface composition measured is not due to the container. As a general rule, the polyethylene press-close bags used in electron microscopy and cell culture plastic ware are clean storage containers. However, abrasive contact must be avoided, and each brand must be evaluated so that a meticulously prepared specimen is not ruined by contamination. Many brands of aluminum foil are useful for packing specimens, but some are treated with a surface layer of stearic acid that can surface-contaminate biomaterials, implants, or medical devices. Aluminum foil should be checked for surface contamination layers by surface analysis methods prior to wrapping important specimens.

Surface Analysis General Comments

Two general principles guide sample analysis. First, all methods used to analyze surfaces also have the potential to alter the surface. The analyst must be aware of the damage potential of the method used. Second, because of the potential for



• **Figure 1.2.4.3** What might be measured to define surface structure? (A) Surfaces can be rough, stepped, or smooth. (B) Surfaces can be comprised of different chemistries (atomic, supramolecular, macromolecular). (C) Surfaces may be structurally or compositionally inhomogeneous in the plane of the surface such as phase-separated domains or microcontact printed lanes. (D) Surfaces may be inhomogeneous with depth into the specimen or simply overlayered with a thin film. (E) Surfaces may be highly crystalline or disordered. (F) Crystalline surfaces are found with many organizations such as a silicon (100) unreconstructed surface or a silicon (111) (7 × 7) reconstructed surface.

artifacts and the need for corroborative information to construct a complete picture of the surface (Fig. 1.2.4.3), more than one method should be used whenever possible. The data derived from two or more methods should be internally consistent. When data are contradictory, be suspicious and question why. A third or fourth method may then be necessary to draw confident conclusions about the nature of a surface. These general principles are applicable to all materials.

There are properties (only a few of which will be presented here) that are specific to specific classes of materials.

TABLE 1.2.4.1 Common Methods to Characterize Biomaterial Surfaces

Method	Principle	Depth Analyzed	Spatial Resolution	Analytical Sensitivity	Cost
Contact angles	Liquid wetting of surfaces is used to estimate the energy of surfaces	3–20Å	1 mm	Low or high depending on the chemistry	$
ESCA (XPS)	X-rays induce the emission of electrons of characteristic energy	10–250Å	5–150 μm	0.1 atom %	$$$
Auger electron spectroscopy[a]	A focused electron beam stimulates the emission of auger electrons	50–100Å	80Å	0.1 atom %	$$$
SIMS	Ion bombardment sputters secondary ions from the surface	10Å–1 μm[b]	100Å	Very high	$$$
FTIR-ATR	IR radiation is adsorbed and excites molecular vibrations	1–5 μm	10 μm	1 mol %	$$
STM	Measurement of the quantum tunneling current between a metal tip and a conductive surface	5Å	1Å	Single atoms	$$
SEM	Secondary electron emission induced by a focused electron beam is spatially imaged	5Å	10–40Å	High, but not quantitative	$$-$$$

$, up to $5000; $$, $5000–$250,000; $$$, >$250,00.
[a]Auger electron spectroscopy is damaging to organic materials, and best used for inorganics.
[b]Static SIMS ≈ 10Å, dynamic SIMS to 1 μm.

Compared to metals, ceramics, and glasses, organic and polymeric materials are more easily damaged by surface analysis methods. Polymeric systems also exhibit greater surface molecular mobility than inorganic systems. The surfaces of inorganic materials are contaminated more rapidly than polymeric materials because of their higher surface energy. Electrically conductive metals and carbons will often be easier to characterize than insulators using electron, X-ray, and ion interaction methods. Insulators accumulate a surface electrical charge that requires special methods (e.g., a low-energy electron beam) to neutralize. To learn about other concerns in surface analysis that are specific to specific classes of materials, published papers become a valuable resource for understanding the pitfalls that can lead to artifact or inaccuracy.

Table 1.2.4.1 summarizes the characteristics of many common surface analysis methods, including their depth of analysis under standard conditions and their spatial resolution (spot size analyzed). A few of the more frequently applied techniques are described in the next section. However, space limitations prevent an intensive discussion of these methods. The reader is referred to many comprehensive books on the general subject of surface analysis (Andrade, 1985; Briggs and Seah, 1983; Feldman and Mayer, 1986; Vickerman and Gilmore, 2009). References describing specific surface analysis methods will be presented in sections on each of the key methods.

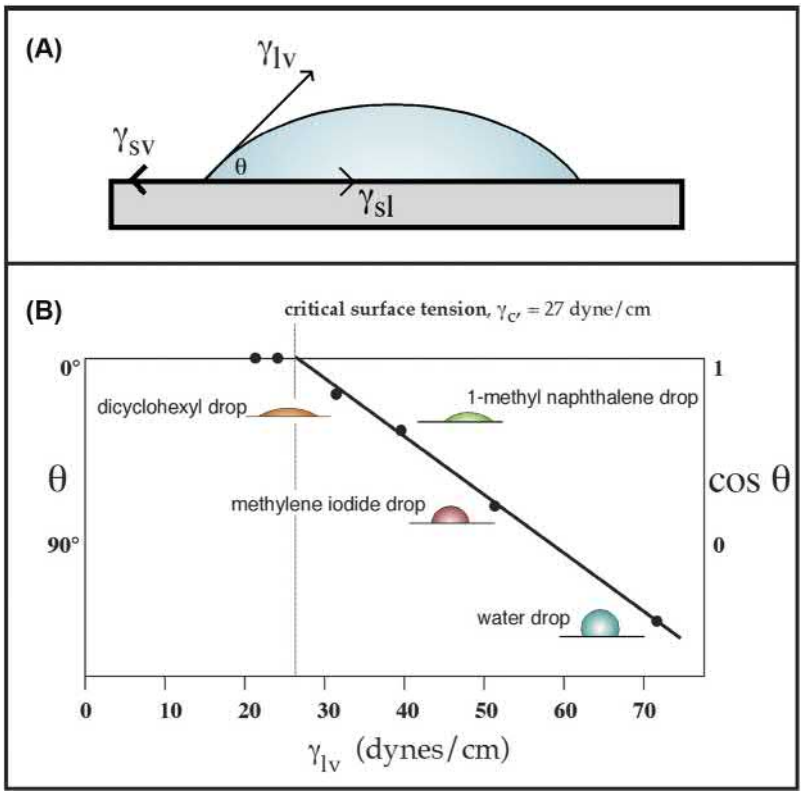
Contact Angle Methods

A drop of liquid sitting on a solid surface represents a simple, but potentially powerful, method to probe surface properties. Experience tells us that a drop of water on a highly polished automobile body surface will stand up (bead up), while on an old, weathered car, the liquid will flow evenly over the surface. This observation, for those knowledgeable about contact angles, tells us that the highly polished car probably has silicones or hydrocarbons at its surface, while the unpolished car surface is oxidized material. Quantitative contact angle measurement has, in fact, been used to predict the performance of vascular grafts and the adhesion of cells to surfaces.

The phenomenon of the contact angle can be explained as a balance between the force with which the molecules of the drop liquid are being attracted to each other (a cohesive force) and the attraction of the liquid molecules for the surface (an adhesive force). An equilibrium is established between these forces. The force balance between the liquid–vapor surface tension (γ_{lv}) of a liquid drop and the interfacial tension between a solid and the drop (γ_{sl}), manifested through the contact angle (θ) of the drop with the surface, can be used to quantitatively characterize the energy of the surface (γ_{sv}) (Fig. 1.2.4.4A). The basic relationship describing this force balance is:

$$\gamma_{sv} = \gamma_{sl} + \gamma_{lv} \cos\theta$$

The surface energy, closely related to wettability, is a useful parameter that has often been correlated with biological interaction. Unfortunately, γ_{sv} cannot be directly obtained since this equation contains two unknowns, γ_{sl} and γ_{sv}. Therefore, the γ_{sv} is sometimes approximated by the Zisman method for obtaining the critical surface tension (Fig. 1.2.4.4B), or calculated by solving simultaneous equations



• **Figure 1.2.4.4** (A) An equilibrium is established between surface tension forces contracting a liquid drop to a spherical shape and forces interacting the drop with the surface. The force balance between the liquid–vapor surface tension (γ_{lv}) of a liquid drop and the interfacial tension between a solid and the drop (γ_{sl}), manifested through the contact angle (θ) of the drop and can be used to quantitatively characterize the surface–vapor interfacial tension (γ_{sv}). (B) The Zisman method permits a critical surface tension value, an approximation to the solid surface tension, to be measured. Drops of liquids of different surface tensions are placed on the solid, and the contact angles of the drops are measured. The plot of liquid surface tension versus angle is extrapolated to zero contact angle to give the critical surface tension value.

TABLE 1.2.4.2 Critical Surface Tension Values for Common Polymeric Materials Calculated From Contact Angle Measurements

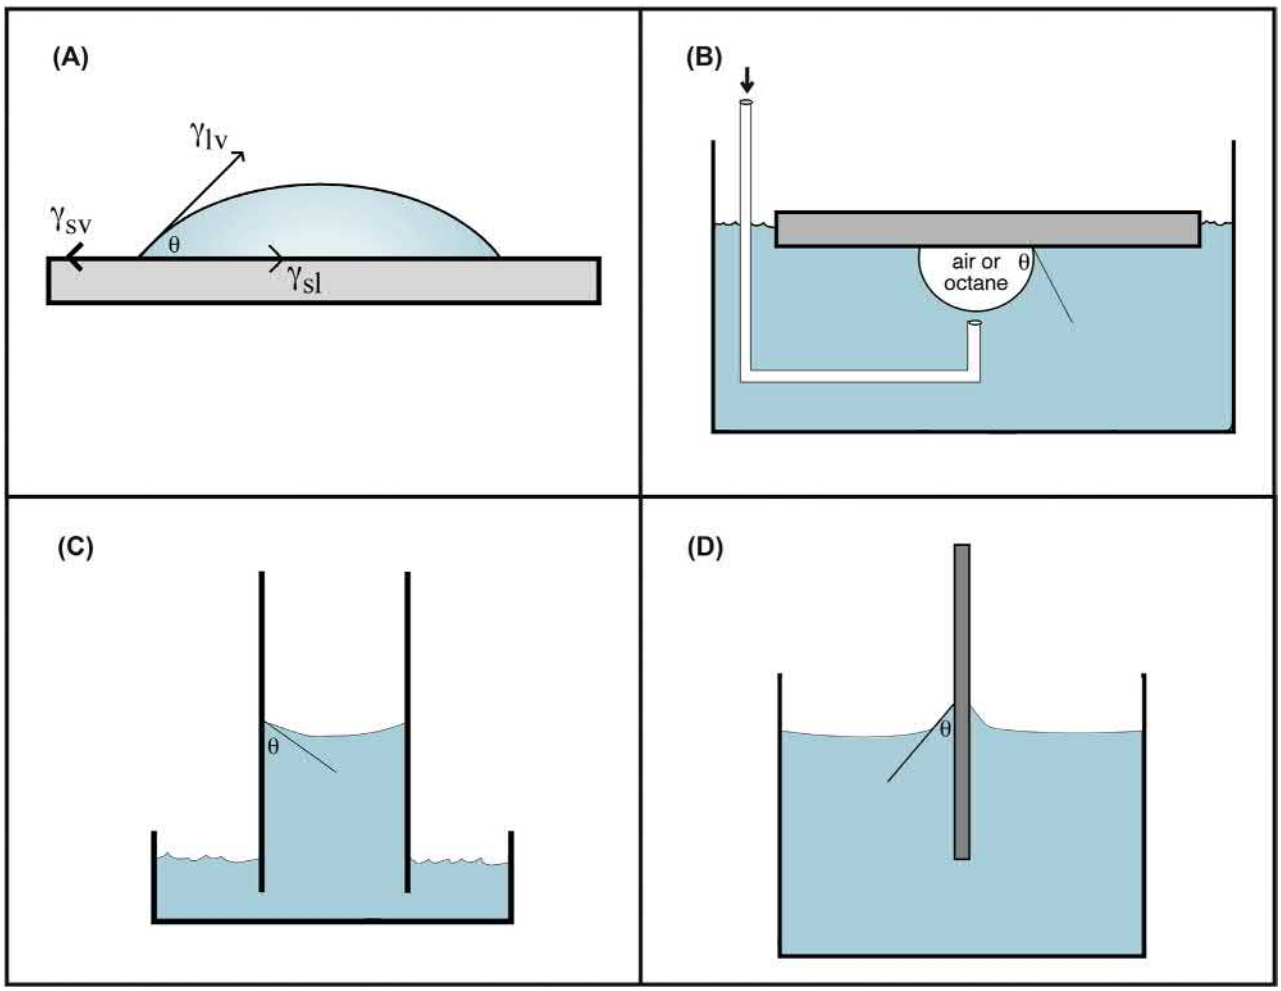
Material	Critical Surface Tension (dynes/Cm)
Polytetrafluoroethylene	19
Poly(dimethyl siloxane)	24
Poly(vinylidine fluoride)	25
Poly(vinyl fluoride)	28
Polyethylene	31
Polystyrene	33
Poly(2-hydroxyethyl methacrylate)	37
Poly(vinyl alcohol)	37
Poly(methyl methacrylate)	39
Poly(vinyl chloride)	39
Polycaproamide (nylon 6)	42
Poly(ethylene oxide)-diol	43
Poly(ethylene terephthalate)	43
Polyacrylonitrile	50

with data from liquids of different surface tensions. Some critical surface tensions for common materials are listed in Table 1.2.4.2.

Experimentally, there are a number of ways to measure the contact angle. Some of these are illustrated in Fig. 1.2.4.5. Contact angle methods can be inexpensive, and, with some practice, easy to perform. A contact angle goniometer (a telescope to observe the drop that is equipped with a protractor eyepiece) is the least expensive method for contact angle measurement. A number of companies now offer video systems that compute the contact angle and other surface energy parameters from digital image analysis of the liquid drop profile. Accessories to control humidity and temperature and deposit drops of liquid are available.

Contact angles directly measure surface wettability and indirectly probe surface energy, roughness, heterogeneity, contamination, and molecular mobility.

Contact angle measurements provide a "first-line" characterization of materials and can be performed in any laboratory. Contact angle measurements provide a unique insight into how the surface will interact with the external world. However, in performing such



• **Figure 1.2.4.5** Four possibilities for contact angle measurement: (A) sessile drop; (B) captive air bubble method; (C) capillary rise method; (D) Wilhelmy plate method.

TABLE 1.2.4.3 Concerns in Contact Angle Measurement

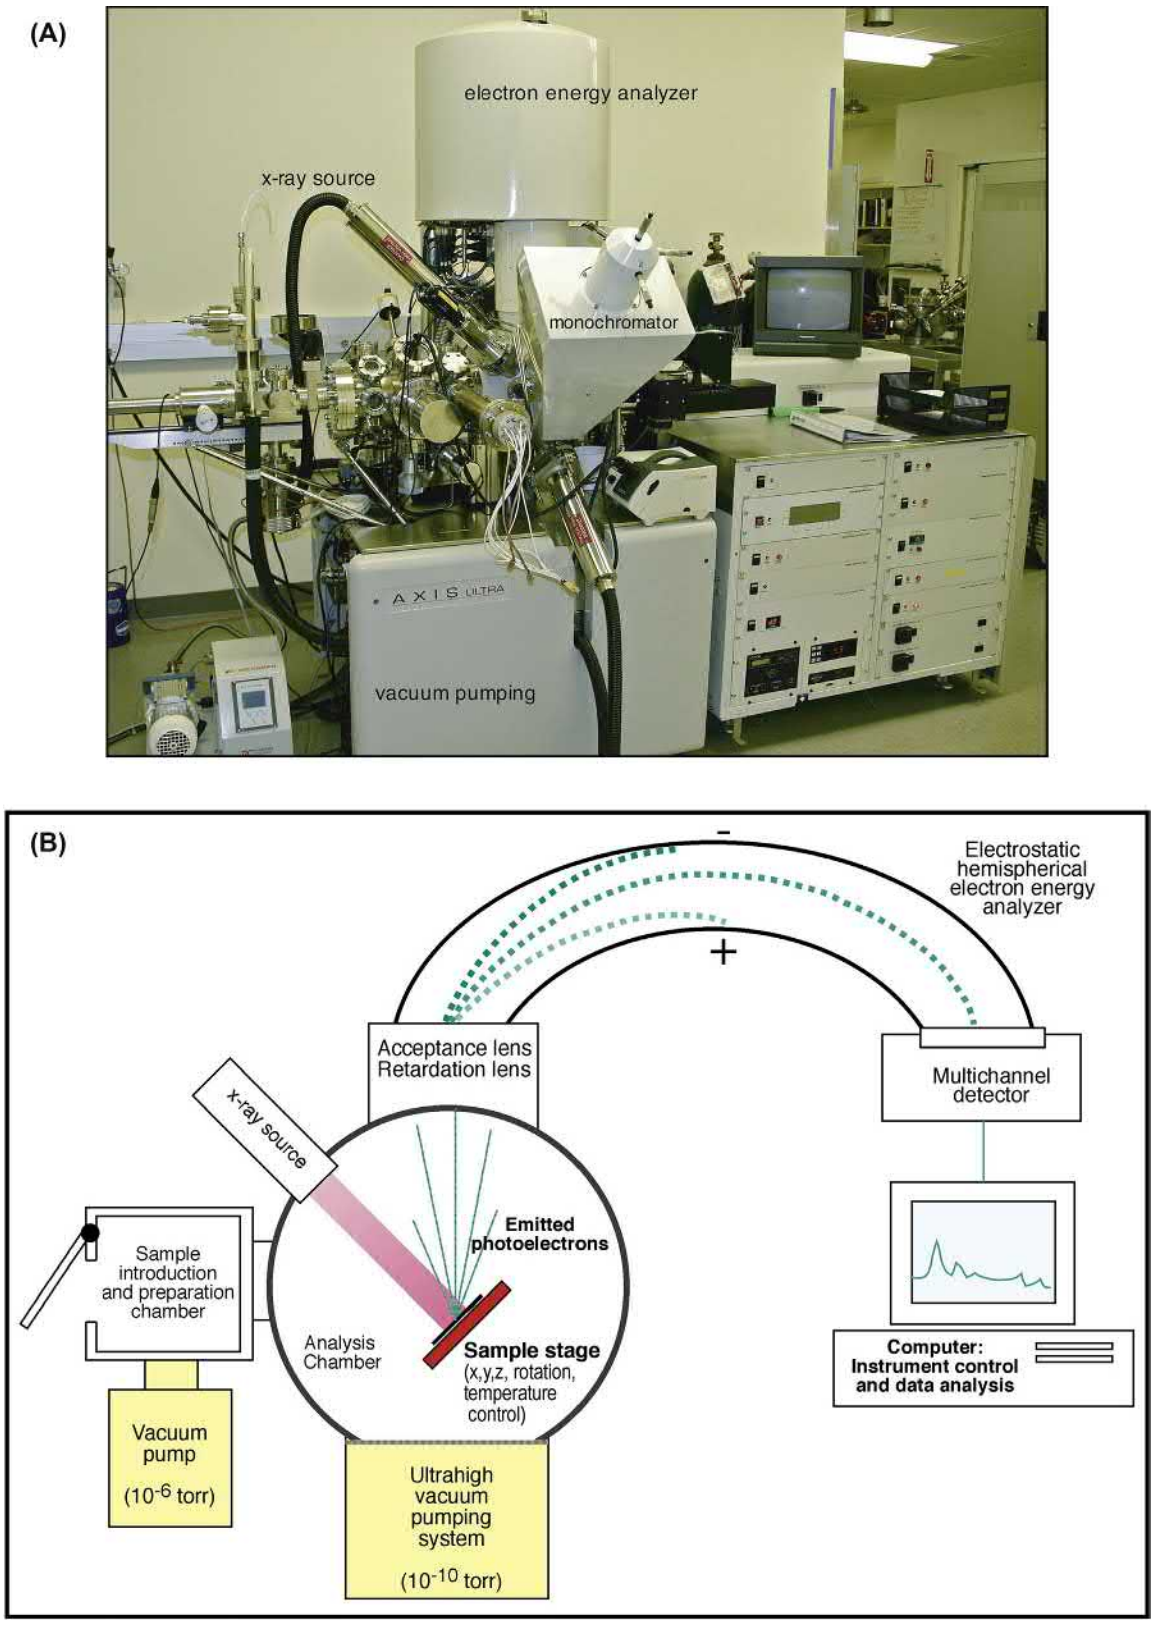
- The measurement is operator dependent (for manual, goniometer instruments)
- Surface roughness influences the results
- Surface heterogeneity influences the results
- The liquids used are easily contaminated (typically reducing their γ_{lv})
- Liquid evaporation and temperature changes can impact measurement
- The liquids used can reorient the surface structure
- The liquids used can absorb into the surface, leading to swelling
- The liquids used can dissolve the surface
- Few sample geometries are appropriate for contact angle measurement
- Information on surface structure must be inferred from the data obtained

measurements, a number of concerns must be addressed to obtain meaningful data (Table 1.2.4.3). Review articles are available on contact angle measurement for surface characterization (Andrade, 1985; Good, 1993; Zisman, 1964; Ratner, 1988).

Electron Spectroscopy for Chemical Analysis

Electron spectroscopy for chemical analysis (ESCA) provides a comprehensive qualitative and quantitative overview of a surface that would be challenging to obtain by other means (Andrade, 1985; Ratner, 1988; Dilks, 1981; Ratner and McElroy, 1986; Ratner and Castner, 2009; Watts and Wolstenholme, 2003; McArthur, 2006). In contrast to the contact angle technique, ESCA requires complex, expensive apparatus (Fig. 1.2.4.6A) and demands considerable training to perform the measurements. However, since ESCA is available from commercial laboratories, university analytical facilities, national centers (for example, NESAC/BIO at the University of Washington), and specialized research laboratories, most biomaterials scientists can access instrumentation for sample analysis. ESCA has contributed significantly to the development of biomaterials and medical devices, and to understanding the fundamentals of biointeraction.

The ESCA method (also called X-ray photoelectron spectroscopy, XPS) is based on the photoelectric effect, properly described by Einstein in 1905. X-rays are focused upon a specimen. The interaction of the X-rays with the atoms in the specimen causes the emission of core level (inner shell)

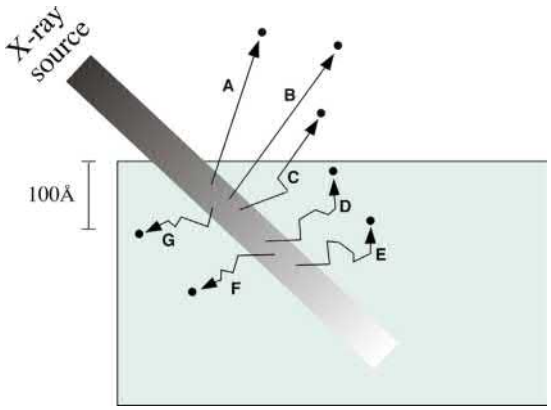


• **Figure 1.2.4.6** (A) Photograph of a contemporary ESCA instrument. (B) Schematic diagram of a monochromatized ESCA instrument. (Photo by Kratos Axis Ultra DLD – contemporary ESCA instrument).

TABLE 1.2.4.4 Information Derived From an ESCA Experiment

In the outermost 100Å of a surface, ESCA can provide:

- Identification of all elements (except H and He) present at concentrations > 0.1 atomic %
- Semiquantitative determination of the approximate elemental surface composition (±10%)
- Information about the molecular environment (oxidation state, bonding atoms, etc.)
- Information about aromatic or unsaturated structures from shake-up ($\pi^* \leftarrow \pi$) transitions
- Identification of organic groups using derivatization reactions
- Nondestructive elemental depth profiles 100Å into the sample and surface heterogeneity assessment using angular-dependent ESCA studies and photoelectrons with differing escape depths
- Destructive elemental depth profiles several thousand angstroms into the sample using argon ion etching (for inorganics) or cluster beam etching (for organics)
- Lateral variations in surface composition (spatial resolution 5–150 μm, depending upon the instrument)
- "Fingerprinting" of materials using valence band spectra and identification of bonding orbitals
- Studies on hydrated (frozen) surfaces



• **Figure 1.2.4.7** ESCA is a surface-sensitive method. Although the X-ray beam can penetrate deeply into a specimen, electrons emitted deep in the specimen (D, E, F ,G) will lose their energy in inelastic collisions and never emerge from the surface. Only those electrons emitted near the surface that loose no energy (A, B) will contribute to the ESCA signal used analytically. Electrons that lose some energy, but still have sufficient energy to emerge from the surface (C) contribute to the background signal.

electrons. The energy of these electrons is measured and their values provide information about the nature and environment of the atom or atoms from which they originated. The basic energy balance describing this process is given by the relationship:

$$BE = h\nu - KE$$

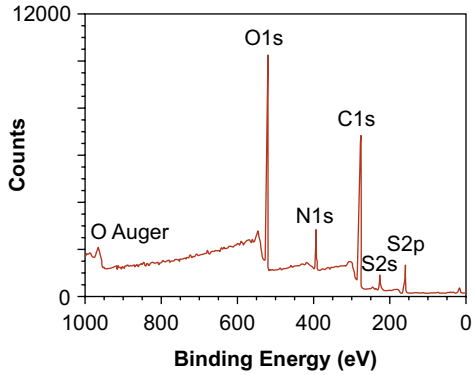
where *BE* is the energy binding the electron to an atom (the value desired), *KE* is the kinetic energy of the emitted electron (the value measured in the ESCA spectrometer), and $h\nu$ is the energy of the X-rays, a known value. A schematic diagram illustrating an ESCA instrument is shown in Fig. 1.2.4.6B. Table 1.2.4.4 lists the types of information about the nature of a surface that can be obtained using ESCA. The origin of the surface sensitivity of ESCA is described in Fig. 1.2.4.7.

ESCA has many advantages, and a few disadvantages, for studying biomaterials. The advantages include high information content, surface localization of the measurement (outermost 8–10 nm), speed of analysis, low damage potential, and the ability to analyze most samples with no special specimen preparation. The latter advantage is particularly important since biomedical devices (or parts of devices) can often be inserted, as fabricated and sterilized, directly in the analysis chamber for study. The disadvantages include the need for vacuum compatibility (i.e., no outgassing of volatile components), the vacuum environment and its impact on the specimen (particularly for hydrated specimens), the possibility of sample damage by X-rays if long analysis times are used, the need for experienced operators, and the cost associated with this complex instrumentation. The vacuum limitations can be sidestepped by using an ESCA system with a cryogenic sample stage. At liquid nitrogen temperatures, samples with volatile components, or even wet, hydrated samples, can be analyzed.

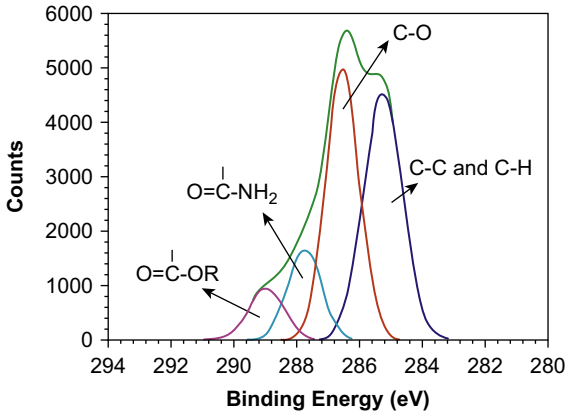
ESCA analyzes to approximately 10 nm and gives information on elements present, their concentrations, and their bonding environments.

The use of ESCA is best illustrated with a brief example. A poly(methyl methacrylate) (PMMA) ophthalmologic device is to be examined. Taking care not to touch or damage the surface of interest, the device is inserted into the ESCA instrument introduction chamber. The introduction chamber is then pumped down to 10^{-7} torr (1.33×10^{-5} Pa) or lower pressure. A gate valve between the introduction chamber and the analytical chamber is opened and the specimen is moved into the analysis chamber. In the analysis chamber, at 10^{-9} torr (1.33×10^{-7} Pa) or lower pressure, the specimen is positioned using a microscope or TV camera and the X-ray source is turned on. The ranges of electron energies to be observed are computer-controlled with the retardation lens on the spectrometer. First, a wide scan is made in which the energies of all emitted electrons over a 1000 eV range are detected (Fig. 1.2.4.8). Then, narrow scans are made in which each of the elements detected in the wide scan is examined in higher resolution (Fig. 1.2.4.9).

From the wide scan, we learn that the specimen contains carbon, oxygen, nitrogen, and sulfur. The presence of sulfur and nitrogen is unexpected for PMMA. We can calculate the atomic % composition from the wide scan spectral data. The sample surface contains 58.2% carbon, 27.7% oxygen, 9.5% nitrogen, and 4.5% sulfur. The narrow scan for the carbon region (C1s spectrum) suggests four classes of compounds: hydrocarbons, carbons singly bonded to oxygen



• **Figure 1.2.4.8** ESCA wide scan of a surface-modified poly(methyl methacrylate) ophthalmologic device.



• **Figure 1.2.4.9** The carbon 1s narrow scan ESCA spectrum of a surface-modified poly(methyl methacrylate) ophthalmologic device. Narrow scan spectra can be generated for each element seen in low energy resolution mode in Fig. 1.2.4.8.

TABLE 1.2.4.5 Analytical Capabilities of SIMS

	Static SIMS	Dynamic SIMS
Identify hydrogen and deuterium	✔	✔
Identify other elements (often must be inferred from the data)	✔	✔
Suggest molecular structures (inferred from the data)	✔	
Observe extremely high-mass fragments (proteins, polymers)	✔	
Detection of extremely low concentrations	✔	✔
Depth profile to 1 μm into the sample	[a]	✔
Observe the outermost 1–2 atomic layers	✔	
High spatial resolution (features as small as approximately 400Å)	✔	✔
Semiquantitative analysis (for limited sets of specimens)	✔	✔
Useful for polymers	✔	[a]
Useful for inorganics (metals, ceramics, etc.)	✔	✔
Useful for powders, films, fibers, etc.	✔	✔

[a]Cluster ion sources allow depth profiling with static-SIMS-like information content.

(the predominant species), carbons in amide-like molecular environments, and carbons in carboxylic acid or ester environments. This is quite different from the spectrum expected for pure PMMA. An examination of the peak position in the narrow scan of the sulfur region (S2p spectrum) suggests sulfonate-type groups. The shape of the C1s spectrum, the position of the sulfur peak, and the presence of nitrogen all suggest that heparin was immobilized to the surface of the PMMA device. Since the stoichiometry of the lens surface does not match that for pure heparin, this suggests that we are seeing either some of the PMMA substrate through a <100Å layer of heparin, or we are seeing some of the bonding links used to immobilize the heparin to the lens surface. Further analysis with ESCA and other surface analysis techniques will permit the extraction of more detail about this surface-modified device, including an estimate of surface modification thickness, further confirmation that the coating is indeed heparin, and additional information about the nature of the immobilization chemistry.

Secondary Ion Mass Spectrometry

Secondary ion mass spectrometry (SIMS) is an information-rich tool that the surface analyst can bring to bear on a biomedical problem. SIMS, in the static mode, produces a mass spectrum of the outermost 1–2 nm of a surface. Like ESCA, it requires complex instrumentation and an ultra-high vacuum chamber for the analysis. However, it provides unique information that is complementary to ESCA and greatly aids in understanding surface composition. Some of the analytical capabilities of SIMS are summarized in Table 1.2.4.5. Review articles on SIMS are available (Ratner, 1988; Scheutzle et al., 1984; Briggs, 1986; Davies and Lynn, 1990; Vickerman et al., 1989; Benninghoven, 1983; Van Vaeck et al., 1999; Belu et al., 2003; Michel and Castner, 2006; Bich et al., 2015; Fletcher and Vickerman, 2013; Fletcher, 2015, Nunez et al., 2018).

In SIMS analysis, a surface is bombarded with a beam of accelerated ions. The collision of these ions with the atoms and molecules in the surface zone can transfer enough energy that they sputter from the surface into the vacuum phase. The process is analogous to racked pool balls that are ejected from the ball cluster by the impact of the cue ball; the harder the cue ball hits the rack of balls, the more balls are emitted from the rack. In SIMS, the "cue balls" are positive ions (cesium, gallium, bismuth, C60-buckyballs, and cluster ions are commonly used) that are accelerated at the surface to be analyzed with energies of 5000–20,000 eV.

The particles ejected from the surface are positive and negative ions (secondary ions), radicals, excited states, and neutrals. Only the secondary ions are measured in SIMS. In ESCA, the energy of emitted particles (electrons) is measured. SIMS measures the mass of emitted ions (more rigorously, the ratio of mass to charge, m/z) using a time-of-flight (TOF) mass analyzer, magnetic sector analyzer or, in older instruments, a quadrupole mass analyzer.

Historically SIMS analysis has been divided into two modes, dynamic and static. Dynamic SIMS uses high ion doses over a given analysis time. The primary ion beam sputters sufficient material from the surface that the surface erodes away at an appreciable rate. We can capitalize on this to depth-profile into a specimen, and this works particularly well for metallic, semiconductor, and ceramic materials. The intensity of the m/z peak of a species of interest (e.g., sodium ion, m/z = 23) might be followed as a function of time. If the ion beam is well controlled and the sputtering rate is constant, the sodium ion signal intensity measured at any time will be directly related to its concentration at the erosion depth of the ion beam into the specimen. A concentration depth profile (sodium concentration vs. depth) can be constructed from the outermost atoms to a micron or more into the specimen. Depending on the primary ion used, for example, cesium or gallium, and its energy, the high-flux ion beam can destroy organic samples and relevant organic fragments and predominantly atomic fragments (e.g., C^-, CH^-, O^-, OH^-, Na^+, etc.) will be detected. Also, as the beam erodes deeper into the specimen, more artifacts are introduced in the data by "knock-in" and scrambling of atoms. However, by using methods like isotope labeling, techniques such as nanoSIMS that fall into the dynamic SIMS category can provide 3D imaging of biological samples (Nunez et al., 2018; Steinhauser et al., 2012).

Static SIMS, in contrast, induces minimal surface destruction. The ion dose is adjusted so that during the period of the analysis less than 10% of one monolayer of surface atoms is sputtered. Since there are typically 10^{13}– 10^{15} atoms in 1 cm^2 of surface, a total ion dose of less than 10^{12} ions/cm^2 during the analysis period is appropriate. Under these conditions, extensive degradation and rearrangement of the chemistry at the surface does not take place, and large, relatively intact molecular fragments can be ejected into the vacuum for measurement. Examples of molecular fragments are shown in Fig. 1.2.4.10. This figure also introduces some of the ideas behind SIMS spectral interpretation. A more complete introduction to the concepts behind static SIMS spectral interpretation can be found in Van Vaeck et al. (1999) or in standard texts on mass spectrometry.

Static SIMS provides qualitative information on the atomic and molecular composition in the outermost 1–2 nm of surface with high analytical sensitivity and excellent x,y spatial resolution.

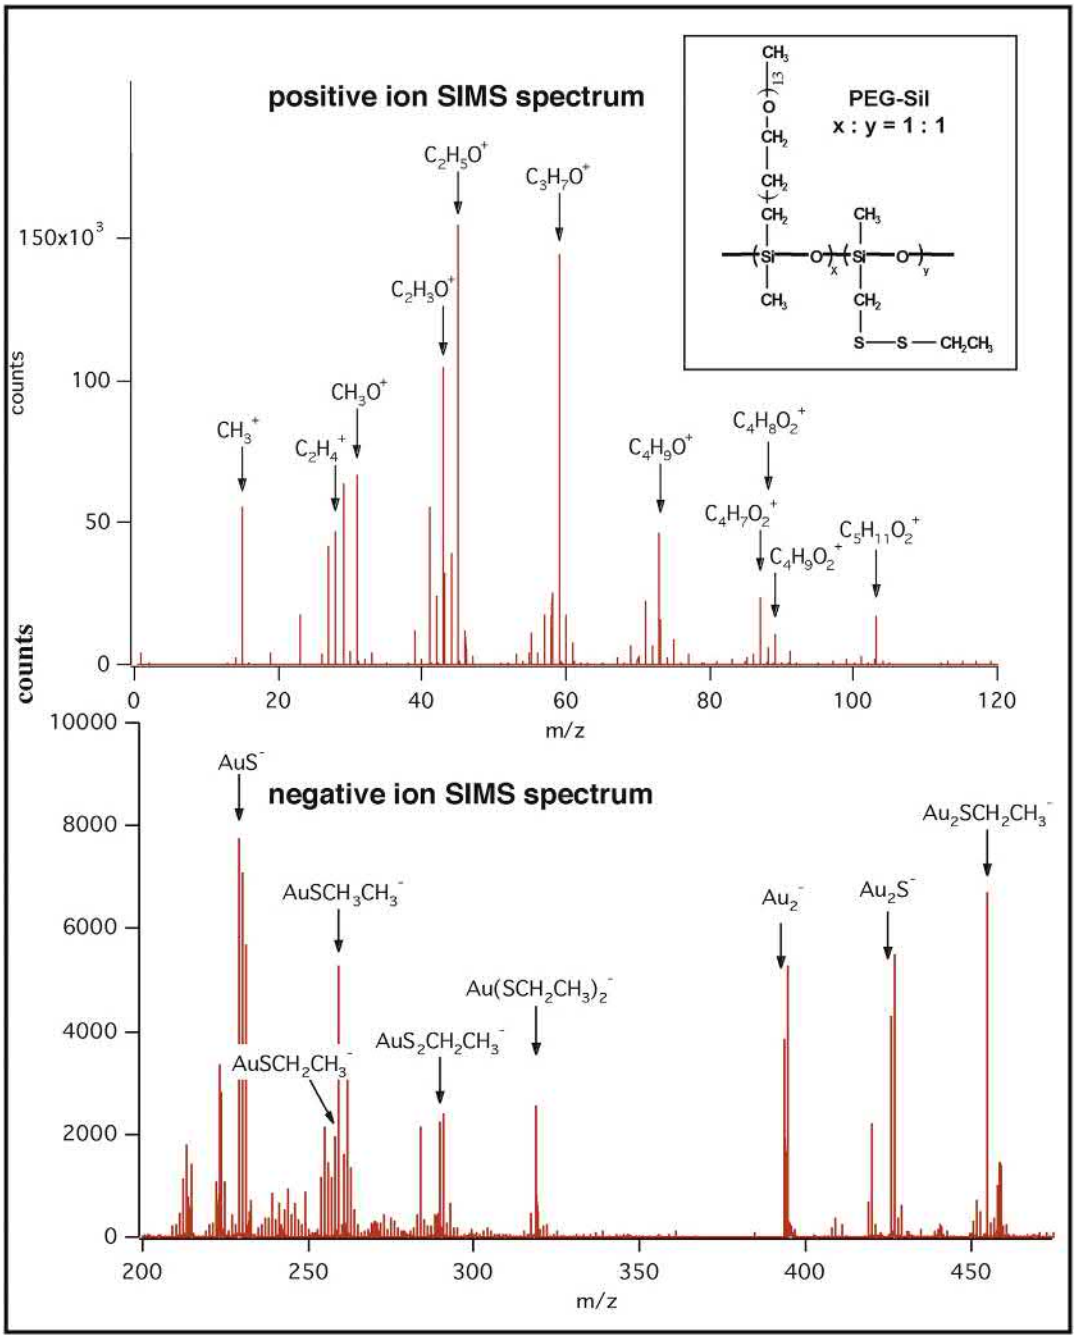
Magnetically or electrostatically focusing the primary ion beam permits the SIMS technique to have high spatial resolution in the x,y plane. In fact, SIMS analysis can be performed in surface regions of 10 nm diameter on optimal specimens. For static SIMS analysis, only 1%–10% of the atoms in any area are sampled. Thus, as the spot size gets smaller, the challenge to achieve high analytical sensitivity increases sharply. Still, static SIMS measurements have been performed in areas as small as 40 nm. Newly developed cluster ion sources (for example, using Bi_3, C_{60}, or large gas clusters as the impacting primary particles) show high secondary ion yields and relatively low surface damage. These improve spatial resolution and also permit depth profiling of organic surfaces by sputtering down into a surface while monitoring secondary ion emission as a function of time (Ninomiya et al., 2009; Brison et al., 2010; Winograd, 2005). Thus, the advent of ion beams such as C_{60} and large Ar clusters for etching has blurred the difference between static and dynamic SIMS.

If the focused primary ion beam is rastered over the surface, and the x,y position of the beam correlated with the signal emitted from a given spot, the SIMS data can be converted into an elemental image. Patterning and spatial control of chemistry is becoming increasingly important in biomaterials surface design. For example, microcontact printing allows patterned chemistry to be transferred to surfaces at the micron level using a relatively simple rubber stamp. Imaging SIMS is well suited to studying and monitoring such spatially defined chemistry (Dubey et al., 2009; Bolles et al., 2010). An example is presented in Fig. 1.2.4.11. Imaging SIMS is also valuable for observing defects in thin films (pinholes), analyzing the chemistry of fine particulates, or assessing causes of implant failure. SIMS instrumentation continues to rapidly evolve. New cluster ion beams are being developed to further enhance the yield of secondary ions (Winograd, 2018; Sheraz et al., 2015). Recently MS/MS capabilities have been added to ToF-SIMS instruments to aid in the identification of high mass species in biological samples. Also, the importance of acquiring images at both high mass resolution and high spatial resolution has been demonstrated (Brison et al., 2013). Now modern instruments can acquire images in the high spatial and mass resolution modes with the option for MS/MS analysis (Passerelli et al., 2017; Fisher et al., 2016; Hill et al., 2011).

Scanning Electron Microscopy

Scanning electron microscopy (SEM) images of surfaces have great resolution and depth of field, with a three-dimensional quality that offers a visual perspective familiar to most users. SEM images are widely used and much has been written about the technique. The comments here are primarily oriented toward SEM as a surface analysis tool.

SEM functions by focusing and rastering a relatively high-energy electron beam (typically, 5–100 keV) on a specimen that is under vacuum. Low-energy secondary electrons (1–20 eV) are emitted from each spot where the focused electron beam impacts. The intensity of the secondary electron emission is a function of the atomic composition of the

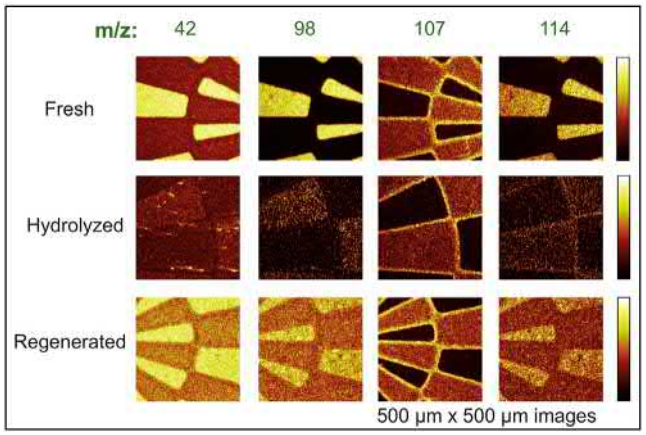


• **Figure 1.2.4.10** Static positive and negative ion SIMS spectra of a poly(ethylene glycol)–poly(dimethyl siloxane) copolymer containing disulfide side groups on a gold surface. The primary peaks are identified. The low mass region of the negative ion spectrum offers little insight into the polymer structure but the high mass region is rich in information. In this case, the low mass positive spectrum is rich in information. (Further details on this class of polymers can be found in Xia, N., Hu, Y., Grainger, D.W., Castner, D.G., 2002. Functionalized poly(ethylene glycol)-grafted polysiloxane monolayers for control of protein binding, Langmuir, 18, 3255–3262).

sample and the geometry of the features under observation. The image of the surface is spatially reconstructed on a phosphor screen (or CCD detector) from the intensity of the secondary electron emission at each point. Because of the shallow penetration depth of low-energy electrons produced by the primary electron beam, only the secondary electrons generated near the surface can escape and be detected (this is analogous to the surface sensitivity described in Fig. 1.2.4.7). Consequently, SEM is a surface analysis method.

SEM provides a high-resolution image of the surface. On insulating materials, a metallic coating is required and the image is actually of the coating surface, not the underlying material.

Nonconductive materials observed in the SEM are typically coated with a thin, electrically grounded layer of metal to minimize negative charge accumulation from the electron beam. However, this metal layer is always sufficiently



• **Figure 1.2.4.11** Negative ToF-SIMS ion images exploring the N-hydroxysuccinimide (NHS) reaction used to immobilize biomolecules to surfaces. Yellow colors show regions rich in NHS groups based on peaks at m/z 42, 98, 107, and 114. The image shows a spatially defined sample with freshly prepared, hydrolyzed, and regenerated photopatterned surfaces. (Further details are in Dubey, M., Emoto, K., Cheng, F., Gamble, L.J., Takahashi, H., Grainger, D.W., Castner, D.G., 2009. Surface analysis of photolithographic patterns using ToF-SIMS and PCA. Surf. Interface Anal. 41 (8), 645–652 (used with permission of the publisher)).

thick (>200Å) that the electrons emitted from the sample beneath cannot penetrate. Therefore, in SEM analysis of nonconductors, the surface of the metal coating is, in effect, what is being monitored. If the metal coat is truly conformal, a good representation of the surface geometry will be conveyed. However, the specimen surface chemistry no longer influences secondary electron emission. Also, at very high magnifications, the texture of the metal coat and not the surface may be under observation.

SEM, in spite of these limitations, is an important corroborative method to use in conjunction with other surface analysis methods. Surface roughness and texture can have a profound influence on data from ESCA, SIMS, and contact angle determinations. Therefore, SEM provides important information in the interpretation of data from these methods.

The development of low-voltage SEM does study the surface chemistry (and geometry) of nonconductors. With the electron-accelerating voltage lowered to approximately 1 keV, charge accumulation is not as critical and metallization is not required. Low-voltage SEM has been used to study platelets and phase separation in polymers. Also, the environmental SEM (ESEM) permits wet, uncoated specimens to be studied.

The primary electron beam also stimulates the emission of X-rays. These X-rays are used to identify elements with the technique called energy-dispersive X-ray analysis (EDXA). However, the high-energy primary electron beam penetrates deeply into a specimen (a micron or more). The X-rays produced from the interaction of these electrons with atoms deep in the bulk of the specimen can penetrate through the material and be detected. Therefore, EDXA is not a surface analysis method.

The primary use of SEM is to image topography. SEM for this application is elaborated upon in the chapter on microscopy in biomaterials research (Chapter 2.3.8 in the previous edition).

Infrared Spectroscopy

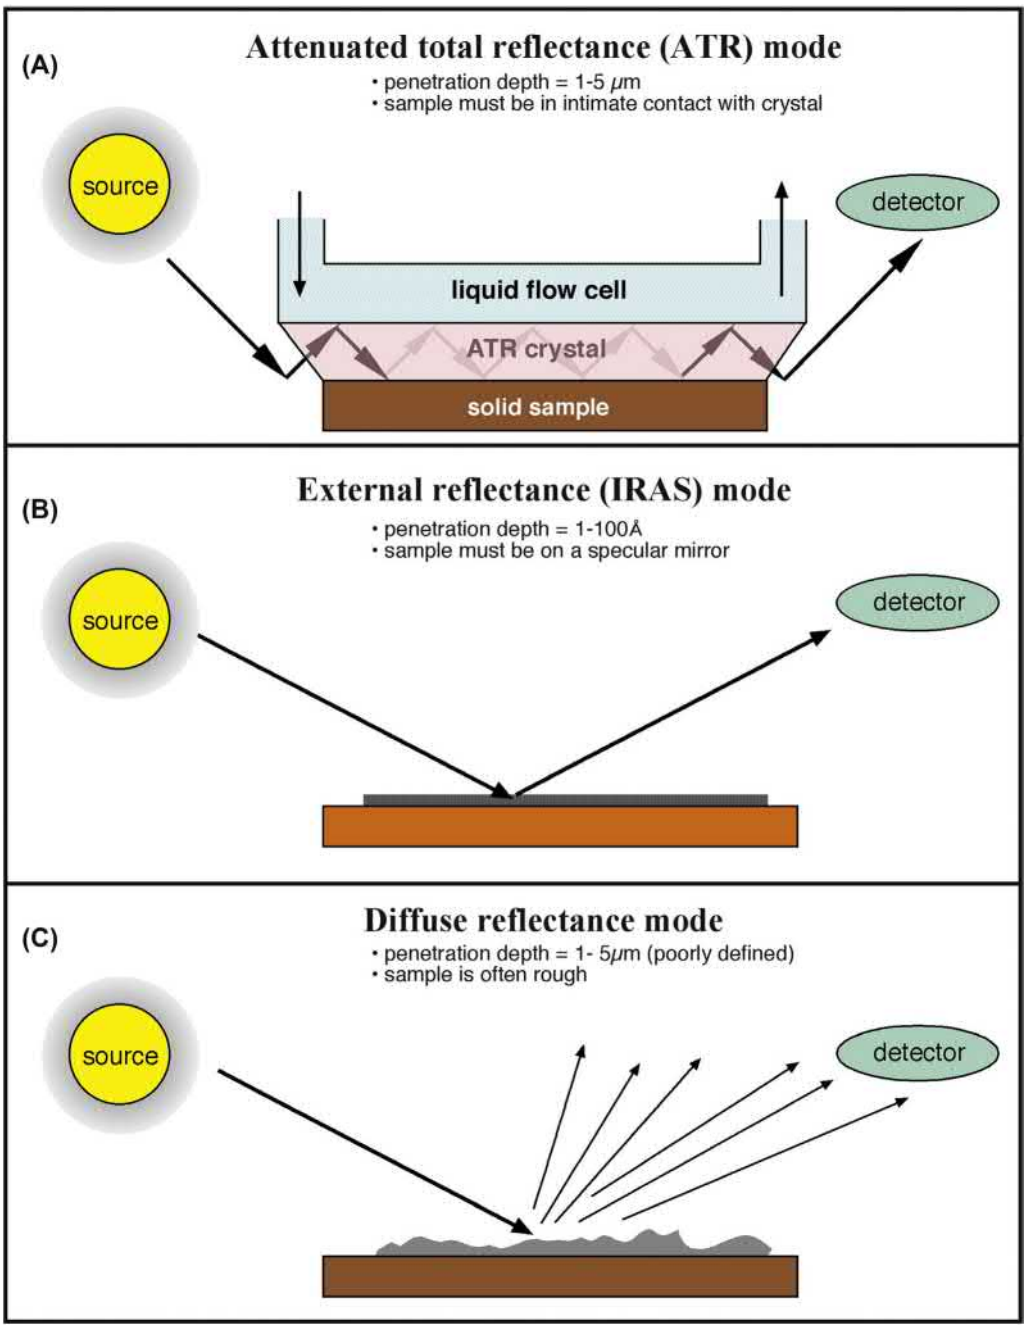
Infrared spectroscopy provides information on the bond vibrations of molecular species. It is a widely used analytical method that can reveal information on specific chemistries and the orientation of structures. Fourier transform infrared (FTIR) spectrometry offers outstanding signal-to-noise ratio (S/N) and spectral accuracy. However, even with this high S/N, the small absorption signal associated with the minute mass of material in a surface region can challenge the sensitivity of the spectrometer. Also, the problem of separating the vastly larger bulk absorption signal from the surface signal must be addressed.

Surface FTIR methods couple the infrared radiation to the sample surface to increase the intensity of the surface signal and reduce the bulk signal (Allara, 1982; Layden and Murthy, 1987; Urban, 1993; Dumas et al., 1999). Some of these sampling modes, and their characteristics, are illustrated in Fig. 1.2.4.12.

The attenuated total reflectance (ATR) mode of sampling has been used most often in biomaterials studies. The penetration depth into the sample is 1–5 µm. Therefore, ATR is not highly surface sensitive, but observes a broad region near the surface. However, it does offer the wealth of rich structural information common to infrared spectra. With extremely high S/N FTIR instruments, ATR studies of proteins and polymers adsorbed from aqueous solutions have been performed. In these experiments, the water signal (which is typically 99% or more of the total signal) is subtracted from the spectrum to leave only the surface material (e.g., adsorbed protein) under observation. Micro-ATR, coupling a microscope, IR spectrometer, and micro-ATR crystal, permits ATR analysis with high spatial resolution (approximately 1 μm^2 pixel size).

ATR-IR permits detailed molecular analysis of the outermost 1–5 microns of a sample.

Another infrared method that has proven immensely valuable for observing extremely thin films on reflective surfaces is infrared reflection absorption spectroscopy (IRAS) (Fig. 1.2.4.12). This method has been widely applied to self-assembled monolayers (SAMs), but is applicable to many surface films that are less than 10 nm thickness. The surface upon which the thin film resides must be highly reflective and metal surfaces work best though a silicon wafer can be used. IRAS gives information about composition, crystallinity, and molecular orientation. Infrared spectroscopy is one member of a family of methods called vibrational spectroscopies. Two other vibrational spectroscopies, sum frequency generation and Raman (in particular, surface enhanced), will be mentioned below in the section on newer methods.

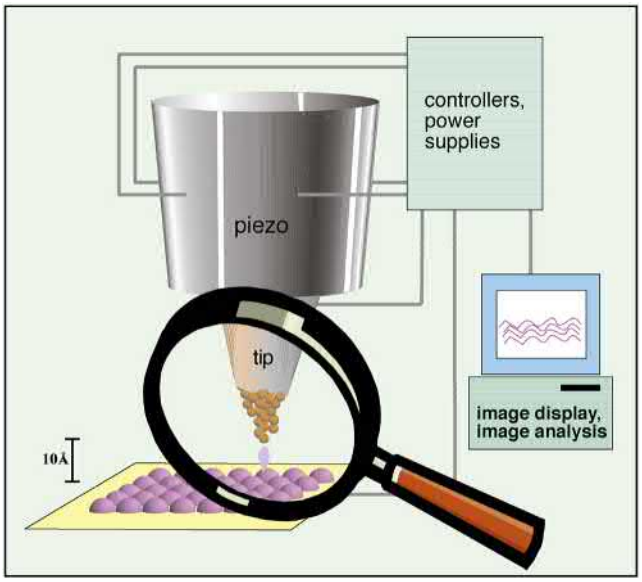


• **Figure 1.2.4.12** Three surface-sensitive infrared sampling modes: (A) attenuated total reflectance infrared (ATR-IR); (B) infrared reflection absorption spectroscopy (IRAS); (C) diffuse reflectance infrared spectroscopy.

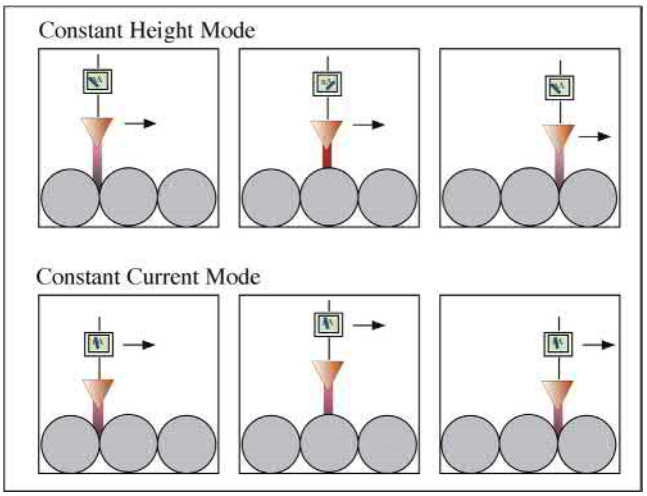
Scanning Tunneling Microscopy (STM), Atomic Force Microscopy (AFM), and the Scanning Probe Microscopies (SPMs)

Since the first edition of this book was published in 1996, scanning tunneling microscopy (STM) and atomic force microscopy (AFM) have devolved from novel research tools to key methods for biomaterials characterization. AFM is more widely used than STM because electrically conductive surfaces are not needed with AFM and quantitative force measurements can be made. General review articles are available (Binnig and Rohrer, 1986; Avouris, 1990; Albrecht et al., 1988) and articles oriented toward biological studies with these methods (Hansma et al., 1988; Miles et al., 1990; Rugar and Hansma, 1990; Jandt, 2001; Dufrene, 2004; Jelinek, 2017; Gross et al., 2018).

The STM was invented in 1981 and led to a Nobel Prize for G. Binnig and H. Rohrer in 1986. The STM capitalizes on quantum tunneling to generate an atom-scale, electron density image of a surface. A metal tip terminating in a single atom is brought within 5–10 Å of an electrically conducting surface. At these distances, the electron cloud of



• **Figure 1.2.4.13** Schematic diagram illustrating the principle of the scanning tunneling microscope—a tip terminating in a single atom permits localized quantum tunneling current from surface features (or atoms) to tip. This tunneling current can be spatially reconstructed to form an image.



• **Figure 1.2.4.14** Scanning tunneling microscopy can be performed in two modes. In constant height mode, the tip is scanned a constant distance from the surface (typically 5–10Å) and the change in tunneling current is recorded. In constant current mode, the tip height is adjusted so that the tunneling current is always constant, and the tip distance from the surface is recorded as a function of distance traveled in the plane of the surface.

the atom at the "tip of the tip" will significantly overlap the electron cloud of an atom on the surface. If a potential is applied between the tip and the surface, an electron tunneling current will be established whose magnitude, J, follows the proportionality:

$$J \propto e^{(-AK_0S)}$$

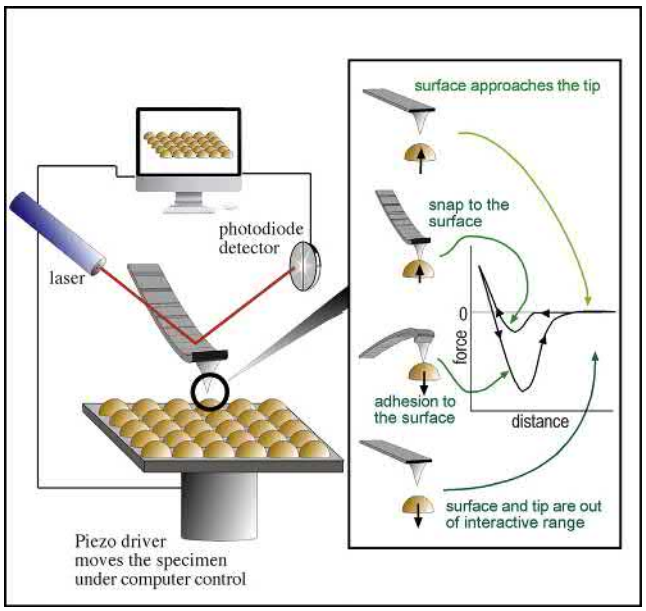
where A is a constant, K_0 is an average inverse decay length (related to the electron affinity of the metals), and S is the separation distance in angstrom units. For most metals, a 1Å change in the distance of the tip to the surface results in an order of magnitude change in tunneling current. Even though this current is small, it can be measured with good accuracy.

To image a surface, this quantum tunneling current is used in one of two ways. In constant current mode, a piezoelectric driver scans a tip over a surface. When the tip approaches an atom protruding above the plane of the surface, the current rapidly increases, and a feedback circuit moves the tip up to keep the current constant. Then, a plot is made of the tip height required to maintain constant current versus distance along the plane. In constant height mode, the tip is moved over the surface and the change in current with distance traveled along the plane of the surface is directly recorded. A schematic diagram of a scanning tunneling microscope is presented in Fig. 1.2.4.13. Two STM scanning modes are illustrated in Fig. 1.2.4.14.

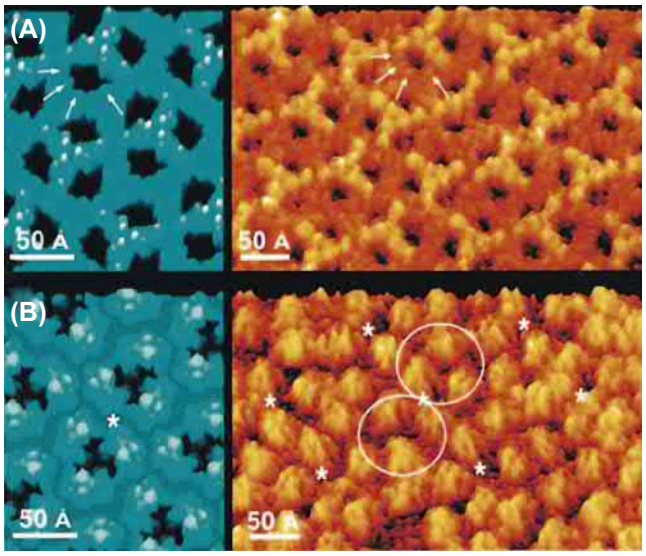
The STM measures electrical current and therefore is well suited for conductive and semiconductor surfaces. However, biomolecules (even proteins) on conductive substrates appear amenable to imaging. STM does not "see" atoms, but rather monitors electron density. The conductive and imaging mechanism for proteins is not well understood. Still, publications suggest that information-rich images of biomolecules on conductive surfaces can be obtained (Campbell et al., 2007).

The AFM uses a similar piezo drive mechanism. However, instead of recording tunneling current, the deflection of a tip mounted on a flexible cantilever arm due to van der Waals forces and electrostatic repulsion/attraction between an atom at the tip and an atom on the surface is measured. Atomic-dimension measurements of cantilever arm movements can be made by reflecting a laser beam off a mirror on the cantilever arm (an optical lever). A one-atom deflection of the cantilever arm can easily be measured by monitoring the position of the laser reflection on a spatially resolved photosensitive detector. Other principles are also used to measure the deflection of the tip. These include capacitance measurements and interferometry. A diagram of a typical AFM is presented in Fig. 1.2.4.15. Images of protein molecules recorded by AFM are shown in Fig. 1.2.4.16 to demonstrate the subnanometer resolution possible on biological specimens.

Tips are important in AFM as the spatial resolution is significantly associated with tip terminal diameter and shape. Tips are made from microlithographically fabricated silicon or silicon nitride. Also carbon whiskers, nanotubes, and a variety of nanospherical particles have been mounted on AFM tips to increase their sharpness or improve the ability to precisely define tip geometry. Tips are also surface-modified to alter the strength and types of interactions with surfaces (static SIMS can be used to image these surface modifications). Finally, cantilevers are sold in a range of stiffnesses so the analysis modes can be tuned to the needs of the sample and the type of data being acquired. The forces associated with the interaction of an AFM tip with a surface as it approaches and is retracted are illustrated in Fig. 1.2.4.15.



• **Figure 1.2.4.15** Schematic diagram illustrating the principle of the atomic force microscope.



• **Figure 1.2.4.16** An AFM image of porin proteins from the outer membrane of *E. coli* imaged with nano-scale resolution. Comparison of high-resolution AFM images of OmpF crystals (in brown-yellow) and the atomic model rendered at 3Å (in blue). (From Müller, D.J., Engel, A., 1999. J. Mol. Biol. 285, 1347, used with permission of the authors and publisher).

Since force is being measured and Hooke's law applies to the deformation of an elastic cantilever, AFM can be used to quantify the forces between surface and tip. Quantitative AFM is now widely used to measure the strength of interaction between biomolecules (Chilkoti et al., 1995; Muller and Dufrêne, 2008) and the mechanical properties of proteins (Li and Cao, 2010).

AFM instruments are commonly applied to surface problems using many possible tip interaction modes. Some AFM modes are contact, lateral force, noncontact, tapping, force modulation, and phase imaging. In contact mode, the tip is in contact with the surface (or at least the electron clouds of tip and surface essentially overlap). The pressures resulting from the force of the cantilever delivered through the extremely small surface area of the tip can be damaging to soft specimens (proteins, polymers, etc.). However, for more rigid specimens, excellent topographical imaging can be achieved in contact mode. In tapping mode, the tip is oscillated at a frequency near the resonant frequency of the cantilever. The tip barely taps the surface. The force interaction of tip and surface can affect the amplitude of oscillation and the oscillating frequency of the tip. In standard tapping mode, the amplitude change is translated into topographic spatial information. Many variants of tapping mode have been developed, allowing imaging under different conditions and using the phase shift between the applied oscillation to the tip and the actual tip oscillation in the force field of the surface to provide information of the mechanical properties of the surface (in essence, the viscoelasticity of the surface can be assessed).

AFM allows imaging of surfaces at subnanometer resolutions and also proves detail on surface mechanics and molecular interactions.

The potential of the AFM to explore surface problems has been greatly expanded by ingenious variants of the technique. In fact, the term "atomic force microscopy" has been generalized to "scanning probe microscopy (SPM)." Table 1.2.4.6 lists many of these creative applications of the AFM/STM idea. Two of the more recently developed variants are photoinduced force microscopy (PiFM) and high-speed AFM imaging (Nowak et al., 2016; Dufrene et al., 2017).

Since the AFM measures force, it can be used with both conductive and nonconductive specimens. Force must be applied to bend a cantilever, so AFM is subject to artifacts caused by damage to fragile structures on the surface. Both AFM and STM can function well for specimens under water, in air, or under vacuum. For exploring biomolecules or mobile organic surfaces, the "pushing around" of structures by the tip is a significant concern. This surface artifact can be capitalized upon to write and fabricate surface structures at the nanometer scale (Fig. 1.2.4.17) (Boland et al., 1998; Quate, 1997; Wilson et al., 2001; Rosa and Liang, 2009).

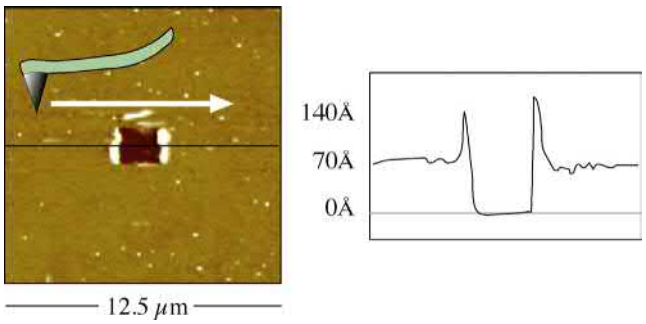
Newer Methods

There are many other surface characterization methods that have the potential to become important in future years. Some of these are listed in Table 1.2.4.7. A few of these evolving techniques that will be specifically mentioned here include nonlinear optical, Raman, and synchrotron methods.

A variety of different nonlinear optical methods have been developed to investigate biological materials (Johansson et al., 2018). Of particular interest is sum frequency generation (SFG) vibration spectroscopy, a method that looks at the outmost surface of materials in aqueous, air, or vacuum. SFG uses two high-intensity, pulsed laser beams,

TABLE 1.2.4.6 Scanning Probe Microscopy (SPM) Modes

Name	Acronym	Use
Contact mode	CM-AFM	Topographic imaging of harder specimens
Tapping (intermittent force) mode	IF-AFM	Imaging softer specimens
Noncontact mode	NCM-AFM	Imaging soft structures
Force modulation (allows slope of force–distance curve to be measured)	FM-AFM	Enhances image contrast based on surface mechanics
Scanning surface potential microscopy (Kelvin probe microscopy)	SSPM, KPM	Measures the spatial distribution of surface potential
Magnetic force microscopy	MFM	Maps the surface magnetic forces
Scanning thermal microcopy	SThM	Maps the thermal conductivity characteristics of a surface
Recognition force microscopy	RFM	Uses a biomolecule on a tip to probe for regions of specific biorecognition on a surface
Chemical force microscopy	CFM	A tip derivatized with a given chemistry is scanned on a surface to spatially measure differences of interaction strength
Lateral force microscopy	LFM	Maps frictional force on a surface
Electrochemical force microscopy	EFM	The tip is scanned under water and the electrochemical potential between tip and surface is spatially measured
Nearfield scanning optical microscopy	NSOM	A sharp optical fiber is scanned over a surface allowing optical microscopy or spectroscopy at 100 nm resolution
Electrostatic force microscopy	EFM	Surface electrostatic potential is mapped
Scanning capacitance microscopy	SCM	Surface capacitance is mapped
Conductive atomic force microscopy	CAFM	Surface conductivity is mapped with an AFM instrument
Nanolithographic AFM		An AFM tip etches, oxidizes, or reacts a space permitting pattern fabrication at the 10 nm or better resolution
Dip-pen nanolithography	DPN	An AFM tip, inked with a thiol or other molecule, writes on a surface at the nanometer scale
Photoinduced force microscopy	PiFM	PiFM measures the photoinduced polarizability of a sample by imaging the force between the tip and the sample at multiple IR wavelengths

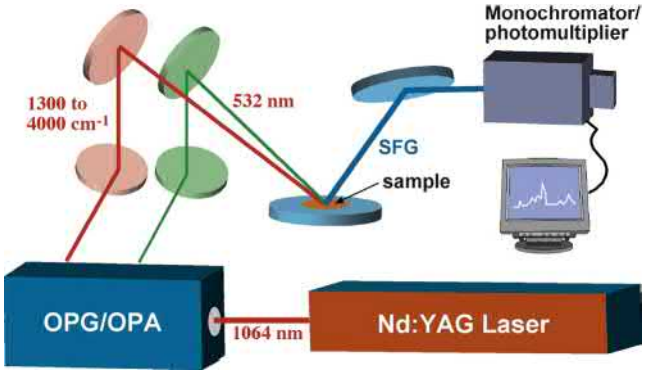


• **Figure 1.2.4.17** An AFM tip, using relatively high force, was used to scratch a rectangular feature into a thin (70Å) plasma-deposited film. The AFM also characterized the feature created.

one in the visible range (frequency = $\omega_{visible}$) and one in the infrared (frequency = ω_{ir}), to illuminate a specimen. The light emitted from the specimen by a nonlinear optical process, $\omega_{sum} = \omega_{visible} + \omega_{ir}$, is detected and quantified (Fig. 1.2.4.18). The intensity of the light at ω_{sum} is proportional to the square of the sample's second-order nonlinear susceptibility ($\chi^{(2)}$). The term susceptibility refers to the effect of the light field strength in polarizing molecules (molecular polarizability). The ω_{sum} light intensity vanishes where a material has inversion symmetry, e.g., in the bulk of a crystalline material or in a disordered liquid solution. At an interface, the inversion symmetry is broken and an SFG signal is generated. Thus, SFG is exquisitely sensitive to the plane of the interface. To generate an SFG spectrum with pico-second lasers ω_{ir} is scanned over a vibrational frequency range. To generate an SFG spectrum with femto-second lasers broadband regions (each ~100 to 200 cm^{-1} in width) are stitched together. This leads to vibrational absorptions that occur with only interface molecules. For this case, the SFG signal is resonantly enhanced and we see a vibrational spectrum. The advantages of SFG are the superb surface sensitivity, the cancellation of bulk spectral intensity (for example, this allows measurements at a water/solid interface), the richness of information from vibrational spectra and the ability to study molecular orientation

TABLE 1.2.4.7 Additional Methods for the Surface Characterization of Biomaterials

Method	Information Obtained
Second-harmonic generation (SHG)	Detect submonolayer amounts of adsorbate at any light-accessible interface (air–liquid, solid–liquid, solid–gas)
Sum frequency generation (SFG) vibrational spectroscopy	Provides structure, orientation and ordering information about molecules at air–liquid, solid–liquid, and solid–gas interfaces
Surface-enhanced raman spectroscopy (SERS)	High-sensitivity Raman at rough metal interfaces
Ion scattering spectroscopy (ISS)	Elastically reflected ions probe only the outermost atomic layer
Laser desorption mass spectrometry (LDMS)	Mass spectra of adsorbates at surfaces
Matrix-assisted laser desorption ionization (MALDI)	Though generally a bulk mass spectrometry method, MALDI has been used to analyze large adsorbed proteins
IR photoacoustic spectroscopy (IR-PAS)	IR spectra of surfaces with no sample preparation based on wavelength-dependent thermal response
High-resolution electron energy loss spectroscopy (HREELS)	Vibrational spectroscopy of a highly surface-localized region, under ultrahigh vacuum
X-ray reflection	Structural information about order at surfaces and interfaces
Neutron reflection	Thickness and refractive index information about interfaces from scattered neutrons—where H and D are used, unique information on interface organization can be obtained
Extended X-ray absorption fine structure (EXAFS)	A synchrotron method providing atomic-level chemical and nearest-neighbor (morphological) information
Near-edge X-ray absorption fine structure (NEXAFS)	A synchrotron method providing information about bonding environments and chain orientation
Quartz Crystal microbalance with dissipation (QCM-D)	An oscillating quartz crystal provides information about the amount and viscoelastic properties of molecules interacting with a surface
Scanning auger microprobe (SAM)	Spatially defined auger analysis at the nanometer scale
Surface plasmon resonance (SPR)	Study aqueous adsorption events in real time by monitoring changes in surface refractive index
Rutherford backscattering spectroscopy (RBS)	Depth profiling of complex, multiplayer interfacial systems

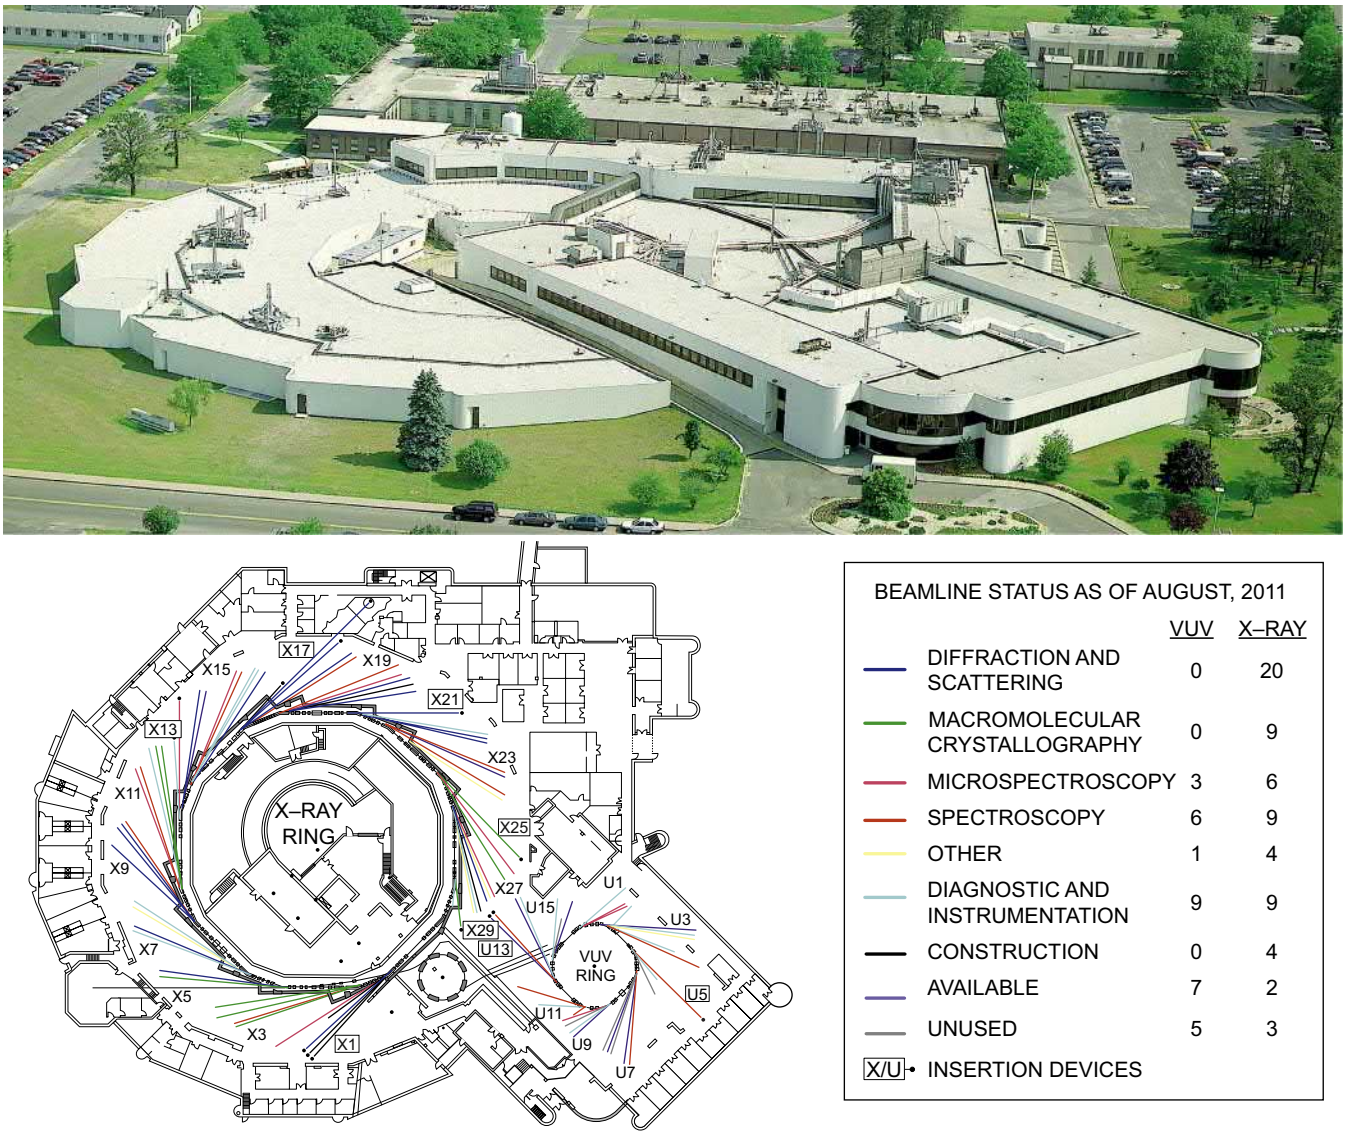


• **Figure 1.2.4.18** Schematic diagram of a sum frequency generation (SFG) apparatus. (Based upon a diagram by Polymer Technology Group, Inc).

by polarization of the laser light. SFG is not yet a routine method. The lasers and optical components are expensive and require precision alignment. However, the power of SFG for biomaterials studies has already been proven with studies on hydrated hydrogels, polyurethanes, surface-active polymer additives, proteins, and nonfouling surfaces (Shen, 1989; Chen et al., 2002; Stein et al., 2009; Johansson et al., 2018).

SFG is among the most surface-sensitive of all surface methods. It provides vibrational spectroscopic detail on surface composition, orientation, and interactions.

In Raman spectroscopy a bright light is focused on a specimen. Most of the light scatters back at the same frequency as the incident beam. However, a tiny fraction of this light excites vibrations in the specimen and thereby loses or gains energy. The frequency shift of the light corresponds to vibrational bands indicative of the molecular structure of the specimen. The Raman spectroscopic technique has been severely limited for surface studies due to its low signal level. However, in recent years, great strides in detector sensitivity have allowed Raman to be applied for studying the minute mass of material at a surface. Also, surface-enhanced Raman spectroscopy (SERS), Raman spectra taken from molecules on a roughened metal surface, can enhance Raman signal intensity by 10^6 or more. Raman spectra will be valuable



• **Figure 1.2.4.19** The National synchrotron light Source, Brookhaven National Laboratories. (Images courtesy of Brookhaven National Laboratory).

for biomedical surface studies because water, which absorbs radiation very strongly in the infrared range, has little effect on Raman spectra that are often acquired with visible light (Storey et al., 1995; Smith, 2008; Henry et al., 2017).

Synchrotron sources generate energetic radiation that can be used to probe matter. Such sources were originally confined to the physics community and devoted to fundamental studies. However, there are now many synchrotron sources offering access to researchers in all communities, better instrumentation, and improved data interpretation. Synchrotron sources are typically national facilities costing >$100M and often occupying hundreds of acres (Fig. 1.2.4.19). By accelerating electrons to near the speed of light in a large, circular ring, energies covering a broad swath of the electromagnetic spectrum (IR to energetic X-rays) are emitted. A synchrotron source (and ancillary equipment) permits a desired energy of the probe beam to be "dialed in" or scanned through a frequency range. Other advantages include high source intensity (bright light) and polarized light. Some of the experimental methods that can be performed with great success at synchrotron sources include crystallography, scattering, spectroscopy, microimaging, and nanofabrication. Specific surface spectroscopic methods include scanning photoemission microscopy (SPEM, 100 nm spatial resolution) (Leung, 2010), ultraESCA (100 μm spatial resolution, high-energy resolution), and near-edge X-ray absorption fine structure (NEXAFS).

Studies With Surface Methods

Hundreds of studies have appeared in the literature in which surface methods have been used to enhance the understanding of biomaterial systems. A few studies that demonstrate the power of surface analytical methods for biomaterials science are briefly described here.

Platelet Consumption and Surface Composition

Using a baboon arteriovenous shunt model of platelet interaction with surfaces, a first-order rate constant of reaction of platelets with a series of polyurethanes was measured. This rate constant, the platelet consumption by the material, correlated in an inverse linear fashion with the fraction of hydrocarbon-type groups in the ESCA C1s spectra of the polyurethanes (Hanson et al., 1982). Thus, surface analysis revealed a chemical parameter about the surface that could be used to predict long-term biological reactivity of materials in a complex ex vivo environment.

Contact-Angle Correlations

The adhesion of a number of cell types, including bacteria, granulocytes, and erythrocytes, has been shown, under certain conditions, to correlate with solid–vapor surface tension as determined from contact-angle measurements. In addition, immunoglobulin G adsorption is related to γ_{sv} (Neumann et al., 1983).

Contamination of Intraocular Lenses

Commercial intraocular lenses were examined by ESCA. The presence of sulfur, sodium, and excess hydrocarbon at their surfaces suggested contamination by sodium dodecyl sulfate (SDS) during the manufacture of the lenses (Ratner, 1983). A cleaning protocol was developed using ESCA to monitor results that produced a lens surface of clean PMMA.

Titanium

The discoloration sometimes observed on titanium implants after autoclaving was examined by ESCA and SIMS (Lausmaa et al., 1985). The discoloration was found to be related to accelerated oxide growth, with oxide thicknesses to 650Å. The oxide contained considerable fluorine, along with alkali metals and silicon. The source of the oxide was the cloth used to wrap the implant storage box during autoclaving. Since fluorine strongly affects oxide growth, and since the oxide layer has been associated with the biocompatibility of titanium implants, the authors advise avoiding fluorinated materials during sterilization of samples. Another paper by this group contains detailed surface characterization of titanium using a battery of surface methods and addresses surface preparation, contamination, and cleaning (Lausmaa, 1996).

SIMS for Adsorbed Protein Identification and Quantification

All proteins are comprised of the same 21 amino acids and thus, on the average, are compositionally similar. Surface analysis methods have shown the ability to detect and quantify surface-bound protein, but biological tools have, until recently, been needed to identify specific proteins. Modern static SIMS instrumentation, using a multivariate statistical analysis of the data, has demonstrated the ability to distinguish between more than 13 different proteins adsorbed on surfaces (Wagner and Castner, 2001; Muramoto et al., 2011). Also, the limits of detection for adsorbed proteins on various surfaces were compared by ESCA and SIMS (Wagner et al., 2002).

Poly(Glycolic Acid) Degradation Studied by SIMS

The degradation of an important polymer for tissue engineering, poly(glycolic acid), has been studied by static SIMS. As well as providing useful information on this degradation process, the study illustrates the power of SIMS for characterizing synthetic polymers and their molecular weight distributions (Chen et al., 2000).

MultiTechnique Characterization of Adsorbed Peptides and Proteins

Though proteins at interfaces are critically important to biomaterials science, we have an incomplete picture of what proteins really look and behave like on surfaces. Multiple techniques are required to obtain detailed information about the structure of proteins at interfaces (Weidner and Castner, 2013). By combining a surface method, SFG, with a traditionally bulk analysis method, solid state NMR, an elegant picture of peptides on surfaces emerges. The study quantified, with site specificity and atomic resolution, the orientation and dynamics of side chains in labeled, synthetic model peptides adsorbed onto a polystyrene surface (Weidner et al., 2010). The combination of SFG, ToF-SIMS, and computational methods provided detailed information about the structure, orientation, and interactions of Protein G with a hydrophobic surface (Harrison et al., 2017).

Conclusions

The instrumentation of surface analysis steadily advances and newer instruments and techniques can provide invaluable information about biomaterials and medical devices. The information obtained can be used to monitor contamination, ensure surface reproducibility, and explore fundamental aspects of the interaction of biological systems with living systems. Considering that biomedical experiments, especially in vivo experiments, are typically expensive to perform, the costs for surface analysis are modest to ensure that the surface is as expected, stable, and identical from experiment to experiment. Surface analysis can also contribute to the understanding of medical device failure (and success). A myriad of applications for surface methods are found in device optimization, manufacture, and quality control. Predicting biological reaction based on measured surface structure is a frontier area for surface analysis.

Acknowledgments

Support was received from the UWEB21 Engineering Research Center and the NESAC/BIO National Resource, NIH grant EB-002027, during the preparation of this chapter and for some of the studies described herein.

Chapter Questions

1. Scan the table of contents and abstracts from the last three issues of *Journal of Biomedical Materials Research or Biomaterials*. List all the surface analysis methods used in the articles therein and briefly describe what was learned by using them.
2. How is critical surface tension related to wettability? For the polymers in Table 1.2.4.2, draw the chemical formulas of the chain repeat units and attempt to relate the structures to the wettability. Where inconsistencies are noted, explain those inconsistencies using Table 1.2.4.3.
3. A titanium dental implant was manufactured by the Biomatter Company for the past 8 years. It performed well clinically. For economic reasons, manufacturing of the titanium device was outsourced to Metalsmed, Inc. Early clinical results on this Metalsmed implant, supposedly identical to the Biomatter implant, suggested increased inflammation. How would you compare the surface chemistry and structure of these two devices to see if a difference that might account for the difference in clinical performance could be identified?

1.2.5

Role of Water in Biomaterials

BUDDY D. RATNER[1], **ROBERT A. LATOUR**[2]

[1]Bioengineering and Chemical Engineering, Director of University of Washington Engineered Biomaterials (UWEB), Seattle, WA, United States

[2]Bioengineering Department, Clemson University, Clemson, SC, United States

This chapter first introduces the physical and chemical properties of water, and then expands upon water's significance for biomaterials and biology. This chapter encourages you to think about how the phenomena you are reading about may be driven or controlled by the water that comprises such a large fraction of all biological systems.

> *In the world there is nothing more submissive and weak than water. Yet for attacking that which is hard and strong nothing can surpass it.*
>
> **LAO TZU.**

Water! Omnipresent, chemically inert, a simple diluent—these words come to mind and prompt the question: "why is there a section of this textbook devoted to water?" The special properties of water, this substance that is critical for life as we know it, significantly impact the "materials-centric" subject of biomaterials, and the biology closely associated with biomaterials.

As will be presented in this chapter, water is not simply a passive molecule that represents the major component of the solvent for biological systems, but instead it is a very dynamic molecule that is an important mediator of essentially all biological interactions. Water is thus a unique, remarkable substance—in this instance, the word "unique" can be used without hyperbole. Although its chemical composition was elucidated in the 1770s by Lavoisier and others, its liquid structure continues to be explored today using state-of-the-art physical characterization methods. The importance of water for life as we know it was appreciated as early as 1913 in an interesting historical volume, *The Fitness of the Environment* (Henderson, 1913; available in reprint).

This chapter will first introduce the physical and chemical properties of water. Then water's significance for biomaterials and biology will be expanded upon.

Water: The Special Molecule

The simple "H_2O" structure of the water molecule does not immediately communicate the ability of one water molecule to interact with many other water molecules, in particular to interact not too strongly, and not too weakly. This interaction, largely via the hydrogen bond, is associated with the dipole of the water molecule (slightly more negatively charged at the oxygen and positively charged at the hydrogen, i.e., partial negative and positive charges). This dipole, combined with the bent shape (bond angle of 104.6 degrees) of the molecule and its small size contributes to the special properties of liquid water. Fig. 1.2.5.1 illustrates schematically the geometry of the water molecule, and suggests some hydrogen bonding possibilities with neighboring water molecules (as well as the occasional H^+ or OH^-).

The physical properties of water are profoundly unique compared with all other substances.

The unique physical and chemical properties of water, attributable to the 104.6 degrees bond angle and the ability to form up to four hydrogen bonds per molecule despite the fact that it is made up of only three atoms, are discussed here. Note how special water is compared with other liquid and solid substances.

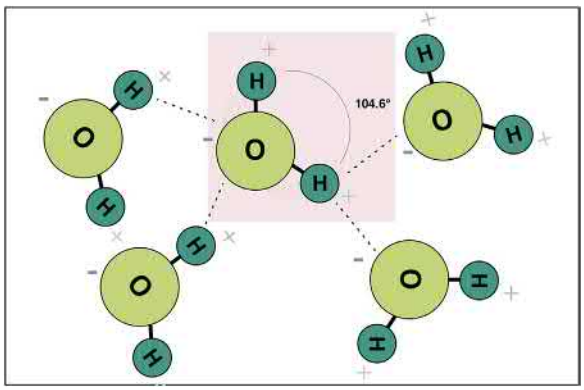
Melting Point and Boiling Point

The physical properties of H_2O that make it stand out from all other related molecules are best appreciated from the data in Table 1.2.5.1.

As the molecular weight for compounds in this series of related molecules decreases, the boiling points also decrease, until you reach water, where the boiling point is (unexpectedly) up to 160°C higher. At common temperatures and pressures on Earth, all the other compounds exist as gases, except water. A similar dramatic trend is seen in the freezing point.

Density and Surface Tension

Water has a density of 0.997 g/mL at 25°C and 1.0atm pressure. As the temperature decreases, water, like most



• **Figure 1.2.5.1** Schematic illustration of five water molecules suggesting their geometry and dipole. A hydrogen bond is represented by a dotted line. Consider the many possibilities for these electrostatic (charge) interactions.

TABLE 1.2.5.1 Boiling Point and Freezing Point of Water Contrasted to Other H_2X Compounds

H_2X Compound		Molecular Weight	Boiling Point	Freezing Point
H_2Te	Hydrogen telluride	130	–2°C	–49°C
H_2Se	Hydrogen selenide	81	–41°C	–66°C
H_2S	Hydrogen sulfide	34	–60°C	–82°C
H_2O	Water	18	100°C	0°C

substances, increases in density, until 4°C where its density is 1.00 g/mL. Then, as temperature is decreased further, an unusual phenomenon is observed. The density actually decreases as the temperature is lowered. At 0°C, the density is 0.92 g/mL. This phenomenon occurs because when water freezes, its hydrogen-bonded structure causes the molecules to crystallize in a manner such as to increase the volume of space that each water molecule occupies. Thus, ice floats on liquid water and metal pipes filled with water may burst when the water freezes. There is special significance to this. If bodies of water froze from the bottom to the top (i.e., if ice were heavier than water), during cold periods in Earth's geological history most aquatic life might have been destroyed.

Surface tension is a measure of the magnitude of cohesive forces holding molecules of a liquid together at an interface. For substances at ambient temperature and pressure, water has the highest surface tension with one exception—mercury. The water surface tension is 72.8 dyne/cm. Compare this to, for example, ethanol at 22.3 dyne/cm and ethylene glycol at 47.7 dyne/cm. This surface tension permits a water strider insect (family Gerridae) to transport across lakes riding on the "surface skin" of water, a metal paper clip to float (Fig. 1.2.5.2), and assists with the transport of water from soil to the tops of tall trees.

• **Figure 1.2.5.2** A metal paper clip floats on the water surface "skin," a manifestation of water's high surface tension. (Photograph by Buddy Ratner.)

Specific Heat and Latent Heats of Fusion and Evaporation

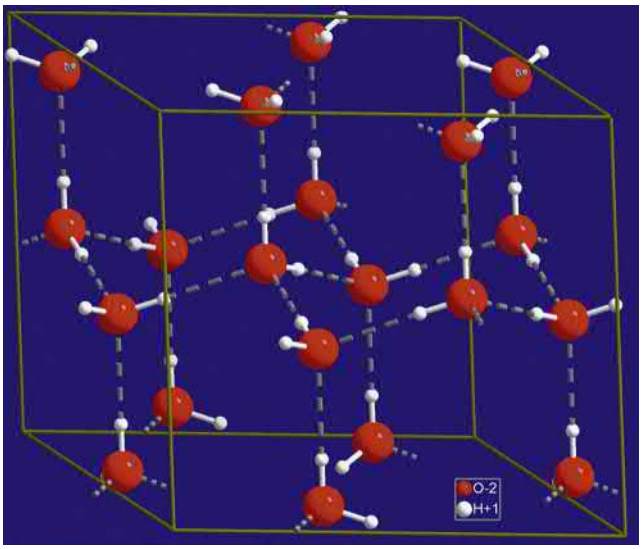
Water has a specific heat of 1.0cal/g°C, that is, the heat per unit mass required to raise the temperature of water 1°C. For comparison, copper has a specific heat of 0.1 cal/g°C, and ethyl alcohol has a specific heat of 0.6 cal/g°C. Water has a higher specific heat than any other common substance. Related to the specific heat is the latent heat of fusion or evaporation. The latent heat is the energy in calories per gram taken up or released by matter changing phase (liquid/solid or solid/liquid) with no change in temperature. Again, water has anomalously high values compared to other common substances.

Water as a Solvent

Water is a remarkably powerful and versatile solvent. It will dissolve proteins, ions, sugars, gases, many organic liquids, and even lipids (up to the critical micelle concentration). In fact, it is the most versatile solvent known.

Water: Structure

Fig. 1.2.5.1 illustrates how water can form extended hydrogen bonding structures. These structures grow in three dimensions. The molecular crystal structure of ice is shown in Fig. 1.2.5.3. At temperatures of 0°C and below, thermal fluctuations of molecules (referred to as kT vibrations, where k is Boltzmann's constant and T is absolute temperature) are low and a continuous, ordered three-dimensional network of water molecules can form. The hydrogen bonds in water are relatively low strength, approximately 5 kcal/mol (21 kJ/mol); in contrast, a C–H bond is approximately 100 kcal/mol. However, unlike covalent bonds, hydrogen bonding is readily reversible, which enables the bonded state of water molecules to rapidly and dynamically respond



• **Figure 1.2.5.3** The hexagonal ice structure. (Wikipedia public domain image.)

to their surrounding molecular environment. At room temperature, the thermal fluctuations of water molecules can disrupt this hydrogen-bond association—if it were not so, water would coalesce into a solid at room temperature. An oft-cited model of water molecule organization suggests that disrupted groupings of water molecules rapidly form new clusters (dimers, trimers, tetramers, pentamers, hexamers, etc.) (Keutsch and Saykally, 2001). This is the "flickering cluster" model of water structure. More recently, it has been established that liquid water is closer to a hydrogen-bonded continuum with much bond-angle distortion from the tetrahedral organization seen in the ice structure, and with bonds breaking and reforming so rapidly (in the order of 200 fs), that the cluster model is not an accurate description (Smith et al., 2005). The continuum model is now the most accepted model for water structure, though there is still much controversy about water structure, and new insights are frequently reported.

The water structure discussion, above, applies to bulk, pure water. The water continuum organization can be disrupted or reorganized by dissolved ions or solutes, by absorption into hydrophilic polymers (e.g., hydrogels when the polymer is cross-linked), and by solid surfaces. Each of these cases will be very briefly addressed.

Dissolved ions and solutes may have a profound impact on water organization (Marcus, 2009). Dissolved salts are dissociated to form an anion and a cation, with each ion having a shell of water of different structure from the bulk. This hydration shell perturbs the structure of water adjacent to it (Marcus, 2009). Much of the study of dissolved ions has centered around studies of the Hofmeister series of anions:

$$CO_3^{-2} > SO_4^{-2} > S_2O_3^{-2} > H_2PO_4^{-} > F^{-} > Cl^{-} > Br^{-} > NO_3^{-} > I^{-} > ClO_4^{-} > SCN^{-}$$

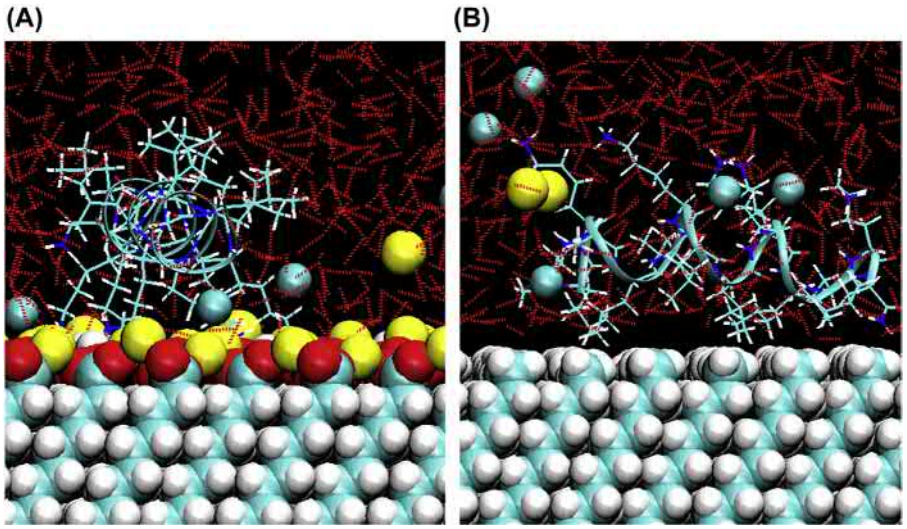
Ions to the left of the series are referred to as kosmotropes ("order makers")—they generally precipitate proteins from solution and inhibit denaturation. Ions on the right side of the series are considered chaotropes ("disorder makers"), and these are more denaturing. Note that chloride is roughly at the center of the series, and thus might be expected to induce little change in proteins and water. Though earlier theories on the Hofmeister series suggested that ions to the left enhanced water structure while those to the right destructured or disordered water, this concept is not fully supported by recent experiments. The Hofmeister effect is impacted by the degree of hydration of ions in water, which cation is involved, and specific interactions of ions with solutes. Review articles that discuss the complexities of the Hofmeister effect and consider contemporary experimental and theoretical work are available (Zhang and Cremer, 2010; Paschek and Ludwig, 2011).

The "swelling" water entrained in gels (hydrogels, see Chapter 1.3.2E) is thought to be in three possible forms. Different nomenclatures are used to describe these forms, but basically three states have been proposed: (1) free water (similar to bulk water); (2) tightly bound water (more structured and with limited mobility); and (3) intermediate water (with characteristics of both free and bound water) (Jhon and Andrade, 1973; Akaike et al., 1979). Below, when the hydrophobic effect is discussed, other possibilities will be suggested. Evidence for different forms of water in gels continues to accumulate (Sekine and Ikeda-Fukazawa, 2009) and implications for biomaterials and biocompatibility have been discussed (Tsuruta, 2010). The nature of the water in the gel may also impact on the diffusion of molecules through it, blood interactions, and its performance as a cell-support in tissue engineering and regenerative medicine. The water that swells a hydrogel is impacted by the polymer chains at a nanoscale, because of its close proximity to the polymer that comprises the mesh of the hydrogel. When macroscopic pores are introduced into the hydrogel, the polymer will impact the water in a different fashion, i.e., the surface of the pores will interact with water in a manner similar to surface effects discussed in the next paragraph; in the interior of the pore (away from the pore wall), the water will have an organization more similar to bulk water.

When a solid surface or biomaterial disrupts the continuum structure of water, the water near the solid surface will adopt a new organization to achieve free-energy minimization for the total system. Since all our biomaterials will first see water before proteins or cells ever diffuse or transport to the surface, the nature of this surface-water layer may be, from a biomaterials-science standpoint, the most important event driving biointeractions at interfaces.

The nature of water in proximity to surfaces may be the primary driver for interactions between biomaterials and biological systems.

There is ample evidence from many analytical techniques, and also from computational methods, that water organization is altered close to a surface compared to the bulk. Most experimental data suggest this difference persists over a length of one to four water molecules (i.e., about 0.3–1.2 nm), before reverting to a structure



• **Figure 1.2.5.4** Snapshots from molecular simulations of a helical leucine-lysine (LK) peptide adsorbing onto (A) a negatively charged hydrophilic surface [self-assembled monolayer (SAM) with COOH/COO^- surface groups], and (B) a hydrophobic surface (SAM with nonpolar CH_3 surface groups) (from studies conducted by Collier et al., 2012). Color coding: greenish-blue surface atoms and "sticks" in the LK peptide = C, white surface atoms and sticks in the peptide = H, red surface atoms and sticks in the LK peptide = O, dark blue sticks in the peptide = N, yellow spheres in solution = Na^+ ions, greenish-blue spheres in solution = Cl^- ions, red dotted lines = hydrogen bonds formed by water molecules. Molecular images created using VMD software (Humphrey et al., 1996).

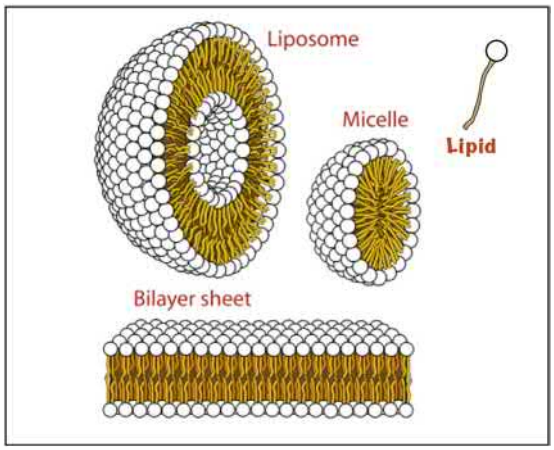
indistinguishable from the bulk water. There is much research on the adsorption of the first layer of water on materials. Clearly, the organization of this first layer will dictate the structure of subsequent layers. On many close-packed metal crystal surfaces (for example, Pt, Ni, Pd) results suggest that a water bilayer exists with a structure analogous to ice (Hodgson and Haq, 2009). This may have led to the somewhat misleading term for interfacial water, "ice-like water." Although the water structure is different from the bulk liquid at all surfaces, the specific ice-like organization is predominantly seen at these close-packed metal crystal surfaces. Above the water bilayer directly in contact with the metal, water structure is altered for a few molecular layers until it becomes indistinguishable from bulk water.

Other studies demonstrate differences between hydrophilic and hydrophobic surfaces as to their interactions with water (Howell et al., 2010). Both types of surfaces have a substantial effect on water organization, but in very different ways. Hydrophilic surfaces have functional groups that are attractive to water molecules by forming hydrogen bonds with them (e.g., surfaces with polar functional groups like O–H or N–H), or strong electrostatic interactions (e.g., charged functional groups), thus resulting in a closely bound layer of water over the surface. In contrast to this, for hydrophobic interfaces, which lack the ability to form hydrogen bonds or strong electrostatic interactions with water molecules, there appears to be a low water density zone, sometimes called a depletion zone, a few angstroms thick over the surface. Fig. 1.2.5.4 presents results from molecular dynamics simulations that illustrate these effects. In this figure, the presence of hydrogen bonds formed by the water molecules over a negatively charged hydrophilic surface (Fig. 1.2.5.4A) and a hydrophobic surface (Fig. 1.2.5.4B) are indicated by the red dotted lines. Over the hydrophilic surface, hydrogen bonds are clearly formed with either the negatively charged surface functional groups or the tightly adsorbed counter-ions with these hydrogen bonds primarily oriented perpendicular to the surface. However, over the hydrophobic surface, which does not have the capability to form hydrogen bonds with the interfacial water molecules, there is a distinct gap a few angstroms thick directly over the surface (i.e., a depletion zone). The hydrogen bonds formed by the water molecules directly above this layer are primarily oriented parallel to the surface, indicating hydrogen bonding only between the water molecules themselves. The resulting hydrophobic effect is also clearly shown in this molecular model, with nonpolar side-chains of the adsorbing peptide being excluded by the surrounding water and tightly adsorbed to the hydrophobic surface.

There are hundreds of recent studies on the water–solid interface, mostly in physical chemistry journals. A comprehensive review of this complex and still controversial subject would be impossible in this textbook. However, the take-home message is relatively straightforward—the presence of an interface alters the water structure adjacent to it.

Water: Significance for Biomaterials

When a protein or a cell approaches a biomaterial, it interacts with the surface water first. This final section will briefly review some implications of this surface water for biomaterials.



• **Figure 1.2.5.5** Lipid molecules with polar head groups (white) and hydrophobic tails (brown), when placed in water, organize themselves to minimize surface area contact between the hydrophobic tail (typically comprised of methylene units, –CH2-) and water. This minimization of contact area, depending on precise conditions, can lead to micelles, liposomes, or bilayer sheets. (Modified from a public domain image on Wikimedia Commons.)

Hydrophobic Effect, Liposomes, and Micelles

If we place a drop of oil under water it will round up to a sphere as it floats to the water surface. The common explanation for this is that because oil molecules do not hydrogen bond with water molecules the oil cannot strongly interact with the bulk water phase. Another way to say this is that the oil disrupts the bulk (continuum) structure of water, and the water molecules at the oil interface then have to restructure to a new (more ordered) organization. This decrease in water entropy is energetically unfavorable according to the second law of thermodynamics (i.e., it results in an increase in the free energy of the system). Therefore, the oil minimizes its interfacial area with the water by coalescing into a sphere (a sphere has the lowest surface area for a given volume). This is called the hydrophobic effect (Tanford, 1978; Widom et al., 2003). It is not driven by the oil–water molecular interactions, but rather by the necessity to minimize the more structured (lower entropy, higher free energy) organization of water molecules.

If we now take a surfactant molecule comprised of an "oily" segment and a polar (water-loving) segment, by shielding the oily phase from the water with the hydrophilic head groups, contact between oil and water is minimized. Fig. 1.2.5.5 illustrates some hydrophobic-effect-driven supramolecular aggregate structures that lead to this free-energy minimization. Liposomes and block copolymer micelles are widely used in drug delivery, where the hydrophobic region (micelle core or liposome bilayer) or the aqueous center (liposome) can carry a hydrophobic drug or hydrophilic drug, respectively (see Chapters 1.3.8A and 1.3.8B). Bilayer sheets are used in biosensors to orient and stabilize receptor proteins.

Hydrogels

The structured water within hydrogels has been discussed. Water structure associated with hydrogels has been implicated in their interactions with blood (Garcia et al., 1980; Tanaka and Mochizuki, 2004). Water structure in hydrogels is also thought to be important in the performance of hydrogel contact lenses, specifically the rate of lens dehydration (Maldonado-Codina and Efron, 2005).

Protein Adsorption

Protein adsorption is discussed in detail in Chapter 2.1.2, and is critically important for understanding the performance of biomaterials. A question commonly posed is: "Why do proteins bind rapidly and tenaciously to almost all surfaces?" A model that can explain this considers structured water at interfaces. All surfaces will organize water structure differently from the bulk structure; this organization almost always gives more structured (lower entropy, higher free energy) water. If a protein can displace the ordered water in binding to the surface, the entropy of the system will increase, and thus the free energy will decrease as the water molecules are released and gain freedom in bulk water. This is probably the driving force for protein adsorption at most interfaces. There are some specially engineered surfaces referred to as "nonfouling" or "protein-resistant" (see Chapter 1.4.3A). These surfaces may resist protein adsorption by binding or structuring water so strongly that the protein molecule cannot "melt" or displace the organized or tightly bound water, and thus there is no driving force for adsorption.

Life

Living systems self-assemble from smaller molecular units. For example, think about the organizational processes in going from an egg, to a fetus, to a mature creature. Much of this assembly is driven by hydrophobic interactions (i.e., entropically by water structure). Another area where water structure has a major impact on life involves DNA and its unique binding of water (Khesbak et al., 2011). Also, consider enzymes that are so essential to life. A substrate molecule enters the active site of an enzyme by displacing water molecules. The unique mechanical properties of cartilage under compression can be modeled by considering water organization. In fact, the average human is 57% by weight water, on a molar basis by far the major component in the human body. Thus we can well appreciate, as Henderson surmised in 1913, that water is essential to this phenomenon we call life.

As you work through this textbook, think about how the phenomena you are reading about may be driven or controlled by water that comprises such a large fraction of all biological systems.

Chapter Exercises

Consider having two types of homogeneous surface chemistries: one with hydrophilic hydroxyl (-OH) groups and the other with hydrophobic methyl (-CH_3) groups.

(a) Which surface would more strongly adsorb a protein in air?

(b) Which surface would more strongly adsorb a protein in water?

Answers:

(a) In air, the –OH surface would more strongly adsorb the protein due to the fact that it would be able to form the strongest type of van der Waals (vdW) interactions (i.e., hydrogen bonds) with the polar groups of the protein, as well as forming moderately strong dipole-induced dipole vdW interactions with the nonpolar groups of the protein. In comparison, the -CH_3 surface would only be able to form the moderate and very weak vdW interactions with the protein (i.e., induced dipole–dipole and induced dipole–-induced dipole interactions, respectively).

(b) In water, the -CH_3 surface would more strongly adsorb the protein due to the ability of water molecules to form hydrogen bonds with the –OH groups of the surface, which will directly compete with the protein, thus weakening the –OH surface's bonding with the protein. In contrast, the -CH_3 surface would form very strong hydrophobic interactions with the hydrophobic domains of the protein due to the thermodynamically unfavorable interactions between the -CH_3 groups of the surface and the surrounding water.

1.3.1 The Materials Side of the Biomaterials Relationship

WILLIAM R. WAGNER

Departments of Surgery, Bioengineering & Chemical Engineering, McGowan Institute for Regenerative Medicine, University of Pittsburgh, Pittsburgh, PA, United States

When seeking to cover the "Classes of Materials Used in Medicine," as this section of the book states, a quick overview of the landscape, together with some caveats and definitions, is in order. What are these materials that will be brought to bear as biomaterials in devices? Materials employed as biomaterials will need to serve many needs: replacement of physiologic functions lost to trauma, disease, or congenital conditions (e.g., cardiac valves); sensing (e.g., ultrasound contrast agents); delivery of materials within the body (e.g., stent-delivery catheters); temporary mechanical support (e.g., sutures); or extracorporeal processes (e.g., dialyzers). It is not surprising that the array of applied biomaterials is very broad and growing.

However, this chapter will not consider specific classes of materials that are used daily in the clinic to meet some of the needs just outlined. Specifically, consider biomedical devices that seek to replace a given physiologic function and the analogous situation with an automobile. For an automobile, tires that no longer grip on wet roads or a battery that cannot start the vehicle elicit a trip to the mechanic's shop and replacement of these parts with "devices" that are fully capable of restoring those functions, or perhaps even exceeding the capabilities and duration of the original equipment manufacturer. The parts are designed to be fully compatible and are readily available for a quick and unambiguous replacement procedure. The situation in the clinic from a needs perspective is similar, but unfortunately society has not advanced to the state where off-the-shelf replacement parts of compositional and functional equivalence are available. Arguably, the best source for such materials in many cases is from the patient: autograft materials. Muscle flaps moved by plastic surgeons for reconstructive procedures, saphenous veins and arteries used for arterial bypass, and skin harvested and mechanically processed to increase its coverage area for burn treatment all represent current gold-standard materials used to meet clinical needs for replacement tissues. Which of these autograft materials are best selected for specific conditions and how they are isolated and processed is the focus of surgical textbooks, but may only be peripherally mentioned here. Yet the reader should be aware that biomaterials and medical device technology falls usually well short of addressing clinical needs as effectively as autografts may. This is true despite the downsides associated with autografting, such as donor site morbidity.

Similar to autografts, allografts (from organ and tissue donation) fill critical needs for tissue replacement where autografts and other material-based approaches are not possible or fall short. For instance, the best option for patients in end-stage cardiac, kidney, liver, and pulmonary failure is currently to receive an allograft. Despite the morbidity associated with immunosuppressant therapy, and issues associated with a limited supply, the quality of life and survival for allograft recipients exceeds similar populations that would be supported by the best current medical support devices for heart, lung, or kidney. The considerations, particularly immunology, surrounding allograft materials are beyond the scope of this text, but the target populations for important classes of medical devices are similar. For both auto- and allografts used in the manner already described, these materials are utilized in a minimally processed state. Particularly for allografts and certainly for xenograft materials, the application of processing methods, from decellularization to cryopreservation and cross-linking, bring these materials into the realm of biomaterials that are considered in this text.

With the preceding discussion the need for extensive consideration of surgical principles as well as broad coverage of allografting, immunology, and immunosuppressive therapy has been taken off the table. At the same time, two critically

important classes of materials used in medicine have been noted, but largely dismissed. Having recognized this, the focus for Section 1.3 is to cover the remaining major classes of materials used in medicine. Studying biomaterials requires the study of the interface between the material and the biological, and in this section the material side of this relationship is covered. To fulfill the design requirements of diverse medical devices, diverse materials are needed that can meet mechanical, chemical, and biological requirements. For some applications it may be that very different material types are being considered due to different design considerations. For instance, in articulating joint replacement devices, some parts have been made from polymer, metal, or ceramic in different designs. In vascular stents a variety of metals have been used, but with recent consideration of degradable stents, both degradable polymeric stents from poly(lactide) and degradable metallic stents made of a magnesium alloy have been tested clinically. Understanding what different material classes and subclasses offer in terms of properties and how structure relates to function is essential knowledge for the biomaterials expert. The chapters here are generally grouped into categories of polymers, metals, ceramics, natural materials, composites, and particulates with subchapters devoted to particularly important material types.

An major trend in the biomaterials community over the past several decades has been the harnessing of advances in molecular biology to design materials with specific biological functionalities. Some of these advances will be covered in this section (Chapter 1.3.2G) and also in select chapters later in the book. More recently there has been a dramatic increase in research focused on particulate biomaterials, where biological knowledge is critically leveraged to impart targeting potential, responsiveness to conditions at a targeted site (e.g., pH), and to orchestrate specific interactions at a cellular level upon arrival. Traditional bulk materials such as polymers, ceramics, and metals may be used as part of these designs, but self-assembly of macromolecules is also often a feature. Chapters 1.3.8A and 1.3.8B seek to summarize this rapidly advancing area in the biomaterials community. Finally, the use of biologically derived materials has been of growing interest and clinical impact. These materials range from highly purified single components that may be from plant or animal sources, to engineered natural materials where functionality such as photocross-linking activity may be added, to materials derived from the extracellular matrix or tissues with processing for degradation resistance (fixation) or intended remodeling (decellularized tissues). The subsections of Chapter 1.3.6 seek to cover this space.

While the theme for this section is firmly on the materials side of the biomaterials relationship, as the field progresses the knowledge bases that inform either side of the material and biological interface are merging, and with some materials the design and control of the biological response has become the critical issue in engineering the intended effect. At the same time, the reality in today's clinics and hospitals is that when autografts and allografts are not available or when devices are needed for other purposes beyond tissue replacement, the vast majority of medical devices remain comprised of materials adopted from the broader materials community to meet the principal design objectives. There remains the need for understanding and working with the fundamentals of materials science.

1.3.2

Polymers: Basic Principles

GARRETT BASS[1], MATTHEW L. BECKER[1], DANIEL E. HEATH[2], STUART L. COOPER[2]

[1]Departments of Chemistry, Mechanical Engineering and Materials Science, Biomedical Engineering and Orthopaedic Surgery, Duke University, Durham, NC, United States

[2]William G. Lowrie Department of Chemical and Biomolecular Engineering, The Ohio State University, Columbus, OH, United States

Polymers represent the largest class of materials used in medicine. They have a range of unique properties making them useful in biomaterial applications, including orthopedics, dental, hard and soft tissue replacements, drug delivery, and cardiovascular devices. This chapter explains the basic principles of polymer science, illustrates how polymer materials can be specifically designed to fill needs in the biomaterials field, and provides examples of how this class of materials is currently used in medical applications. Structure–property relationships, including molecular architecture, molecular mass, and chemical composition related to the physical and chemical properties of the macroscopic material, are included. A biomaterials scientist aware of structure–property relationships can engineer a polymer system for a specific need.

Introduction

Polymer materials possess an array of unique properties that make them useful in a variety of biomaterial applications such as orthopedics, dental, hard and soft tissue replacements, drug delivery and cardiovascular devices. In fact, polymers represent the largest class of materials used in medicine. This chapter introduces the basic principles in polymer science, illustrates how polymer materials can be specifically designed to fill needs in the biomaterials field, and provides examples of how this class of materials is currently used in medical applications.

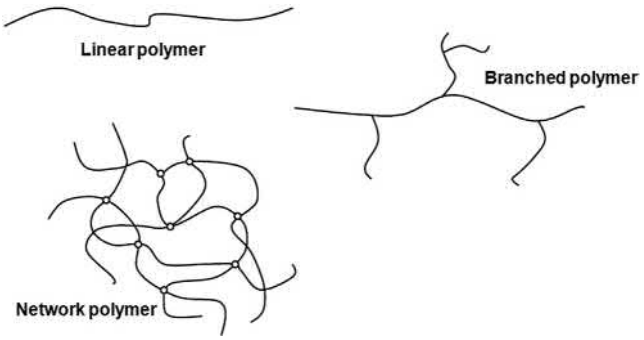
The central idea of this chapter is structure–property relationships, which means how molecular characteristics such as molecular architecture, molecular mass, and chemical composition are directly related to the physical and chemical properties of the macroscopic material. It also includes a brief introduction to polymer synthesis, presents advantages and disadvantages of these methods, and outlines recent developments in postpolymerization functionalization. For instance, polymer scientists in other fields have been able to exploit structure–property relationships to create nonstick coatings, pressure-sensitive adhesives, and the penetration-resistant materials used in bulletproof vests. A biomaterials scientist aware of structure–property relationships can rationally engineer a polymer system for a specific need.

The Polymer Molecule

Molecular Structure of Single Polymer Molecules

The hallmark of polymer molecules is high molecular mass. A single polymer molecule could have a molecular mass of 2,000,000 Da compared to a water molecule, which has a molecular mass of 18 Da. Furthermore, polymer molecules are organized into very interesting architectures. Common architectures of polymer molecules are shown in Fig. 1.3.2.1. The simplest is the linear chain where there is a single molecular backbone. When linear chains of two different compositions (e.g., polymers A and B) are linked together, the resultant polymer is called an A–B block copolymer. If another chain is added to the second chain, it may be called an A–B–C triblock copolymer, or more simply an A–B–C block copolymer. Differences in monomer reactivity can also lead to random or gradient copolymers where the chain sequence of monomer addition is altered. Branched structures are also possible where a central polymer backbone has smaller side chains extending from it. Branches can occur due to undesired side reactions during synthesis, or can be purposefully incorporated into the molecular structure. The type and extent of branching introduces significant changes in properties to a polymer system.

Star-shaped polymers consist of a multifunctional core molecule from which at least three polymer chains (arms) radiate. These arms can be chemically identical (homostars) or different (heteroarm stars). Star polymers have been widely used in biomedical applications such as drug and



• **Figure 1.3.2.1** Three polymer architectures commonly seen.

gene delivery, tissue engineering, diagnostics, and antifouling biomaterials. The intensified interest in star polymers is attributed to their unique topological structures and physical/chemical properties.

Polymer brushes are a branched polymer system in which chains of polymer molecules are attached along a linear polymer backbone in such a way that the graft density of the polymers is sufficiently high to force stretching of the tethered chains away from the backbone. Some examples of naturally occurring polymer brushes include extracellular polysaccharides on bacterial surfaces and the proteoglycans of cartilage.

Dendrimers are monodisperse, precisely branched macromolecules in which all bonds emerge radially from a central focal point with a regular branching pattern and with repeat units that each contribute a branch point. These structures exhibit a high degree of molecular uniformity, precise molecular mass, tunable size, shape, and number of functional groups.

So far we have discussed polymer systems in which there are discrete polymer molecules. However, what would happen if you took a linear polymer molecule and covalently bonded it to the backbone of another linear chain? A few of these bonding events would produce a branched structure as noted previously. If you repeated this act many times over you would eventually link all of the polymer chains together into one very large *network* polymer. This is also possible by using small di- or trifunctional "cross-linker" molecules to react with pendant or terminal reactive groups on linear polymer chains, eventually yielding a network polymer.

Chemical Structure of Single Polymer Molecules

If you were able to see the individual atoms making up a polymer molecule, you would notice the same basic structure repeats over and over again. This structure is called the *repeat unit* of a polymer molecule. Etymologically, polymer comes from the Greek "poly," meaning many, and "meros," meaning part—many parts. In polymer molecules the "mer" is the repeat unit. Fig. 1.3.2.2 shows a schematic of a linear polypropylene molecule. The polymer chain is composed of many $–(–CH_2–CHCH_3–)–$ repeat units covalently linked end to end. The repeat unit itself consists of the polymer backbone, a series of carbon–carbon single bonds, while the hydrogen atoms and methyl group are *pendant groups*. The repeat unit can be controlled through choice of synthetic method and plays a large role in the macroscopic behavior of the polymer. Fig. 1.3.2.3 shows the repeat units of several synthetic and natural polymers commonly used in the biomaterials field.

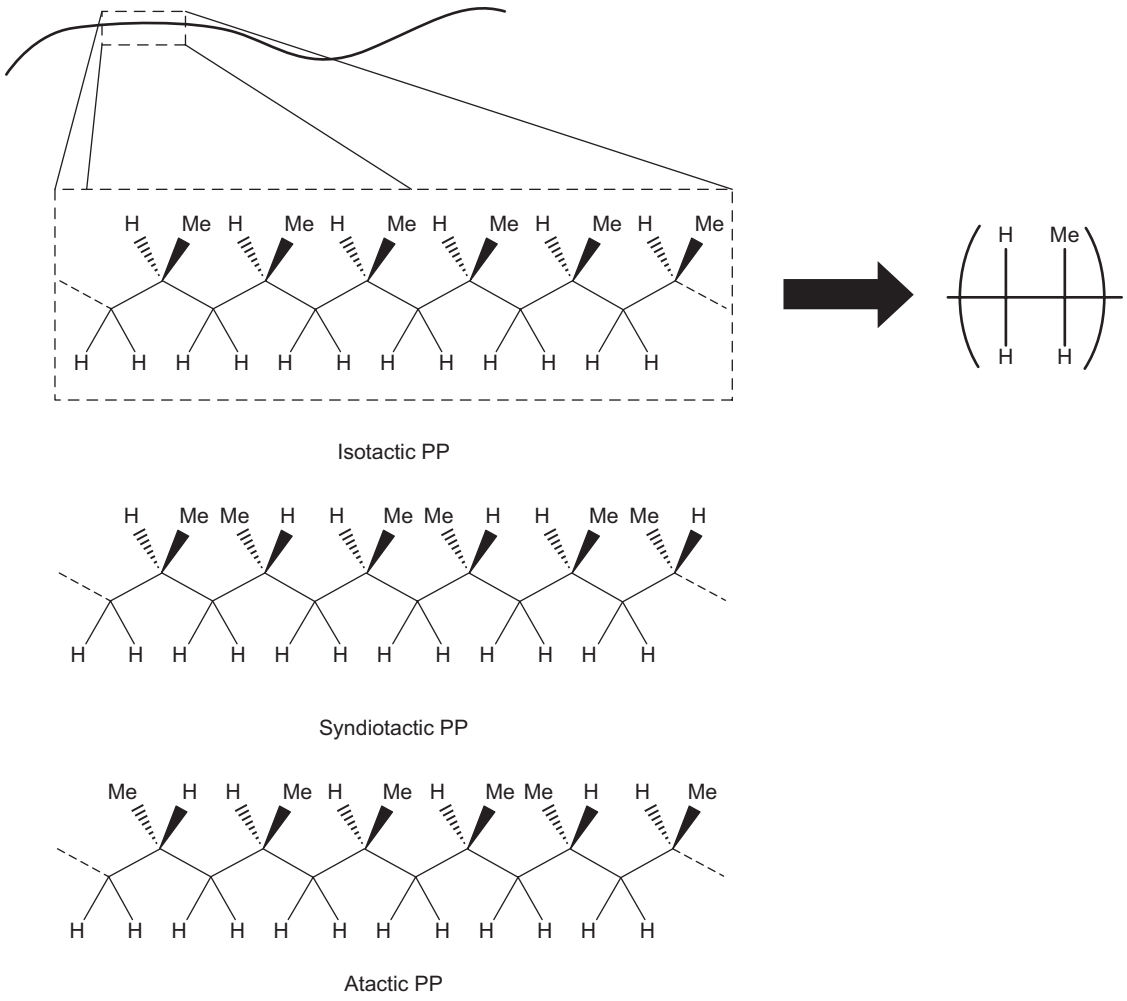
Copolymers

Sometimes it is advantageous to synthesize copolymers—polymers containing more than one chemically distinct repeat unit. For instance, a researcher may synthesize a polymer that contains repeat units "A" and "B." As shown in Fig. 1.3.2.4, there are many different ways the repeat units could be organized. Random copolymers occur when the "A" and "B" repeat units have no order in the backbone; however, alternating, block, gradient, and graft copolymers are also possible and the arrangement of repeat units affects the physical behavior of the biomaterial. The repeat units of two random copolymers commonly used in the biomaterials field are shown in Fig. 1.3.2.5.

Determination of Chemical Composition

A researcher will often need to verify the chemical structure of polymers or determine the composition of copolymer systems. Two common techniques a scientist would use are nuclear magnetic resonance (NMR) spectroscopy and infrared (IR) spectroscopy. NMR is an analytical technique that exploits the magnetic moments associated with isotopes that contain an odd number of protons and/or neutrons. These atoms have an intrinsic nuclear magnetic moment and angular momentum, in other words a nonzero nuclear spin, while all nuclides with even numbers of both have a total spin of zero. The most commonly used nuclei are ^{1}H, ^{13}C, and ^{19}F although isotopes of many other elements can be studied by high-field NMR spectroscopy as well. In a typical experiment, these nuclei are excited to a higher energy state through a burst of radiofrequency radiation. The nuclei relax to a lower energy state, which is measured as an electric signal. Fourier transform analysis is used to convert this time domain electrical signal into the frequency domain. Due to electron shielding, protons attached to different structural units will display chemical shifts, meaning their resonances in the NMR spectrum will be at different frequencies. Through analysis of the resonance placement, splitting patterns, and intensity, the chemical structure of molecules can be determined.

IR spectroscopy is also used to determine the chemical composition of polymers. In a typical experiment, a sample of interest is irradiated with IR radiation. The sample absorbs certain wavelengths, resulting in specific molecular motion or vibrations (such as C–H stretching). The IR spectrum is created by plotting absorbance versus wavelength. Like NMR, analysis of the spectra can lead to the verification of a polymer's composition.



• **Figure 1.3.2.2** Polypropylene repeat unit and its different tactic isomers. In the schematic Me indicates a methyl group.

Often the chemical composition of the polymer surface is different from the bulk. For a medical implant the surface composition is highly important, since it will interface with the biological environment. To probe the surface composition, X-ray photoelectron spectroscopy—also known as electron spectroscopy for chemical analysis—is a common technique. A sample is bombarded with X-rays, which results in the ejection of inner shell electrons from the atoms displayed on the material surface. The kinetic energies of the ejected electrons are measured and interpreted into information about the chemical composition of the surface (for more information on surface characterization techniques, see Chapter 1.2.4).

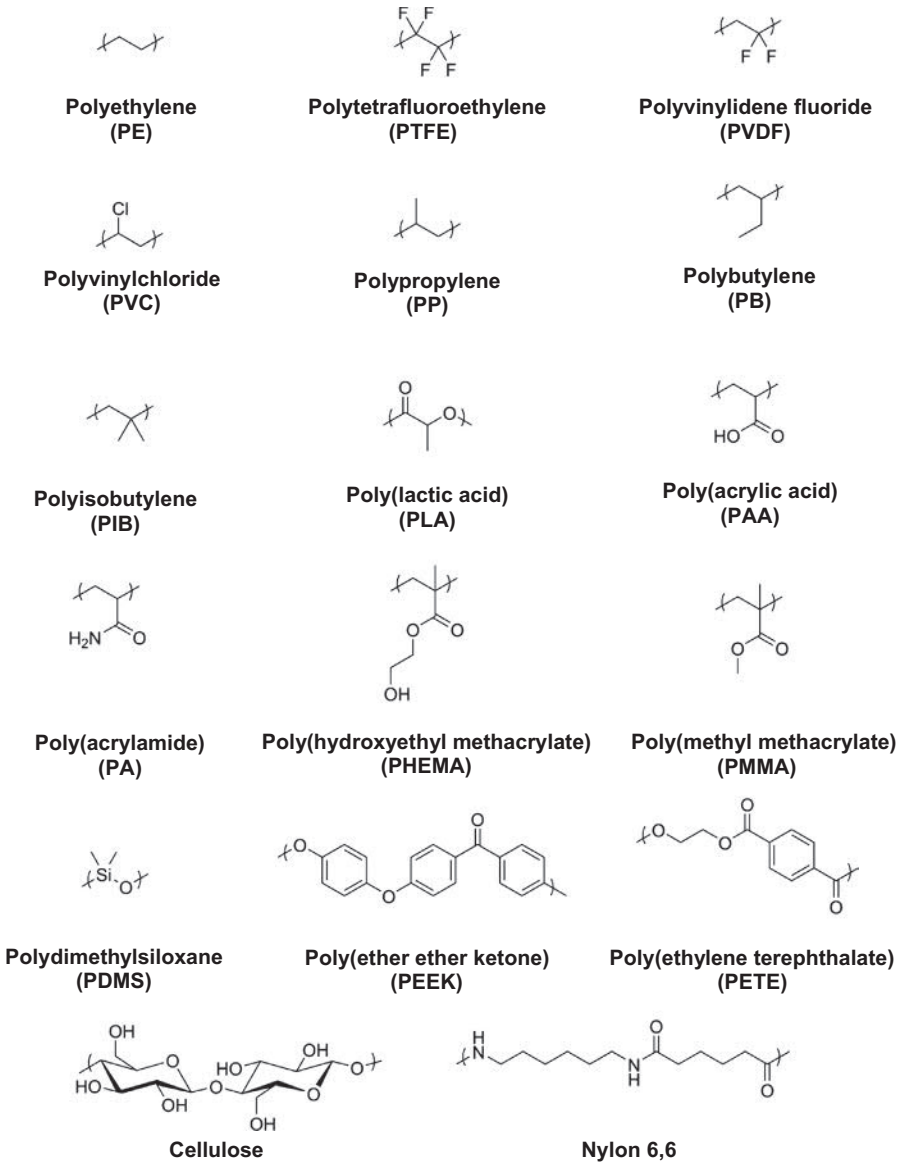
Tacticity

Tacticity describes the stereochemistry of the repeat units in polymer chains. To illustrate the discussion on tacticity, let us consider a molecule of polypropylene (PP). When stretched into its *planar zigzag* form, as seen in Fig. 1.3.2.2, you can see that sometimes the methyl groups are all on one side of the backbone, sometimes they alternate from side to side, and sometimes they are randomly distributed. During routine synthesis, a polymer chemist would normally produce an *atactic* version of PP, one where the methyl group is randomly located in front of and behind the polymer backbone. However, when a special catalyst is used during synthesis a chemist can produce *isotactic* PP, where all the methyl groups are located on one side of the "stretched-out" polymer backbone, or *syndiotactic* PP, where the methyl groups regularly alternate from side to side. As will be discussed later, tacticity can drastically affect the physical behavior of the polymer system, largely by affecting the ability of the polymer molecules to crystallize. Tactic isomers occur whenever an atom in the polymer backbone has the capacity to form tetrahedral bonding and is bonded to four different chemical groups. Such atoms (generally carbon) are referred to as *asymmetric*.

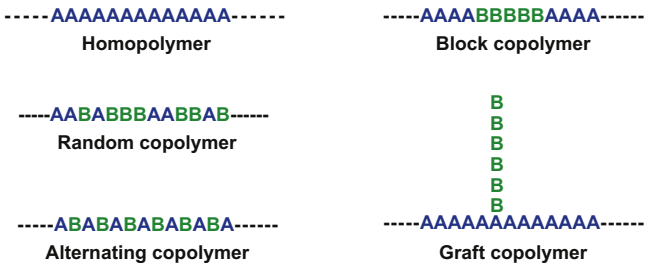
Molecular Mass

The Molecular Mass Distribution and Its Averages

During polymerization, polymer chains are built up from monomers to a desired molecular mass. Polymers with identical composition but different molecular mass (different chain length) may exhibit different physical properties. The number of monomer repeat units in each polymer chain is called the *degree of polymerization* (DP).



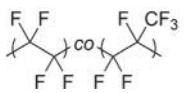
• **Figure 1.3.2.3** Repeat units of common polymer biomaterials.



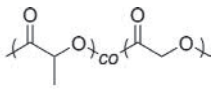
• **Figure 1.3.2.4** Various copolymers formed by varying the arrangement of two monomers.

For a homopolymer, there is only one type of monomeric unit and the number average degree of polymerization is given by $M_n = M_0 \times DP$, where M_n is the number average molecular mass and M_0 is the molecular mass (or formal weight) of the monomer unit.

However, in a traditional free radical or condensation polymerization synthesis, each polymer chain will not have the same DP. For instance, in the free radical polymerization of polyethylene (PE), one polymer chain may add 3000 monomers, a second may add 4500 monomers, and a third may only add 1500. Therefore most polymer systems have a *distribution of molecular masses*. Since polymer materials are made from molecules with a variety of molecular mass, it is incorrect to talk about *the* molecular mass of a polymer system. Instead, polymer systems are described by average values of molecular mass. The two most commonly used averages are the number average molecular mass (M_n) and the weight average molecular weight (M_w). The mathematical definitions of these averages are supplied in Eqs. (1.3.2.1) and (1.3.2.2), where N_i is the number of molecules with "i" repeat units and M_i is the molecular weight of a polymer chain with "i"



Poly(tetrafluoroethylene-*co*-hexafluoropropylene) random copolymer



Poly(lactic-*co*-glycolic acid) random copolymer

• **Figure 1.3.2.5** Repeat units of two common copolymer biomaterials.

repeat units. Since M_w is calculated using the square of the molecular weight it is almost always greater than or equal to M_n:

$$Đ_m > 1 \qquad \textbf{(1.3.2.1)}$$

$$M_n = \frac{\sum_i N_i M_i}{\sum_i N_i} \qquad \textbf{(1.3.2.2)}$$

$$M_w = \frac{\sum_i N_i M_i^2}{\sum_i N_i M_i}$$

The ratio of M_w to M_n is the molecular mass distribution ($Đ_m$) (Eq. 1.3.2.3), which is a measurement of the breadth of the chain length populations. If the $Đ_m$ of a polymer system is unity (1), the number average and weight average molecular masses are identical, meaning the polymer sample is monodisperse (all chains have the same degree of polymerization). This level of precision is only found in dendrimers and biopolymers.

For most condensation polymers, the $Đ_m$ is approximately 2:

$$Đ_m = \frac{M_w}{M_n} \qquad \textbf{(1.3.2.3)}$$

The higher the average molecular mass, the stronger a polymer material will be (up to a point). However, the melt/solution viscosity increases with increasing average molecular mass, making the material more difficult to process. Often a molecular mass range exists within which most desired physical behaviors are achieved, yet the material is still easily processed. Generally, condensation polymerizations are suitable for a number average molecular mass range from 25,000 to 50,000 Da, while addition polymerizations are preferred for values from about 50,000 Da up to hundreds of thousands.

Characterizing the Molecular Mass Distribution

Through understanding the importance of molecular mass and its mass distribution, polymer scientists have developed many methods for measuring average molecular mass values. For instance, M_n can be determined through techniques such as end-group analysis by NMR, vapor pressure lowering, and freezing point depression. In the following paragraphs we will first discuss common methods historically used to measure M_n (osmotic pressure) and M_w (light scattering). Although osmotic pressure and light scattering are powerful and useful techniques in the field of polymer science, they have been replaced in recent years by size exclusion chromatography (SEC), which gives much more detail about the molecular mass distribution, and does so much quicker. From the molecular mass distribution obtained by SEC, the first and second moments of the distribution, M_n and M_w, are readily determined.

In osmotic pressure experiments, a dilute polymer solution is separated from pure solvent by a semipermeable membrane through which solvent can freely pass but which excludes polymer. The activity of the pure solvent differs from that of the solvent molecules in the solution phase resulting in a thermodynamic driving force—the osmotic pressure (π or P) causes molecules of pure solvent to diffuse across a membrane (which is permeable only to solvent) and into a compartment containing a solute (e.g., polymer) in solution. This causes the fluid level in the solution compartment to rise, resulting in a hydrostatic pressure head. Equilibrium is reached when the pressure head exactly offsets the osmotic pressure. By measuring the rise in fluid level, the osmotic pressure can be calculated and related to the number average molecular weight. A number of polymer solutions are prepared, each with a distinct concentration. The osmotic pressure is measured for each solution and plotted against concentration, the concentration is then extrapolated to zero, and the number average molecular weight can be determined from the intercept of the regression line.

Light scattering is a common technique to determine the M_w of a polymer system. In dilute solutions, the scattering of light is directly proportional to the number of molecules. The scattered intensity is observed at a distance r and angle Q from the incident beam, and is related to the size or weight average molecular weight of the molecule. The light-scattering behavior of a series of polymer solutions with varying concentrations is measured and the data are extrapolated to zero concentration to determine M_w. Once the M_n and M_w values are determined, the $Đ_m$ of the polymer system can be calculated.

SEC is the most commonly used molecular mass characterization technique in modern polymer science laboratories. Unlike osmotic pressure and light scattering, which provide *average* values of molecular mass, SEC provides the entire molecular mass distribution from which all the desired average values can be calculated. Different average values can be defined using SEC, depending on the statistical method applied. In practice, two averages are commonly used, representing the weighted mean taken with the mole fraction and the weight fraction. In an SEC experiment, a dilute polymer solution flows through a column packed with solid

separation media that contains pores on the same size scale as the polymer molecules. As the polymer molecules flow though the column, smaller chains diffuse into the pores and thus must travel a further distance, while larger polymer chains move through the column faster since they are excluded from the pore structure, resulting in higher molecular mass material eluting from the column first, followed by lower molecular mass species. The concentration of the effluent stream is monitored and a plot of detector signal (which is proportional to polymer concentration) versus retention time can be generated. The use of narrow molecular mass distribution standards allows the user to correlate retention time with molecular mass, although the actual correlation is with the hydrodynamic volume of the known standards. If the relationship between molar mass and the hydrodynamic volume changes (i.e., the polymer is not the same shape in solution, i.e., branched, cyclic, as the standard, or is of a differing chemical makeup), then the calibration for mass is in error.

Connecting Physical Behavior With Chemical Characteristics

We have discussed the key characteristics of polymer molecules (molecular architecture, chemical composition, tacticity, and molecular mass). Now we will relate these molecular characteristics to macroscopic properties, and illustrate how these characteristics can be manipulated to create a polymer system with the desired behavior. We will focus on the tensile properties, hydrophilicity, and biodegradability of polymer systems.

Physical States of Linear Polymers

When designing a biomaterial, physical properties are key features. For instance, if you were creating a cement for use in loadbearing bones (tibia or femur) you would have to ensure the material is both strong enough to act as a cement, but not so brittle that it would fail due to low fracture toughness. The physical properties of a polymer stem from the intermolecular interactions occurring between individual polymer molecules; thus the molecular characteristics we have discussed up to this point are of extreme importance. As you will see in the following text, the four most fundamental molecular characteristics of polymer chains that determine the physical behavior of a polymer are chain stiffness, chain composition or polarity, chain architecture or regularity, and molecular mass. They determine two important temperatures that characterize polymer molecules: T_g, the glass transition temperature, and T_m, the crystalline melting temperature. T_m is only present when there are crystalline regions in a polymer.

In Fig. 1.3.2.2, we see polypropylene molecules extended into planar zigzags. Although this is a convenient way to draw polymer molecules, this type of extended structure is rarely seen in nature. More often, polymer molecules are found as unorganized and three-dimensional structures called a *random coil*. In an *amorphous* structure, each random coil is highly entangled with its neighbors. Polymers in the rubbery state or the glassy state have this amorphous molecular arrangement. Under certain conditions, some polymers will arrange themselves into highly organized crystalline domains resulting in a semicrystalline material. Each of these states will now be explored in more depth.

The Rubbery State

Rubbery polymers are amorphous. However, the random coils have enough thermal energy for rotation to occur around single bonds. If you were able to look at polymer molecules in the melt state, you would see that each random coil is continuously changing shape (conformation). This molecular motion becomes more intense as the thermal energy in the system increases. Macroscopically these materials are soft, flexible, and extensible, due to the molecular motion available to the molecules.

The Glassy State

As the polymer system is cooled, rotation around bonds becomes hindered due to energy barriers created by a segment of a chain having to move (rotate) past a neighboring segment. As the temperature drops, the rate of segmental motion in a polymer chain becomes slower and slower, and the chain gets stiffer and stiffer. As the system approaches the T_g the interpenetrated random coils become frozen in space. This is called the glassy state. A material below its T_g is called a glass because it is hard, stiff, and brittle. Molecules in the glassy state can no longer rearrange themselves under applied stress, so deformation results in straining the secondary interactions between molecules. The opposite occurs when an amorphous polymer is heated: the amorphous region goes from hard and glassy, to "leathery," to rubbery, and if the material is not cross-linked, it will eventually flow as a viscous fluid and can be processed into shapes.

RAMEN NOODLES: GLASSY VERSUS RUBBERY POLYMER CHAINS

If you are reading this you are probably a college student, which means you are very familiar with Ramen noodles. A package of noodles can be cooked in about 10 min. When you first remove the noodles from the package, you will notice that the individual noodles are rather random in shape and intertwined with their neighbors. Furthermore, before boiling, these noodles are very rigid and fixed in relation to one another. This food product is a pretty good example of a polymer in the glassy state, where each noodle represents one polymer molecule. As the noodles are boiled, they become flexible and can easily change their shape and slip around; however, they retain their intertwined character. These noodles are a good example of a polymer material in the rubbery state.

The Semicrystalline State

All polymer systems form glasses at sufficiently low temperatures. However, as a melt is cooled, certain polymers have the ability to pack into a regular lattice, leading to the formation of stable crystalline domains. In PE, these stable crystalline domains are formed by chains in the planar zigzag conformation, while the crystalline chains

TABLE 1.3.2.1 Physical Properties and Equilibrium Water Absorption of Common Polymeric Biomaterials

Material	Tensile Modulus (GPa)	Tensile Strength (MPa)	Elongation at Break (%)	Water Absorption (%)
Polyethylene	0.8–2.2	30–40	130–500	0.001–0.02
Poly(methyl methacrylate)	3–4.8	38–80	2.5–6	0.1–0.4
Polytetrafluoroethylene	1–2	15–40	250–550	0.1–0.5
Polylactide	3.4	53	4.1	<0.5
Poly(hydroxyethyl methacrylate)[a]	0.29	0.15	71	40
Polypropylene	1.6–2.5	21–40	100–300	0.01–0.035
Poly(ethylene terephthalate)	3–4.9	42–80	50–500	0.06–0.3
Poly(ether ether ketone) (Liu et al., 2018)	3.6–5.0	92	9	0.1
Poly(vinylidene fluoride) (Shackelford and Alexander, 2001)	1.7–2.0	5.2 – 8.6	200-300	0.03–0.06
Poly(lactic-*co*-glycolic acid) (Gentile et al., 2014; Avgoustakis, 2008)	2.0–4.0	6.0–10.0	3–10	0.06–0.08

[a]Tensile properties were measured after the polymer was equilibrated with water.

in syndiotactic poly(vinyl chloride) (PVC) have a helical conformation. Since only a portion of the long polymer chains can crystallize (some segments will not be able to pack into the crystallites) this state is called semicrystalline. Crystallites act to stiffen and reinforce the bulk material, and extend the stiffness and strength properties of a material well above the T_g until the T_m is reached.

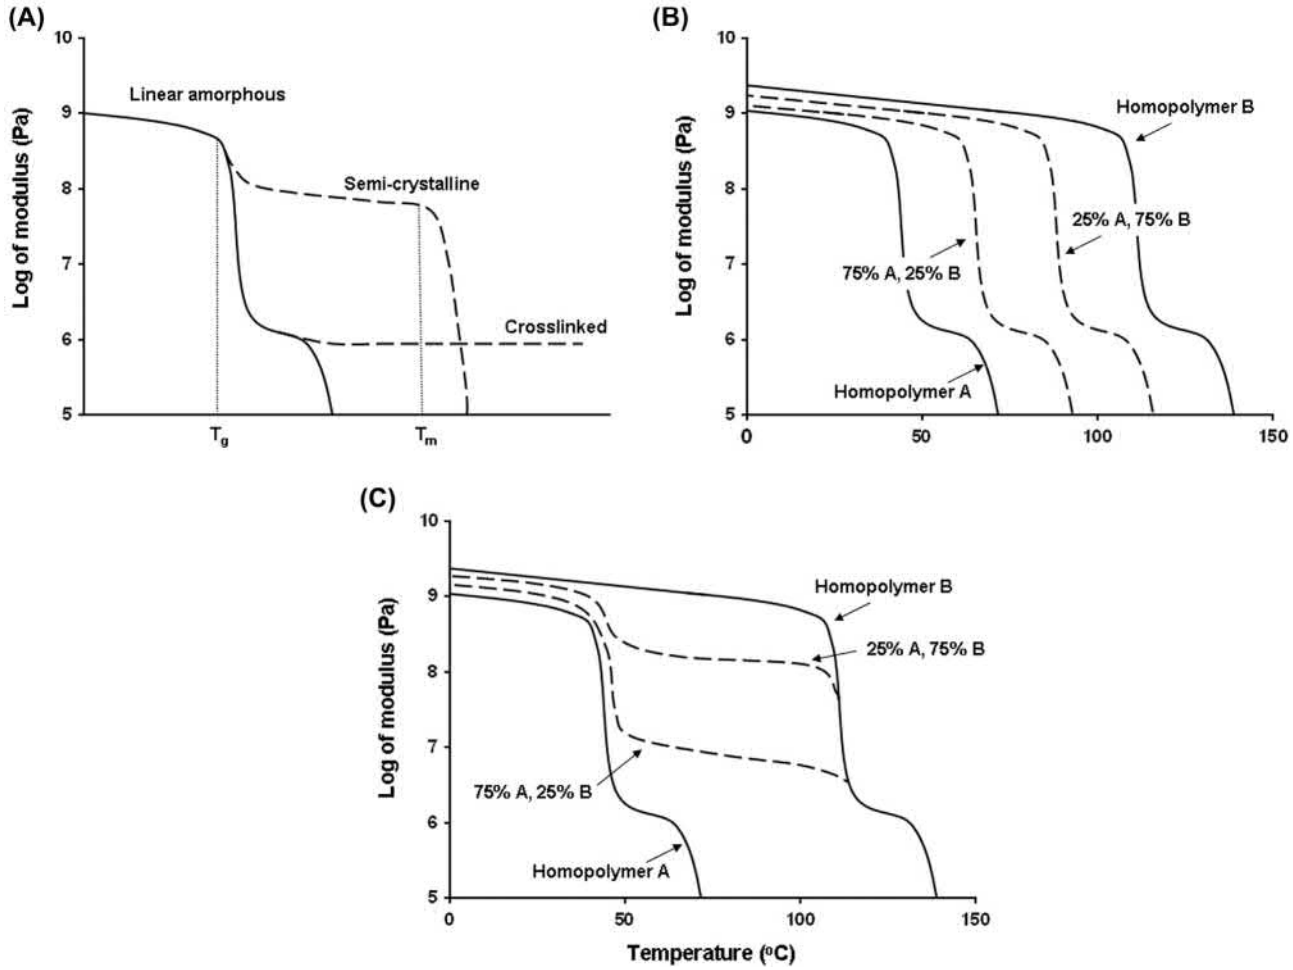
The Physical Behavior of Linear and Amorphous Polymers

Unlike metals, which are held together by metallic bonds, and atomic crystals, which are held together by covalent bonds, polymer materials are held together by secondary interactions such as van der Waals forces, dipole–dipole interactions, and hydrogen bonding. For this reason, polymers are often mechanically weaker than other classes of materials; however, they can display physical behavior more similar to native tissue.

The simplest polymer system is an amorphous rubbery or glassy polymer composed of linear polymer chains. When rubbery materials are strained, the polymer molecules are able to deform and extend resulting in a material that is macroscopically soft and weak, yet highly extensible. However, as the T_g of the material approaches and exceeds the environmental conditions, the material becomes a glass and is much stronger and stiffer. The mechanical behavior of polymer systems is often probed through stress–strain analysis. From this analysis, several key material properties can be determined: modulus (a measurement of material stiffness); tensile strength (the stress at failure); and percent elongation (the amount of deformation at failure). The room temperature mechanical properties of several polymeric biomaterials are presented in Table 1.3.2.1.

The Physical Behavior of Other Physical States

Cross-linking, crystallinity, and copolymerization greatly affect the physical behavior of polymer systems, and controlling these parameters gives polymer scientists ways of specifying the physical behavior of a polymer system. Fig. 1.3.2.6 illustrates how each of these parameters affects polymer modulus as a function of temperature. In Fig. 1.3.2.6A we see the standard modulus–temperature behavior of a linear and amorphous polymer system (solid line). Below the T_g the material is a glass and has a high modulus. However, at the T_g we see a dramatic drop in modulus due to the increased mobility within the polymer structure. At temperatures just higher than the T_g we see a plateau on the curve where modulus declines more slowly with temperature. This is called the rubbery plateau, and in this region the polymer is still solid-like but soft, flexible, and extensible. Eventually, as the temperature is increased more, we see the modulus curve take another drop corresponding to the material beginning to flow. Notice that amorphous materials do not have a melting temperature. Melting refers to the loss of crystallinity, and since these materials are noncrystalline, they never truly melt. As we will discover later, the architecture of the polymer chains, especially where there is a specific tacticity, determines if segments of a polymer chain can pack together and form crystallites.



• **Figure 1.3.2.6** Modulus versus temperature behavior for: (A) linear amorphous, semi-crystalline, and cross-linked polymer; (B) random copolymer; and (C) block or graft copolymer.

In Fig. 1.3.2.6A we can also see the modulus–temperature behavior of a semicrystalline material. In this curve we see a small drop in the modulus at the T_g, due to the onset of backbone rotation in the amorphous regions of the polymer. Since crystallites are unaffected by the T_g, the magnitude of this drop is greatly affected by the amount of crystallinity in the system. After the T_g we see that the modulus holds steady until the melting point, illustrating that crystallinity is a way to increase the window of temperatures in which a polymer can be employed. At T_m the crystallites melt and the polymer begins to flow. The ability of chains to crystallize is a special feature of chain architecture that is sometimes called "symmetry" or "regularity," i.e., a streamline profile in cross-section with small side groups that allows the chain segments to pack into crystallites. In special cases, a stereospecific property of some chains with asymmetric atoms is called tacticity; it can also control the ability of a polymer to crystallize. Polymers without asymmetric atoms in the backbone (and therefore having no tactic isomers) can crystallize along with isotactic and syndiotactic polymers. However, atactic materials cannot organize themselves into a lattice due to the irregularity in their chemical structure, and are therefore permanently amorphous. Branched polymers have difficulty crystallizing, since the branch sites interfere with the ability of the polymer to organize into a lattice. In cases where branch sites are purposefully incorporated into the material, they will lower the extent of crystallization (such as in the case of low-density PE).

Also, in Fig. 1.3.2.6A one can see the modulus–temperature behavior of a cross-linked polymer. Again, at the T_g you will see a decrease in modulus due to the onset of single bond rotation; however, above the T_g the modulus is relatively independent of temperature because the cross-links act to tether the polymer chains in place. In fact, the crosslinked polymer will not experience a large decrease in modulus until the temperature is high enough to begin thermally degrading the bonds holding the structure together.

Copolymerization of more than one monomer unit could also be used to control the physical behavior of a material. Fig. 1.3.2.6B shows modulus–temperature curves for a random copolymer system where the shape of the curve is maintained, but shifted laterally. If block or graft copolymers are produced, one would see the distinct transition of both materials used to generate the copolymer, as seen in Fig. 1.3.2.6C.

TABLE 1.3.2.2 Structural Factors Affecting the Glass Transition Temperature and the Crystalline Melting Point of Polymers

Material	T_g (°C)	T_m (°C)

[c]Reports vary drastically.

Table 1.3.2.2 provides the repeat unit, T_g, and T_m of common polymers. Chemical characteristics that facilitate backbone rotation result in lower T_g materials, while structural characteristics that hinder backbone rotation result in higher T_g materials. For instance, the –Si–O– bond in polydimethylsiloxane is unhindered, and is a freely rotating bond down to very low temperatures, resulting in a very low T_g. As pendant group bulkiness increases, the polymer chains along the backbone have more difficulty rotating due to steric hindrances, illustrated by the much higher T_g of polystyrene in comparison with PE. However, pendant groups of four or more carbon atoms tend to create "free volume" around the polymer backbone, making main chain rotation easier, and the T_g may be lowered, as seen in the alkyl methacrylate family as the alkyl group increases in length. Increased polarity, especially where hydrogen bonds may act between side groups, increases the polar interactions between chains, slowing the rate of main chain rotations and resulting in a higher T_g. In general, the structural factors that affect the T_g (backbone flexibility, pendant group structure and polarity, main chain symmetry and polarity) similarly affect T_m, as illustrated by the data in Table 1.3.2.2.

A TRAGEDY CAUSED BY A CHANGE IN TEMPERATURE AND ITS EFFECT ON T_G AND POLYMER PROPERTIES

In 1986 the space shuttle *Challenger* broke apart during lift-off, killing the seven crew members aboard and halting all US space flights for the next two and a half years. This tragedy was caused by the failure of an O-ring—a polymer gasket—connecting the shuttle's external fuel tank to one of its solid rocket boosters. The O-ring failed, in part, due to the abnormally cold weather on the morning of the launch, causing stiffening of the gasket as the polymer approached its T_g, and that undermined its ability to form a tight seal. The gasket failure allowed a tongue of flame to reach both the solid rocket booster and the external fuel tank, and resulted in the structural failure of both. The shuttle then broke apart due to extreme aerodynamic loads (see NASA, 1986).

Characterizing a Polymer's Physical State and Behavior

Crystallinity plays a large role in determining polymer behavior. The *degree of crystallinity*—a measurement of how much of the polymer is incorporated into crystalline regions—can be studied with techniques such as measurement of density, X-ray diffraction (XRD), and IR spectroscopy. In XRD experiments a polymer sample is bombarded with X-ray radiation and the intensity of the scattered X-rays is measured as a function of scattering angle. A fully amorphous material would produce a very broad peak, covering all scattering angles. However, crystalline materials will produce sharp peaks at specific angles. Furthermore, the placement of these peaks corresponds to a particular crystalline structure. By integrating the areas under the amorphous peak and the crystalline peaks, and then calculating the fractional area of the crystalline peaks relative to the total area, a researcher can determine the degree of crystallinity.

Stress–strain analysis provides information about the mechanical behavior of a polymeric biomaterial. In this test a polymer sample of known dimensions is deformed at a given rate, and the force needed to cause the deformation is recorded.

Measuring the Transition Temperatures Between States

Measuring transition temperatures (T_g and T_m) is important to understanding how a material will behave in a certain application. Two common methods for determining the transition temperatures in polymer systems are differential

scanning calorimetry (DSC) and dynamic mechanical analysis (DMA). In DSC experiments a polymer sample is heated at a constant temperature rate (generally 10–20°C/min) and the amount of heat supplied to the sample to obtain the temperature increase is recorded. The output from this experiment is a plot of supplied heat versus temperature. The curves exhibit a step change at T_g due to a change in heat capacity at the onset of backbone rotation. An endothermic peak occurs in the DSC spectra at the melting point of the polymer due to the increased energy needed to melt the crystalline regions.

When performing a DMA experiment, one measures the modulus (stiffness) of the material over a temperature range, yielding the types of curves shown in Fig. 1.3.2.6. The T_g of the material is physically observed as the softening point of the material. In a DMA study the modulus drops by approximately three orders of magnitude at the T_g. At the T_m, another drop is observed, associated with softening due to melting of the polymer crystalline units and the onset of flow behavior.

Interactions With Water

Biomaterials are often employed in highly hydrated environments, so their interaction with water is an important design characteristic. Relatively nonpolar and electrically neutral polymers such as PE or poly(methyl methacrylate) (PMMA) are very hydrophobic and absorb <1 wt% water. However, as polarity and, in some cases, ionic character are incorporated into the polymer, it will imbibe more water due to polar (and coulombic) interactions. For instance, poly(hydroxyethyl methacrylate) (PHEMA) (the first soft contact lens) absorbs approximately 40 wt% water due to the polar hydroxyl moieties of the pendant groups. Eventually, if enough polarity or ionic character is incorporated into the material, it becomes water soluble, e.g., poly(ethylene glycol) and poly(methacrylic acid). The equilibrium water absorption of common biomaterials is presented in Table 1.3.2.1.

One can tailor the interaction of a polymer with water in several ways, such as by controlling the ratio of hydrophobic and hydrophilic monomers in a copolymer. Also, crystalline regions in polymers usually resist infiltration of water molecules. If a polymer is processed in a way to control the degree of crystallization, the swelling character of the polymer can thereby be controlled. Cross-linked hydrophilic polymers generate hydrogels that can imbibe upward of 200 wt% water. However, increasing the cross-link density can reduce the swelling of such a material, providing another method of tailoring the interactions of a polymer with water.

In addition to swelling behavior, the surface hydrophilicity of a polymer is also an important design feature. Though it is beyond the scope of this chapter, you will learn elsewhere in this text that a biomaterial surface can be physically or chemically coated with peptides or proteins to enhance cellular attachment and growth. Surfaces may also be treated to be "antifouling," i.e., to resist protein adsorption and cell attachment.

Measuring the Hydrophilicity of Polymer Materials

Equilibrium swelling experiments are performed to study the interactions between bulk polymer and water. A dry sample of polymer of known mass is submerged in water, and the change in mass is recorded over time. Eventually the sample weight will become constant, and from this value the equilibrium water absorption can be calculated.

The surface hydrophilicity is probed through either static or dynamic contact angle experiments. In static experiments, a droplet of water is placed on a flat polymer surface and the angle the droplet makes with the material (as measured through the water phase) is measured. The degree to which water spreads on the surface is a measurement of the polarity of the interface. For instance, a material with a water contact angle of 20 degrees has a *more polar* surface than a material with a water contact angle of 95 degrees.

The surface composition of some materials can change depending on the external environment. For instance, a polymer may expose its hydrophobic portions to an air environment, yet it will reorganize its surface to display its hydrophilic portions when exposed to water (unless the interface has been oxidized to increase hydrophilicity). Dynamic contact angle experiments allow a researcher to probe the ability of the surface molecules to rearrange depending on the phase to which they are exposed. In such an experiment a polymer film is dipped into a bath of water and then removed. The force between the polymer sample and water is measured during immersion and retraction, and converted into contact angles. Materials with surface molecules that have the mobility to rearrange in air versus water will exhibit contact angle hysteresis, and the advancing and receding contact angles will not be the same. The advancing angle is always greater than the receding angle.

Degradation Characteristics

Depending on the application, one may desire a polymer material that is either biodegradable or biostable. For instance, a polymer that will be used for a tissue-engineered scaffold needs to be biodegradable, and to "disappear" or be resorbed as functioning tissue is regenerated by cells. However, some biomaterials, such as dental implants, vascular grafts, and intraocular lenses need to be biostable so that they retain their function for the lifetime of the patient. The main type of polymer degradation reaction occurring in the body is *hydrolysis*, i.e., the reaction of the polymer backbone bonds with water, which results in the cleavage of those bonds and loss of the polymer's mechanical properties. Eventually the polymer breaks up into small fragments that are metabolized and/or dissolve, and the residual molecules are eliminated from the body. The ultimate stability of polymers in the body

depends on two key factors: water absorption and the susceptibility of main chain bonds to hydrolysis.

The carbon–carbon single bond is very stable and those materials with main chain C–C bonds, such as PE, PP, or PMMA, do not lose their properties due to degradation of the backbone. However, the presence of other bonds in the polymer backbone (*heterochain* polymers) can lead to hydrolytic breakdown, and the rate of this hydrolysis is greatly affected by the polymer's molecular structure. For instance, the hydrolysis of amide bonds in nylon 6,6 is so slow that it is almost nonexistent at physiological conditions, making polyamide biomaterials relatively biostable. On the other hand, water can hydrolyze ester bonds (–CO–O–C–) present in some polymers. For example, poly(lactide-*co*-glycolide) copolymers (Fig. 1.3.2.5) degrade by such hydrolysis. An exception to this is poly(ethylene terephthalate) or PET, which is crystalline and hydrophobic, so that even though it has main chain ester bonds, water absorption is so low it is resistant to hydrolysis. The reader is referred to Chapter 2.4.1 on degradation of biomaterial implants and to Chapter 2.5.12 on drug delivery from degradable matrices for further discussion of this important topic.

Polymer Synthesis

A polymer scientist who understands structure–property relationships can design polymer molecules to fit a particular application. In this section we discuss the synthesis of polymers.

Polymerization Mechanisms

Condensation and *addition polymerization* are the two most common methods for polymer synthesis. In organic chemistry, reactions are described that occur between different functional groups. For instance, a carboxylic acid group can react with an amine group to form an amide bond and liberate a water molecule. Table 1.3.2.3 illustrates some of these major organic reactions for bond formation. The same reactions as those seen in Table 1.3.2.3 are used to produce a number of condensation polymers. The only difference is that instead of using monofunctional molecules (which contain only one functional group) difunctional monomers (which contain two functional groups) are used. Fig. 1.3.2.7A illustrates the formation of a PET repeat unit through the

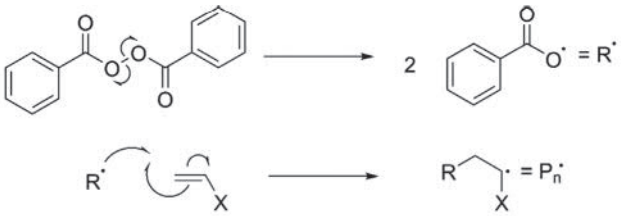
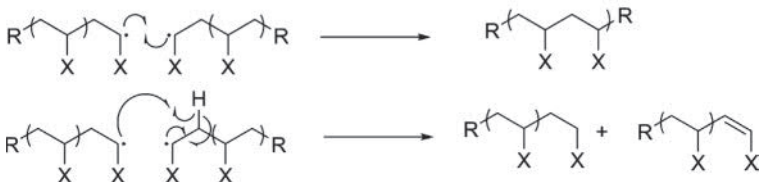
• **Figure 1.3.2.7** Condensation reactions between: (A) ethylene glycol and dimethyl terephthalate to produce poly(ethylene terephthalate); and (B) adipoyl chloride and hexamethylenediamine to produce Nylon 6,6.

(A) Initiation: Benzoyl peroxideinitiatorundergoes homolytic cleavage to produce two free radicals, which can then initiate polymerization by adding to a monomer unit.



(B) Propagation: Polymer chain ends continue to add monomer units, increasing the chain length.

(C) Termination: Termination of polymer chain ends can occur by two methods. Combination occurs with two radical chain ends coupling to result in linking of two polymers. Disproportionation occurs when a proton is transferred from one chain to another, resulting in an elimination reaction.

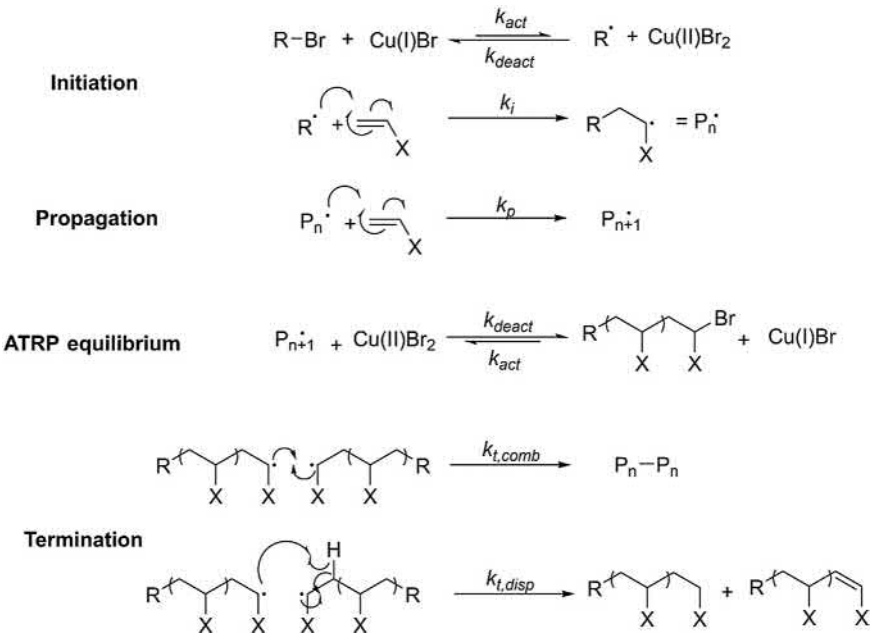


• **Figure 1.3.2.8** Free radical polymerization of a vinyl monomer to a polymer chain: (A) the initiation step where the free radical is produced and is added to a monomer unit; (B) the propagation step where the chain end free radical adds across the vinyl monomer's double bond; and (C) the termination step where two radicals react to produce dead polymer chains. In the schematic, X represents a generic side group.

reaction of ethylene glycol and dimethyl terephthalate, while Fig. 1.3.2.7B shows the production of a nylon 6,6 repeat unit through the reaction of adipoyl chloride and hexamethylenediamine. Notice that all of the monomers are difunctional molecules. Furthermore, the products from each reaction are also difunctional, allowing further, similar reactions to gradually produce higher molecular mass linear polymer chains.

The addition or chain-growth polymerization mechanisms are quite different from condensation polymerization. Chain-growth polymerization includes radical polymerization but also cationic polymerization and anionic polymerization. In chain-growth polymerization, the only chain-extension reaction step is the addition of a monomer to a growing chain that possesses an active center such as a free radical or ion (cation or anion). Once the growth of a chain is initiated by formation of an active species, chain propagation is usually rapid by addition of a sequence of monomers. Chain-growth polymerization often involves the linking together of molecules incorporating unsaturated double (alkene) or triple (alkyne) carbon–carbon bonds. Chain-growth polymerization is used heavily by industry in the manufacture of polymers such as PE, PP, polyisobutylene, and PVC.

Fig. 1.3.2.8 is a schematic of a typical radical polymerization. Chains are initiated by radicals, formed from an initiator, which then adds to the monomer. These chains



• **Figure 1.3.2.9** Atom transfer radical polymerization (ATRP) of a vinyl monomer. Initiation begins when a radical species is formed through redox chemistry. Propagation occurs until the growing chain end is reversibly deactivated in the ATRP equilibrium. Termination can occur through chain combination or chain disproportionation by hydrogen abstraction (Wang and Matyjaszewski 1995; Ribelli et al., 2019).

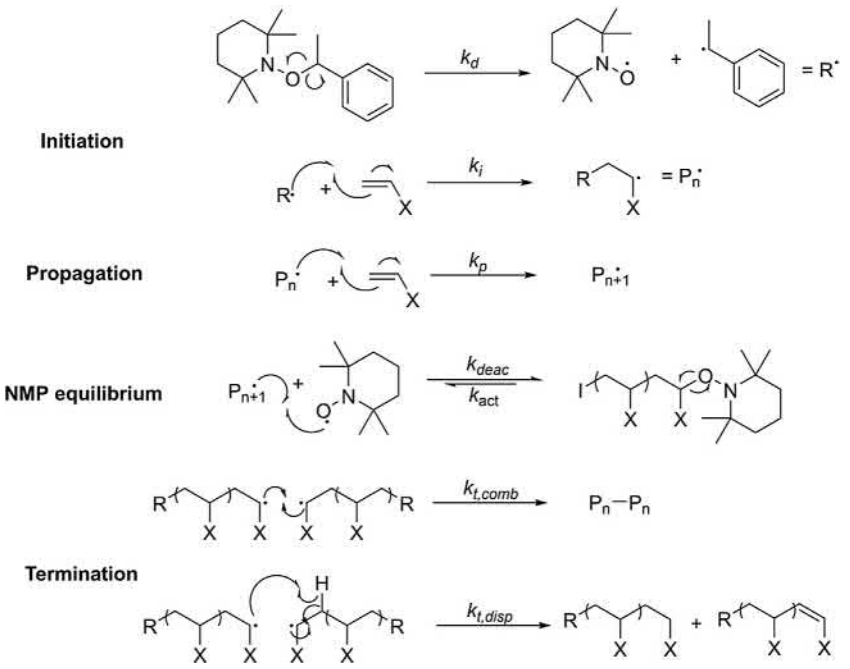
propagate by sequential addition of monomer units. Chain termination occurs when the propagating radicals self-react by combination or disproportionation. Continuous initiation and termination yield a steady-state radical concentration of ~10^{-7} M and the lifetimes of individual chains are typically ~5–10 s within a reaction span that may be many hours. In the absence of chain transfer, the lengths (DP) of the chains formed during the early stages of polymerization are high. The breadth of the molecular mass distribution is governed by statistical factors. The molecular mass distribution ($Đ_m$) is ideally 2.0 if termination is by disproportionation or chain transfer, or 1.5 if termination is by combination.

There are newer polymerization techniques that are known as "controlled living free radical polymerizations" or "reversible-deactivation radical polymerizations" (RDRPs) where the growth, chain transfer, and termination reactions are controlled to yield polymers with a desired molecular mass and narrow $Đ_m$. The most popular of these techniques are known as atom transfer radical polymerization (ATRP) (Kato et al., 1995; Wang and Matyjaszewski, 1995), nitroxide-mediated radical polymerization (NMP) (Moad and Rizzardo, 1995; Nicolas et al., 2013), and reversible addition-fragmentation chain-transfer polymerization (RAFT) (Chiefari et al., 1998). A commonality between these techniques is the use of reversible activation and deactivation reactions to limit the concentration of active chains at any one time, effectively increasing the polymerization control.

ATRP is a catalytic process that can be mediated by several redox-active transition metal complexes. In ATRP, radicals are generated through a reversible redox process in which the transition metal complex undergoes a single-electron oxidation with simultaneous abstraction of a halogen atom, X, from a dormant species, R–X. This process, which generates an active chain end, follows rate constants k_{act} and k_{deact}, corresponding to the formation of the active and dormant species, respectively. The active species propagates and terminates as in conventional free radical polymerization with a rate constant k_p and a termination constant k_t, but the low concentration of active species prevents significant termination events. The result is well-defined polymer chains with defined end groups and narrow molecular mass distribution ($Đ_m < 1.2$) (Fig. 1.3.2.9).

Like ATRP, NMP is also based on a reversible termination mechanism, but this time between a propagating radical and a stable nitroxide radical. At high temperatures, the initiator species undergoes homolytic cleavage to produce a stable nitroxide radical and an alkyl radical that can initiate the polymerization. The chain is then able to propagate or form the dormant species by addition to the nitroxide radical. This reversible termination event establishes the activation–deactivation equilibrium between the dormant and active species. As with ATRP, termination events are possible, but not significant under appropriate conditions (Fig. 1.3.2.10).

RAFT is also an RDRP technique as with ATRP and NMP, but instead uses reversible radical transfer reactions to limit the number of active chain ends. While ATRP and NMP rely on reversible termination events to limit the concentration of radicals, RAFT relies on these reactions to reversibly transfer the radical to the chain transfer agent (CTA), thus temporarily deactivating the polymer chain. A thiocarbonylthio compound, such as dithioesters, thiocarbamates, or xanthates, serves as a CTA, and is required for



• **Figure 1.3.2.10** Nitroxide-mediated radical polymerization (NMP) of a vinyl monomer. Initiation begins through homolytic cleavage of a nitroxide-containing molecule to generate radical species. Propagation continues until the active chain-end is reversibly deactivated by the nitroxide species in the NMP equilibrium. Termination can occur through chain combination or chain disproportionation by hydrogen abstraction (Moad and Rizzardo 1995; Nicolas et al. 2013).

RAFT polymerization. RAFT offers excellent control over the polymerization, such as predefined molecular weights and narrow molecular mass distributions, and is experimentally simple compared to ATRP, often involving only the addition of a CTA to the conventional free radical polymerization (Fig. 1.3.2.11).

The reader is referred to recent polymer textbooks (see Bibliography) for further reading on polymerization and controlled radical polymerization techniques.

Using Synthesis Conditions to Build the Desired Polymer

The first step toward producing a material with the desired behavior is selection of the appropriate monomer species. For instance, a researcher developing a bone cement could select a monomer with a bulky pendant group to produce a glassy polymer, while another biomaterials scientist creating a hydrogel could select a monomer with a polar pendant group to improve hydrogen bonding interactions with water.

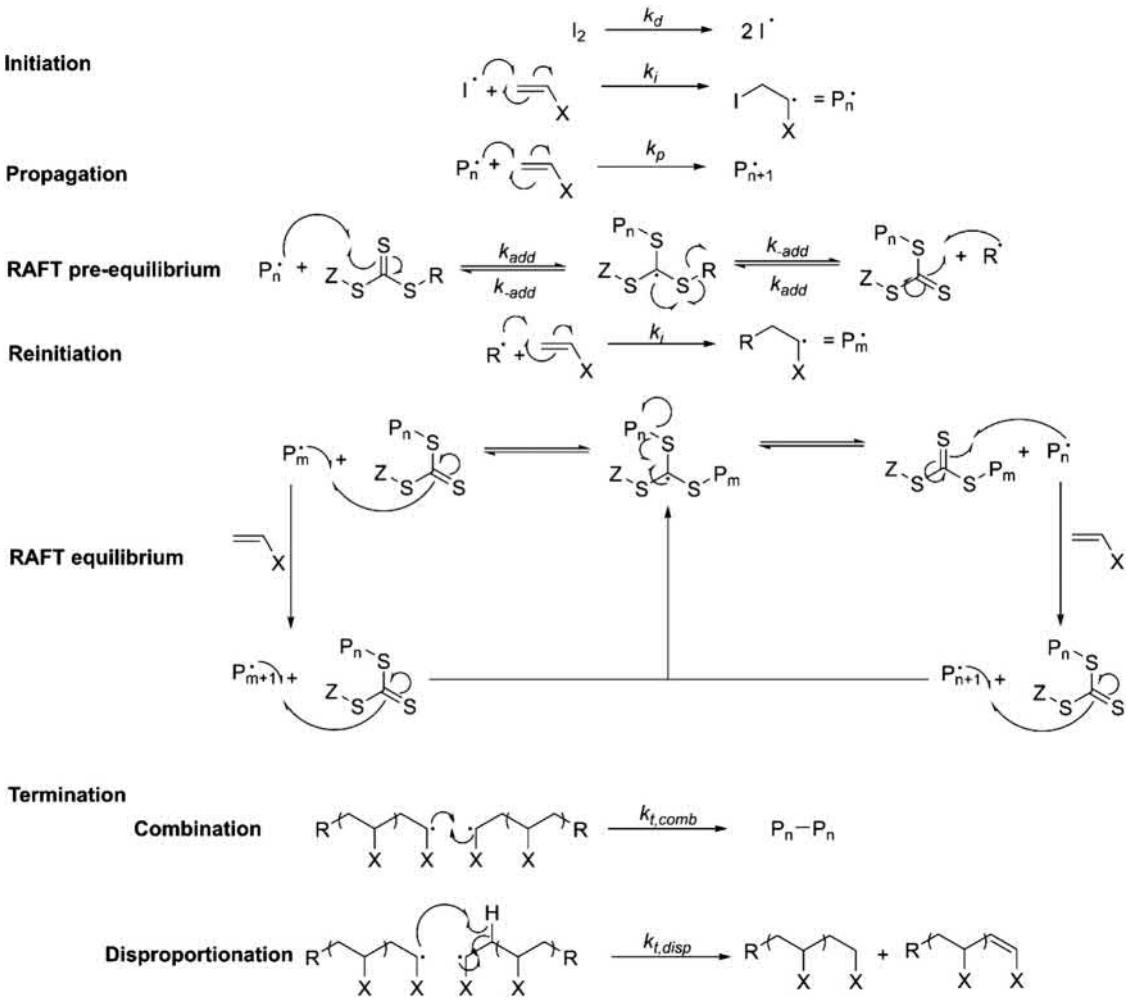
Physical behavior can be further tailored through crystallinity and cross-linking. Addition polymers containing asymmetric carbon atoms are generally atactic, meaning the polymer will be predominantly amorphous. However, one can use special catalysts to produce isotactic or syndiotactic addition polymers that can crystallize.

In condensation polymerization, monomers containing two functional groups produce linear polymer chains. However, if one adds a small amount of a monomer with three or more functional groups, cross-linked materials are produced. Similarly, addition of vinyl-type monomers containing two or more vinyl groups can produce networked materials. Linear polymers can also be cross-linked after synthesis through techniques such as vulcanization, or UV or gamma ray irradiation.

SO WHAT IS A NETWORK POLYMER?

A common example of a network polymer is an automobile tire. The main polymer component of a tire tread is a polystyrene/polybutadiene copolymer (SBR). The individual SBR polymer chains are covalently cross-linked into a network polymer through reaction with sulfur (a process known as vulcanization). There are other additives in car tires (carbon black, for instance, which gives the tire its black color); however, the polymer component of the tire is actually one very large, covalently cross-linked molecule.

If degradation characteristics are desired, they can be achieved through control of the composition of the backbone groups. Addition or chain-growth polymerization produces polymers with carbon–carbon backbones that are generally biostable. Sometimes condensation polymerization mechanisms may produce a water molecule as a residual. The reverse reaction can occur between the polymer bonds being formed and the water molecule, resulting in hydrolytic degradation of the polymer. In that case, water must be removed as it is formed.



• **Figure 1.3.2.11** Reversible addition-fragmentation chain-transfer (RAFT) polymerization of a vinyl monomer. The initiation phase occurs with homolytic cleavage of an initiator to form two radicals, followed by addition to the double bond of the monomer. Propagation continues until radicals are transferred to the RAFT chain transfer agent (CTA), deactivating the polymer chain. Homolytic cleavage of the CTA "R" group reinitiates, forming a new polymer chain. The polymer chains then enter the RAFT equilibrium phase, where polymer chains alternate between active propagation and deactivated dormant phases. Termination can occur through chain combination or chain disproportionation by hydrogen abstraction (Chiefari et al., 1998; Perrier 2017).

Case Studies

We have discussed the basic molecular characteristics that govern polymer behavior, and how to exploit chemistry to build polymers with the desired characteristics. Table 1.3.2.4 compiles the chemical characteristics of several polymeric biomaterials, and reports their clinical applications. We will also look in more depth at the development of three polymer biomaterials that have achieved clinical success.

The Present and the Future

In the early days of biomaterials science, materials were not designed for biomedical applications. Preexisting materials were used and their biocompatibility was empirically assessed. As you will learn through this book, much of the current work in the biomaterials field focuses on creating materials that exhibit specific interactions with biology to achieve improved performance and better healing.

TABLE 1.3.2.4 Common Polymeric Biomaterials With Their Applications and the Properties That Make Them Useful in the Medical Field

Material	Characteristics	Uses
Poly(methyl methacrylate)	Hydrophobic polymer that is hard, rigid, and biostable. The amorphous material is clear allowing light transmittance	Bone cement Intraocular lenses Hard contact lenses
Polyacrylamide	Cross-linking produces a hydrogel with molecular-sized pores that allow the gel to be used as a separation medium	Separation gel used in electrophoresis
Poly(acrylic acid)	The liquid monomer can be cured with a photoinitiator. If inorganic salts are added, ionic cross-linking can occur. The material is glassy and rigid, and has the potential to bond to enamel.	Glass ionomer cement used in dental restoration
Polyethylene (high density) (PE)	Low-density PE cannot withstand sterilization temperatures; however, high-density PE has good toughness and wear resistance	Tubing for drains and catheters Prosthetic joints
Poly(vinyl chloride) (PVC)	PVC is plasticized to make flexible materials. This material is used for short-term applications since plasticizers can be leached resulting in embrittlement of the material.	Tubing Blood storage bags
Polypropylene (PP)	Isotactic PP is semicrystalline, has high rigidity and tensile strength, and good biostability	Nondegradable sutures Hernia repair
Polydimethylsiloxane	Due to its silicone backbone, this material has a very low T_g making it extremely flexible and providing it with good fatigue resistance at physiological conditions	Finger joints Heart valves Breast implants Ear, chin, and nose reconstruction
Poly(ethylene terephthalate)	The aromatic rings in the backbone generate a polymer with a high melting point (T_m = 267°C). It is semicrystalline and possesses excellent tensile strength.	Vascular grafts Fixation of implants Hernia repair Ligament reconstruction
Cellulose acetate	Unique transport properties make it excellent for use in the separation of complex biological mixtures	Dialysis membranes Osmotic drug delivery devices
Polyether ether ketone (PEEK)	PEEK is a semicrystalline polyaromatic thermoplastic. It is chemically resistant and displays high thermal transitions (T_g = 145°C, T_m = 334°C). It is often used as a composite material for biomedical applications.	Engineering plastics Cranial defect repair Dental implants
Poly(lactic acid) (PLA)	PLA is a biodegradable polyester that can range from amorphous to crystalline depending on the stereochemical makeup, which also influences its mechanical properties	3D-printing filaments Surgical screws, pins, and meshes Drug delivery
Poly(lactic-*co*-glycolic acid)	This copolymer shows enhanced processability over the corresponding homopolymers and allows for tunable glass transition temperatures and degradation rates based on composition	Degradable sutures Implantable meshes

CASE STUDY I: RESORBABLE SUTURES

What Problems can Occur?

Sutures are often needed to hold tissue together after injury, incision, or surgery. If a nonbiodegradable material is used to suture an internal wound, a secondary surgery would be necessary to remove the stitches after healing.

What Properties are Required of the Biomaterial?

For a suture material, the most fundamental property required is appropriate tensile strength, so the wound does not reopen during healing. Also, the suture materials should degrade in the body during healing, making retrieval or removal unnecessary. Further, the degradation must occur at an appropriate rate, and the degradation products must be nontoxic.

What Polymeric Biomaterial is Used?

Early resorbable sutures were made from sheep or beef gut. However, synthetics are more commonly used due to their ease of handling, low cost, consistent performance, and low chance of disease transfer. One commonly used material is a poly(lactide-*co*-glycolide) copolymer. This is a random copolymer so the material is permanently amorphous; however, it still possesses the high tensile strength and flexibility required for this application. Also, the material biodegrades through hydrolysis of the ester bonds in the polymer backbone into lactic and glycolic acids. Both of these chemicals occur naturally in the body's metabolic pathway, and so are nontoxic in small amounts. Furthermore, the ester bonds in the lactide and glycolide repeat units hydrolyze at different rates, allowing the degradation rate to be tailored.

CASE STUDY II: SOFT CONTACT LENSES

What Problem was Addressed?

The first contact lens, developed in 1888, was made of glass, and could not be worn for long periods of time. A generation of PMMA lenses were developed (hard contact lenses) and experienced clinical success. However, these rigid lenses caused eye irritation, and did not allow enough oxygen to be transported to the cornea of the eye (an avascular tissue that must receive oxygen from the environment for normal metabolism to occur). The Czech scientists Wichterle and Lim wanted to make a lens that was more comfortable and would allow better transport of oxygen to the cornea. (Otto Wichterle and Drahoslav Lim, "Process for producing shaped articles from three-dimensional hydrophilic high polymers", US Patent 2,976,576, March 28, 1961.)

What Properties Were Required of the Biomaterial?

Strong mechanical properties were not a major factor in the design of soft contact lenses, since the device does not need to support large stresses. However, a successful lens needed to: (1) be transparent so that clear vision could be achieved; (2) be dimensionally stable to maintain the optical correction desired; (3) be soft and flexible to minimize eye irritation; (4) allow appropriate transport of oxygen and nutrients to the cornea; and (5) have sufficient surface wettability so as not to damage the corneal cells.

What Polymeric Biomaterial is Used?

The major component of most modern soft contact lenses is loosely cross-linked PHEMA. Semicrystalline polymers are often translucent due to light refracted by crystallites. Since PHEMA is atactic the polymer is transparent. When dry, PHEMA is glassy, allowing the lens to be fabricated through milling procedures (as is done with hard contact lenses). However, the hydroxyl-containing pendant group results in a hydrophilic polymer that imbibes 40 wt% water. The absorbed water plasticizes the polymer, producing a soft and supple material that is less irritating to the eye. Pure PHEMA lenses are not capable of providing the necessary oxygen to the cornea of the eye, so PHEMA is often copolymerized with other monomers, such as fluorinated or "siliconized" methacrylates, to improve oxygen transport either by increasing the oxygen solubility in the lens or by allowing the fabrication of a thinner lens.

Recently, much research in contact lens development has focused on the design of extended wear lenses (contacts that can be worn for up to 7–14 days without removal). A leading material for extended wear contacts is a silicone hydrogel that is composed of a silicone polymer network with an entrapped water-soluble polymer such as poly(vinyl pyrrolidone). This combination creates a material with excellent oxygen and ion permeability, and good lubricity of the lens against the cornea (for example, see http://en.wikipedia.org/wiki/Contact_lens).

CASE STUDY III: ARTIFICIAL HIP JOINTS

What Problem was Addressed?

A surgeon may perform hip arthroplasty (implantation of an artificial hip) to alleviate the pain and stiffness of severe arthritis or to repair the joint after physical damage. An artificial hip implant has two pieces: the femoral ball and stem, and the acetabular cup. The femoral ball and stem implant is a metal shaft that inserts into the femoral bone core, and is capped by a ball that articulates with the acetabular cup.

What Properties Were Required of the Biomaterial?

Sir John Charnley— a British orthopedic surgeon— conceived the initial concept that led to the modern artificial hip. Focusing on the acetabular component, tribology (the study of friction, lubrication, and wear) is of utmost importance. The ideal polymer for use in an articulating joint would be low friction and resistant to wear.

What Polymeric Biomaterial was Used?

Initially, Charnley used poly(tetrafluoroethylene) (PTFE), a very nonpolar and low-friction material, for the acetabular cup. He also used stainless steel for the femoral ball and stem. Two problems arose: first, PTFE did not have the necessary wear resistance, and small pieces of PTFE debris eroded from the surface of the cup, causing severe inflammation of the surrounding tissue. Second, Charnley had to force-fit the femoral stem into the femur, and it loosened during use. Although PE has a higher-friction surface than PTFE, very high molecular weight PE is a superior biomaterial for this application, since PE did not produce excessive wear debris. Also, PE could be simultaneously gamma radiation sterilized and cross-linked, increasing its wear resistance. It could also be machined to a fine smoothness to further minimize wear. Charnley was advised by Dennis Smith, a biomaterials chemist working on dental implants, to use PMMA dental cement to hold the femoral stem in place during wear, and that solved the second problem.

1.3.2A
Polyurethanes

DANIEL E. HEATH[1], SCOTT A. GUELCHER[2], STUART L. COOPER[1]

[1]William G. Lowrie Department of Chemical and Biomolecular Engineering, The Ohio State University, Columbus, OH, United States

[2]Department of Chemical and Biomolecular Engineering, Vanderbilt University, Nashville, TN, United States

Introduction

Polyurethanes are widely used in medical devices such as pacemakers, artificial hearts, and other blood-contacting applications. Their excellent mechanical properties, stability, and good biocompatibility give them a special place in medicine (Lamba et al., 1998). Polyurethanes were developed in the 1930s. Around that time, Nylon 6,6——a condensation polymer of hexamethylenediamine and adipic acid——was developed and patented by Du Pont. This polymer achieved commercial success due to its good mechanical properties and fiber-producing ability. German scientists led by Otto Bayer began to explore new polymerization techniques in the hope of creating a material competitive with nylon. Initial work reacted difunctional isocyanates and amines to produce polyureas; however, these materials were too hydrophilic to be used as plastics or textiles. Diisocyanates were also reacted with diols to produce polyurethanes. One nylon-like polyurethane produced through the reaction of 1,4-butanediol and hexamethylene diisocyanate, as shown in Fig. 1.3.2A.1, was used commercially in Germany. Chemically the polymer is the same as nylon except for the two additional oxygens per repeat unit, and the properties are similar except that the polyurethane has a lower melting point. These early polyurethanes also had lower water absorption, and better electrical and mechanical stability upon aging compared to nylon. Subsequently block polymers including polyester or polyether polyols were developed both in Germany and the United States (Saunders and Frisch, 1965).

Today, polyurethanes (PUs) are a class of polymer which has achieved industrial relevance due to their tough and elastomeric properties, and good fatigue resistance (Randall and Lee, 2002). PUs are used as adhesives, coatings, sealants, rigid and flexible foams, and textile fibers. Furthermore, PUs have also been employed in biomaterial applications such as artificial pacemaker lead insulation, catheters, vascular grafts, heart assist balloon pumps, artificial heart bladders, wound dressings, tissue adhesives, bone grafts, and drug-delivery vehicles.

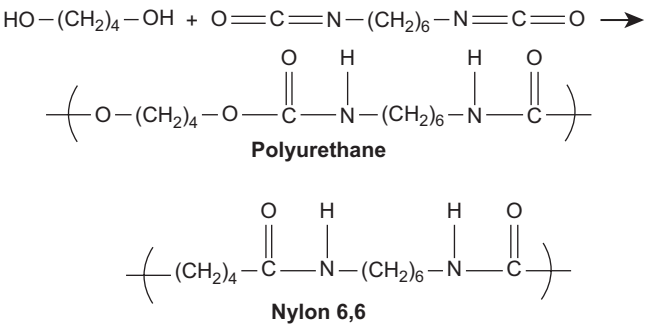
Anatomy of a Polyurethane Molecule

The polyurethane molecule presented in Fig. 1.3.2A.1 has a very simple architecture. Most commercially relevant PUs today are actually block copolymers (as seen in Chapter 1.3.2, Figure 1.3.2.4) meaning there are alternating segments in the polymer molecules composed of solely "A" or "B" repeat units. Furthermore, the materials are designed so that one of the segments——called the *hard segment*——is glassy or crystalline at the use temperature, while the other segment——referred to as the *soft segment*——is rubbery. If the monomers are appropriately selected, the hard and soft segments of the polyurethane will be incompatible, leading to phase separation so that the composition of the bulk polymer will not be homogeneous. Instead, there will be nanometer-sized regions which are rich in hard segments, and other regions rich in soft segments. The unique block copolymer structure and phase separation of PUs results in unique and useful properties. One can consider the hard phase domains as providing highly efficient reinforcing microdomains which give rise to the unusual and very attractive properties of polyurethanes, such as strength and toughness.

The Physical Properties of Polyurethanes

Thermosets

Most polymer elastomers——such as rubber bands——are produced by lightly cross-linking a low T_g polymer into a loose network (as seen in Chapters 1.2.2 and 1.3.2, Figure 1.3.2.3). When such a material is strained, the segments between cross-links can deform and elongate; however,



• **Figure 1.3.2A.1** Synthesis scheme of a polyurethane through the condensation of 1,4-butanediol and hexamethylene diisocyanate. The repeat units of the PU and of Nylon 6, 6 are presented for comparison.

when the load is removed the cross-links result in the material returning to its original form. Although these elastomers are useful, they are *thermosets*. Since the material is essentially one large molecule it cannot be dissolved, neither can it be made to flow through the introduction of heat and pressure. This means that once a thermoset elastomer is formed, it cannot be processed further. Prior to completion of the setting reaction, PU thermosets are flowable, making them useful as injectable or moldable biomedical devices (e.g., tissue adhesives, scaffolds, and bone grafts) that cure in situ after implantation.

Thermoplastic Elastomers

The unique segmented structure of PUs allows *thermoplastic elastomers* to be formed. When such materials are strained, the polymer segments in the soft phase will deform and elongate, while the hard phase will stabilize the structure, resulting in recovery of the original form once the load is removed. However, unlike the covalent cross-links in thermosets, the physical cross-links present between hard segments can be undermined through the application of heat, and then reformed upon cooling, allowing the useful properties of elastomers to be combined with the simple processing procedures of thermoplastics. In addition to elastomeric properties, PUs have several useful interfacial characteristics. Foremost, PUs are abrasion- and impact-resistant, making them useful as coatings, and the materials also have good blood-contacting properties, making them useful in biomaterial applications.

Polyurethane Synthesis

Precursors

When synthesizing most PU block copolymers a two-step synthesis strategy is typically employed which involves three precursor molecules: diisocyanates, diols, and chain extenders. In the final polymer molecule the diisocyanates and chain extenders will form the hard segments, while the diols form the soft segments. Table 1.3.2A.1 illustrates the chemical structure of molecules often used to synthesize PU block copolymers. Thermoplastic PU elastomers are synthesized from diisocyanates and diols (functionality equal to two), while PU thermosets are synthesized from polyisocyanates and polyols with functionality greater than two.

The diisocyanate molecules used in biostable polyurethane synthesis can be aliphatic (such as Fig. 1.3.2A.1), but most often aromatics are used (Table 1.3.2A.1). The two most commonly used diisocyanates employed in biostable PU synthesis are 2,4 and 2,6 mixed-toluene diisocyanates (TDI) and methylene-bis(4) phenyl isocyanate (MDI). The soft segments are formed from polyether or polyester diols (sometimes referred to as *polyols*). These molecules have a molecular weight of 1000–2000 Da, and are well above their T_gs and melting points at use conditions, which impart a rubbery character to the resulting polyurethane. Polyether diols are often preferred to form the soft segments since they are more resistant to hydrolytic degradation than polyesters. The last precursor is the chain extender. These molecules are often short aliphatic diols or diamines containing two to six carbon atoms, and are used to build the polymer up to its final high molecular weight.

Aromatic diisocyanates can result in carcinogenic degradation products; therefore, resorbable PUs for tissue engineering applications require the use of diisocyanates other than MDI and TDI (Table 1.3.2A.1). Resorbable PU segmented elastomers and thermosets have been synthesized using lysine-diisocyanate (LDI), hexamethylene diisocyanate (HDI), and 1,4 diisocyanatobutane (BDI), which degrade to nontoxic breakdown products (Takanari et al., 2017). Soft segment structure is often designed to build in the appropriate degradability. For instance, soft segments containing copolymers of lactide, glycolide, and ε-caprolactone have been investigated, all of which are susceptible to hydrolytic degradation, and the degradation rates vary based on chemical composition (Santerre et al., 2006). Similar to biostable polyurethanes, short-chain aliphatic diols or diamines are often used as chain extenders, although recent work has focused on synthesizing cell-degradable or biologically active chain extenders (Xu et al., 2015). In some applications, water is used as a chain extender to generate porous foam scaffolds for tissue regeneration or to facilitate in situ cure after implantation in the body (Guelcher, 2008).

Synthesis Reactions

The isocyanate group contains two unsaturated bonds and is a highly reactive moiety. When reacted with a hydroxyl group, the result is a urethane bond, as illustrated in Fig. 1.3.2A.1. The first step in PU synthesis reacts the diisocyanates with the polyether or polyester diols. Excess diisocyanate is used to ensure the resulting materials are end terminated with isocyanate groups, as seen in Fig. 1.3.2A.2A. The result of this reaction is a *prepolymer* with a degree of polymerization commonly between two and five. Next, the prepolymer is further reacted with the chain extenders to produce high-molecular-weight polyurethane molecules, as shown in Fig. 1.3.2A.2B.

CASE STUDY I

What Problem Was Addressed?

An individual may require an artificial pacemaker to regulate their heartbeat. The pacemaker is an implanted device which monitors heartbeat and provides electrical stimulation to the muscles of the heart, resulting in muscle contraction when needed. The pacemaker is connected to the appropriate heart muscles through pacemaker leads, electrically conductive wires which are fed to the heart through the vasculature.

The pacemaker leads require insulation. Initially poly(dimethyl siloxane) (PDMS) or polyethylene was used as the insulator for the leads. However, both of these materials resulted in a fibrous endocardial reaction. Furthermore, PDMS has a low tensile modulus and poor tear resistance.

What Properties Were Required of the Biomaterial?

A successful insulator for pacemaker leads would not elicit a fibrous reaction from the heart, and would have high tensile strength and resistance to tearing, allowing for thinner lead insulations to be produced.

What Polymeric Biomaterial is Used?

In 1978, polyurethane was introduced as a lead insulator. Although not as flexible as PDMS, the PU had superior tensile properties and tear resistance. This allowed much thinner lead insulations to be fabricated without compromising handling properties. The thinner insulation allows multiple leads to be inserted per vein, enabling sequential pacing. Furthermore, the PU surface has lower friction in contact with blood and tissue than the PDMS surface, allowing easier insertion of the leads.

The search for the optimum lead insulation material is not over yet, however. In the 1980s it was found that metal-induced oxidation from lead metals resulted in undesired degradation of the polyurethane insulation. Lower ether content in the polyurethane was one solution to this problem, although this results in higher modulus insulation. In subsequent years there have been changes to the material used for the lead wire, and silicone rubber remains in use as well as polyurethanes for pacemaker insulation. Research is under way to find more biostable polyurethanes for this application.

CASE STUDY II: RESORBABLE POLYURETHANE ADHESIVE

What Problem Was Addressed?

An individual may require an abdominoplasty procedure, in which excess skin and fat are removed from the abdomen to tighten the muscle of the abdominal wall. Most patients who undergo large flap procedures require implantation of drains to remove fluid that accumulates under the skin at the surgical site. Drains can cause discomfort and lead to complications for the patient. Tissue adhesives, such as cyanoacrylates, can be used to hold the remaining layers of tissue in place and reduce the voids between layers, thereby eliminating the need for drains. However, cyanoacrylates are nonresorbable and are potentially toxic to patients and health professionals.

What Properties Were Required of the Biomaterial?

A successful surgical adhesive would be easily administered, cure inside the body within minutes to form a strong tissue bond, and break down into nontoxic and resorbable components as the tissues continue to heal.

What Polymeric Biomaterial is Used?

In 2015, TissuGlu polyurethane surgical adhesive was approved by the FDA for use during abdominoplasty. TissuGlu consists of a prepolymer prepared by reacting lysine diisocyanate ethyl ester with trimethlyolpropane. The prepolymer, which is delivered by a handheld applicator, reacts with moisture present at the surgical site to form a strong tissue bond that eliminates voids between tissue layers. In clinical trials, TissuGlu was found to be a safe and effective alternative to postoperative fluid collection drains. Patients treated with TissuGlu Surgical Adhesive required fewer postoperative treatments and resumed daily activities sooner than those receiving surgical drains. Research is under way to expand the use of TissuGlu Surgical Adhesive to other surgical procedures, including mastectomy, inguinal lymph node dissection, and colorectal anastomosis.

Tailoring Polyurethane Behavior

Many of the techniques described in Chapter 1.3.2 to modulate polymer properties can easily be applied to polyurethanes. For instance, monomers with functionality greater than two can be used in order to produce cross-linked PU thermosets. Also, as the cross-link density in thermosets controls material stiffness, the relative amounts of hard and soft segments in the PU can vary the modulus. Similarly, the length and chemical nature of the soft segment can be adjusted to further tune physical behavior.

Resorbable PUs have been explored more recently for tissue regeneration and repair. For these applications, the degradation rate must be controlled to match that of tissue ingrowth and the degradation products need to be nontoxic and readily cleared from the body. Examples include moisture-cure surgical adhesives as an alternative to surgical drains (Ohlinger et al., 2018), resorbable electrospun elastomers for tissue reconstruction and repair (Takanari et al., 2017), resorbable bone cements for repair of weight-bearing fractures (Lu et al., 2018), and injectable high internal phase emulsions (polyHIPEs) for production of high-porosity scaffolds (Moglia et al., 2011).

There have been many advances in the application of polyurethane chemistry to create novel biomaterials. Examples include smart materials for drug delivery that exhibit pH and/or temperature sensitivity (Zhao et al., 2011),

shape change materials (Zheng et al., 2016), and antimicrobial polyurethanes (Grapski et al., 2001). Additionally, thermoplastic polyurethanes lend themselves to electrospinning and additive manufacturing techniques (3D printing) for a variety of tissue engineering applications (Cooper and Guan, 2016).

Concluding Remarks

Polyurethanes are a unique family of polymers with interesting properties which arise from their block copolymer nature and the resulting phase separation. These materials have achieved industrial success in everyday applications, as well as in the biomaterials field.

Chapter Exercises

1. Describe the structure of the polyurethane molecule and how it gives rise to the favorable properties of polyurethanes, such as high strength and toughness.
2. Describe the differences between thermosets and thermoplastic elastomers and give examples of each of these types of materials that are useful for biomedical devices.
3. Draw schematics of monodentate and bidentate hydrogen bonding between urethane and urea groups in the hard segments of polyurethanes. Discuss how hydrogen bonding between adjacent hard segments enhances polyurethane properties.
4. Discuss the targeted design properties for resorbable polyurethanes for tissue repair and nonresorbable polyurethane permanent implants. How can the properties of the polyurethane be tailored to the application by modifying the structure?
5. Draw the schematic for synthesizing a nonresorbable thermoplastic elastomer from MDI, butanediol, and poly(tetramethylene oxide) (PTMO, 2000 g/mol). Highlight the hard and soft blocks in the polyurethane molecule.
6. Draw the schematic for synthesizing a resorbable polyurethane thermoset from LDI and a polyester triol (900 g/mol).
7. List the optimal mechanical, rheological, biological, and degradation properties of polyurethane elastomers for 3D printing scaffolds for tissue repair using fused deposition modeling.

1.3.2B

Silicones

JIM CURTIS, STEPHANIE D. STEICHEN

DuPont Health Care Solutions, Midland, MI, United States

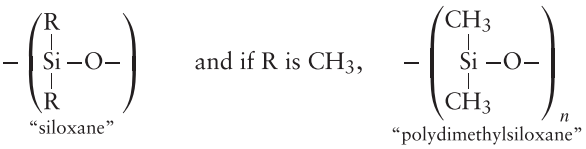
Silicone materials have been extensively used in a variety of industries for over 70 years. These materials are typically composed of an alternating inorganic silicon–oxygen backbone with pendant organic groups. The simultaneous presence of inorganic and organic moieties provides unique chemical and physical properties, while also enabling control over those characteristics through molecular architecture. Silicones are available in an assortment of material types including fluids, emulsions, compounds, resins, etc., which can be further formulated into elastomers, gels, adhesives, and more.

Silicones have remarkably low glass-transition temperatures and maintain their flexibility over a wide temperature range, permitting them to withstand conditions from cold storage to steam autoclaving. This robust temperature performance makes them ideal for use in the aerospace and automotive industries. In the electronics field, silicones are used as electrical insulation, potting compounds, and in other applications specific to semiconductor manufacture. Their long-term durability has made silicone sealants, adhesives, and waterproof coatings commonplace in the construction industry. Silicones possess high permeability to gases and many drugs, advantageous, respectively, in wound care or transdermal drug delivery. Excellent biocompatibility, facilitated by low surface tension and remarkable chemical stability, makes many silicones well suited for use in personal care, pharmaceutical, and medical device applications, including long-term implant applications. Since the 1960s, silicones have enjoyed expanded medical applications and today are one of the most widely used biomaterials.

Chemical Structure and Nomenclature

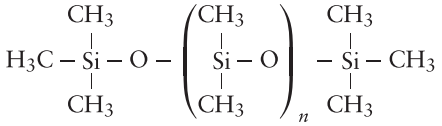
Silicones were so named due to their similarity with ketones, specifically because, in most cases, there is on average one silicon atom for one oxygen and two methyl groups (Kipping, 1904). Later, as these materials and their applications flourished, more specific nomenclature was developed. Key milestones in the development of silicone chemistry are summarized in Table 1.3.2B.1.

The basic repeating unit became known as "siloxane," and the most common silicone is polydimethylsiloxane, abbreviated as PDMS.



Many other groups (e.g., phenyl, vinyl, and trifluoropropyl) can be substituted for the methyl groups along the chain.

The most common silicones are the trimethylsilyloxy end-blocked polydimethylsiloxanes, with the following structure:



$(n = 0,1,\ldots)$

These are linear polymers and remain liquids, even for large values of *n*. The main chain unit, $–(Si(CH_3)_2O)–$, or alternatively $(CH_3)_2SiO_{2/2}$, is often represented by the letter D, because when the silicon atom is connected to two oxygen atoms, this unit is capable of expanding the polymer in two directions. M, T, and Q units are defined in a similar manner, being capable of expanding the chain in one, three, and four directions, respectively. These are shown in Table 1.3.2B.2.

The system is sometimes modified by the use of superscript letters to designate nonmethyl substituents, for example, $D^H = H(CH_3)SiO_{2/2}$ and M^Φ or $M^{Ph} = (CH_3)_2(C_6H_5)SiO_{1/2}$ (Smith, 1991). Further examples are shown in Table 1.3.2B.3.

Preparation

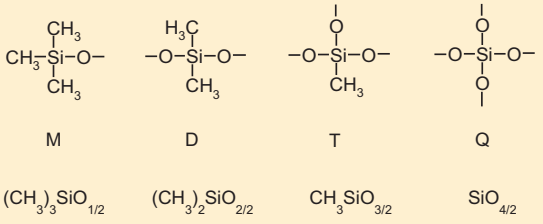
Silicone Polymers

The modern synthesis of silicone polymers is a complex, multistage process. It typically involves the four basic steps described in Table 1.3.2B.4. Only step 4 in this table will be elaborated upon here.

TABLE 1.3.2B.1 Key Milestones in the Development of Silicone Chemistry (Lane and Burns, 1996; Rochow, 1945; and Noll, 1968)

1824	Berzelius discovers silicon by the reduction of potassium fluorosilicate with potassium: $4K + K_2SiF_6 \rightarrow Si + 6KF$. Reacting silicon with chlorine gives a volatile compound later identified as tetrachlorosilane, $SiCl_4$: $Si + 2Cl_2 \rightarrow SiCl_4$
1863	Friedel and Crafts synthesize the first silicon organic compound, tetraethylsilane: $2Zn(C_2H_5)_2 + SiCl_4 \rightarrow Si(C_2H_5)_4 + 2ZnCl_2$
1871	Ladenburg observes that diethyldiethoxysilane $(C_2H_5)_2Si(OC_2H_5)_2$, in the presence of a diluted acid gives an oil that decomposes only at a "very high temperature."
1901–1930s	Kipping lays the foundation of organosilicon chemistry with the preparation of various silanes by means of Grignard reactions and the hydrolysis of chlorosilanes to yield "large molecules." The polymeric nature of the silicones is confirmed by the work of Stock.
1940s	In the 1940s, silicones become commercial materials after Hyde of Dow Corning demonstrates the thermal stability and high electrical resistance of silicone resins, and Rochow of General Electric finds a direct method to prepare silicones from silicon and methylchloride.

TABLE 1.3.2B.2 Shorthand Notation for Siloxane Polymer Units

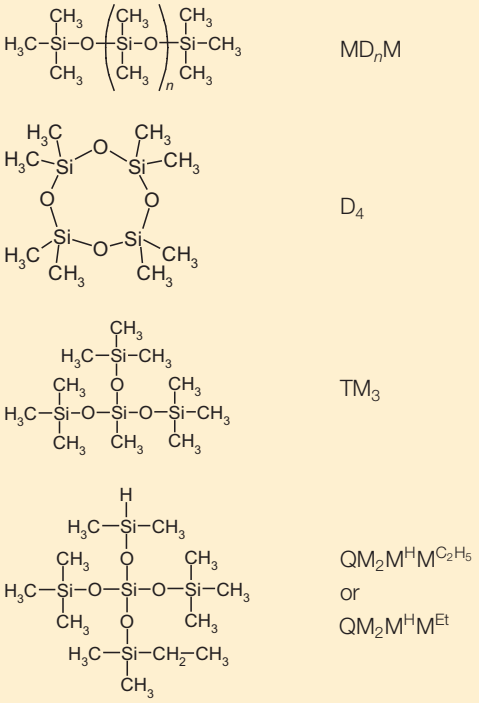


Polymerization and Polycondensation

The linear and cyclic oligomers resulting from dimethyldichlorosilane hydrolysis (step 3) have chain lengths too short for most applications. The cyclics must be polymerized, and the linears condensed, to give macromolecules of sufficient length (Noll, 1968).

Catalyzed by acids or bases, cyclosiloxanes $(R_2SiO)_m$ are ring-opened and polymerized to form long linear chains. At equilibrium, the reaction results in a mixture of cyclic oligomers plus a distribution of linear polymers. The proportion of cyclics depends on the substituents along the Si–O chain, the temperature, and the presence of a solvent. Polymer chain length depends on the presence and concentration of substances capable of giving chain ends. For example, in the KOH-catalyzed

TABLE 1.3.2B.3 Examples of Silicone Shorthand Notation



polymerization of the cyclic tetramer octamethylcyclotetrasiloxane $(Me_2SiO)_4$ (or D_4 in shorthand notation), the average length of the polymer chains depends on the KOH concentration:

$$x(Me_2SiO)_4 + KOH \rightarrow (Me_2SiO)_y + KO(Me_2SiO)_zH$$

A stable hydroxy-terminated polymer, $HO(Me_2SiO)_zH$, can be isolated after neutralization by stripping the mixture under vacuum at elevated temperature. This removes the remaining cyclics and leaves a distribution of linear chains with different lengths.

The reaction can also be made in the presence of Me_3Si-$OSiMe_3$, which acts as a chain end-blocker:

$$\sim\!\!\sim Me_2SiOK + Me_3SiOSiMe_3$$
$$\rightarrow \sim\!\!\sim Me_2SiOSiMe_3 + Me_3SiOK$$

where $\sim\!\!\sim$ represents the main chain.

The Me_3SiOK formed attacks another chain to reduce the average molecular weight of the linear polymer formed.

Substitution of the KOH catalyst for ME_4NOH and introduction of the chain end-blocker, $Me_3SiOSiMe_3$, has significant and interesting effects on the copolymerization of $(Me_2SiO)_4$ (Noll, 1968). The cyclics are initially polymerized into very long, viscous chains that are subsequently reduced in length by the addition of terminal groups provided by the end blocker, which is slower to react. The viscosity of the material correspondingly peaks at the beginning of the reaction and then decreases. This behavior is attributed to the silicon in the cyclics being more susceptible to nucleophilic attack by the base catalyst because of its

TABLE 1.3.2B.4 The Basic Steps in Silicone Polymer Synthesis

1. Silica reduction to silicon	$SiO_2 + 2C \rightarrow Si + 2CO$
2. Chlorosilanes synthesis	$Si + 2CH_3Cl \rightarrow (CH_3)_2SiCl_2 + CH_3SiCl_3 + (CH_3)_3SiCl + CH_3HSiCl_2 + \ldots$
3. Chlorosilanes hydrolysis	4. Polymerization and poly-condensation	
two flanking oxygen atoms, as opposed to the silicon in the end-blocker, which is substituted by only one oxygen atom. This reaction can be described as follows:

$$Me_3SiOSiMe_3 + x(Me_2SiO)_4 \overset{cat}{\rightarrow} Me_3SiO(Me_2SiO)_nSiMe_3$$

or, in shorthand notation:

$$MM + xD_4 \overset{cat}{\rightarrow} MD_nM$$

where $n = 4x$ (theoretically).

The ratio between D and M units defines the average molecular weight of the polymer formed.

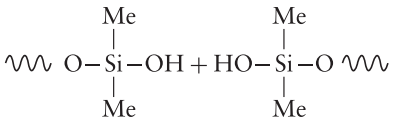
Catalyst removal (or neutralization) is always an important step in silicone preparation. Most catalysts used to prepare silicones can also catalyze the depolymerization (attack along the chain), particularly at elevated temperatures when in the presence of traces of water.

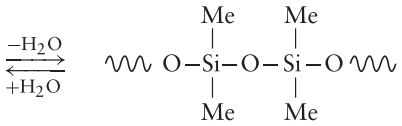
$$\sim\!\sim(Me_2SiO)_n\sim\!\sim + H_2O$$
$$\xrightarrow{cat} \sim\!\sim(Me_2SiO)_yH + HO(Me_2SiO)_z\sim\!\sim$$

It is therefore essential to remove all remaining traces of the catalyst to provide the silicone optimal thermal stability. Labile catalysts have been developed that either decompose or volatilize above the optimum polymerization temperature and can, consequently, be eliminated. Thus, catalyst neutralization or filtration can be avoided (Noll, 1968).

The cyclic trimer $(Me_2SiO)_3$, D_3, has internal ring tension and can be polymerized without reequilibration of the resulting polymers. With this cyclic, polymers with narrow molecular weight distribution can be prepared, as well as polymers only carrying one terminal reactive functionality (living polymerization). Starting from a mixture of cyclics with different internal ring tensions also allows preparation of block or sequential polymers (Noll, 1968).

When catalyzed, linears can combine into long chains by intermolecular condensation of the silanol terminal groups (Noll, 1968; Stark et al., 1982).





This reaction yields a distribution of chain lengths. Adjustment of reaction conditions, e.g., reduction or residual water by increasing temperature or applying vacuum, can shift the distribution.

In addition to the polymers described above, reactive polymers can also be prepared. This result can be achieved when reequilibrating oligomers or existing polymers to first produce a polydimethylmethylhydrosiloxane, $MD_zD^H_wM$.

$$Me_3SiOSiMe_3 + x(Me_2SiO)_4 + Me_3SiO(MeHSiO)_ySiMe_3$$
$$\overset{cat}{\rightarrow} \text{cyclics} + Me_3SiO(Me_2SiO)_z(MeHSiO)_wSiMe_3$$

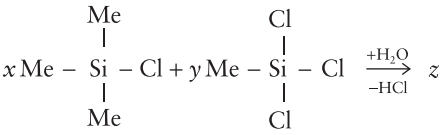
Additional functional groups can be attached to this polymer using an addition reaction.

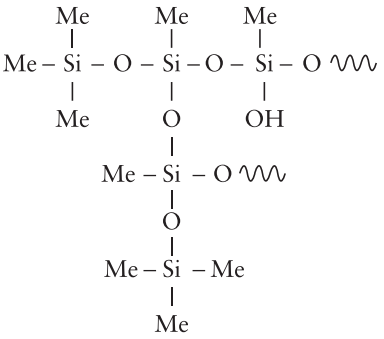
$$Me_3SiO(Me_2SiO)_z(MeHSiO)_wSiMe_3 + H_2C = CHR$$

$$\xrightarrow{Pt\ cat} Me_3SiO(Me_2SiO)_z(Me\underset{\displaystyle CH_2CH_2R}{\underset{|}{Si}}O)_wSiMe_3$$

All the polymers heretofore shown are linear or cyclic, comprising mainly of difunctional units, D. Branched polymers, or resins, can be prepared if, during hydrolysis of the chlorosilanes, a certain amount of T or Q units are included; this allows molecular expansion in three or four directions, as opposed to just two. For example, consider

the hydrolysis of methyltrichlorosilane in the presence of trimethylchlorosilane, which leads to a branched polymer:





The resulting polymer can be described as $(Me_3SiO_{1/2})_x(MeSiO_{3/2})_y$, or M_xT_y using shorthand notation. The formation of three silanols on the $MeSiCl_3$ by hydrolysis yields a three-dimensional structure, or resin, after condensation, rather than a linear polymer. The average molecular weight depends upon the number of M units that come from the trimethylchlorosilane, which limits the growth of the resin molecule. Most of these resins are prepared in a solvent and usually contain some residual hydroxyl groups. These groups could subsequently be used to cross-link the resin and form a continuous network.

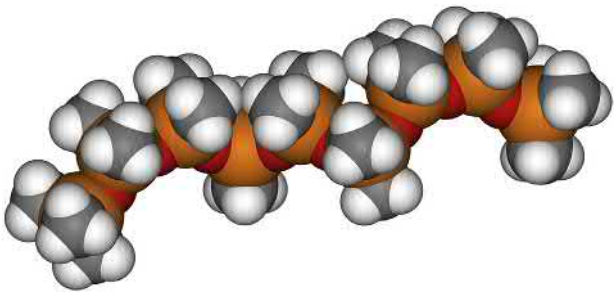
Physicochemical Properties

The position of silicon just under carbon in the periodic table led to a belief in the existence of analog compounds where silicon would replace carbon. Most of these analog compounds do not exist, or behave very differently from their carbon counterparts. There are few similarities between Si–X bonds and C–X bonds (Stark et al., 1982; Corey, 1989; Hardman, 1989; Lane and Burns, 1996).

Between any given element and Si, bond lengths are longer than for the element and C. The lower electronegativity of silicon ($\chi_{Si} \approx 1.80$, $\chi_C \approx 2.55$) leads to a very polar Si–O bond compared to C–O. This bond polarity also contributes to strong silicon bonding; for example, the Si–O bond is highly ionic and has a high bond energy. To some extent, these values explain the stability of silicones. The Si–O bond is highly resistant to homolytic scission. On the other hand, heterolytic scissions are easy, as demonstrated by the reequilibration reactions occurring during polymerizations catalyzed by acids or bases.

Silicones exhibit the unusual combination of an inorganic chain similar to silicates and often associated with high surface energy, but with side methyl groups that are very organic and often associated with low surface energy (Owen, 1981). The Si–O bonds are moderately polar, and without protection would lead to strong intermolecular interactions (Stark et al., 1982). Yet, the methyl groups, only weakly interacting with each other, shield the main chain (see Fig. 1.3.2B.1).

This shielding is made easier by the high flexibility of the siloxane chain. Rotation energy around a $H_2C–CH_2$ bond in polyethylene is 13.8 kJ/mol, but is only 3.3 kJ/mol around a $Me_2Si–O$ bond, corresponding to nearly free rotation. Thus, barriers to rotation are low, enabling the siloxane chain to adopt many configurations. In general, the configuration adopted by the siloxane chain will expose the maximum number of methyl groups to the outside. Conversely, the relative rigidity of the hydrocarbon polymer backbone will not allow selective exposure of the organic and hydrophobic methyl groups. In silicones, chain-to-chain interactions are low and the distance between adjacent chains is also great. Despite a very polar chain, silicones can be compared to paraffin, with a low critical surface tension of wetting (Owen, 1981).



• **Figure 1.3.2B.1** Space-filling model of polydimethylsiloxane (PDMS).

Types, Properties, and Preparation of Silicone Materials

The versatility of silicone polymers enables their formulation into a variety of materials with vastly different cure chemistries, material properties, and processing requirements. The end-use will dictate the appropriate material selection and covers a diverse set of applications ranging from orthopedic soft-gel inserts to tubing for bio-pharma processing to prosthetic attachment. A brief overview of these silicone-based materials is described below and summarized in Table 1.3.2B.5.

Silicone Elastomers

Silicone polymers can easily be transformed into a three-dimensional network by way of a cross-linking reaction (often called "curing"), which allows formation of chemical bonds between adjacent chains. The majority of silicone elastomers are cross-linked according to one of the following three reactions, which are summarized in Table 1.3.2B.6.

1. Cross-linking with radicals
2. Cross-linking by condensation
3. Cross-linking by addition.

The preferred cure system can vary by application. For example, silicone medical bonding adhesives often use acetoxy cure (condensation cross-linking), while platinum cure (cross-linking by addition) is typically used for precise silicone parts with no byproducts.

Elastomer Filler

Most silicone elastomers incorporate "filler." Besides acting as a material extender, as the name implies, filler acts to reinforce the cross-linked matrix. The strength of silicone polymers without filler is unsatisfactory for most applications (Noll, 1968).

TABLE 1.3.2B.5 Types of Silicone Materials and Processing for Medical Applications

Type of Silicone Material	Primary Processing Technique(s)	Examples of Use in Medical Applications
High consistency rubber	High-shear mixing (e.g., two-roll mill, twin conical screw mixer) followed by compression, transfer, or injection molding	Catheters, shunts, drains, tubing for bio-pharma processing
Liquid silicone rubber	Liquid injection molding	High-volume silicone parts molding
Room-temperature vulcanizing elastomer	Hand-mixing, de-airing, and casting	Dental impression molds, encapsulation
Silicone gel	Mixing and filling into envelope shell	Breast, testicular, and soft-tissue implants or external prosthetics
Silicone bonding adhesives	Application onto surfaces to be adhered	Medical device assembly, electrical component encapsulation
Silicone pressure-sensitive adhesives	Coating onto substrate, optional heating to remove solvent	Attachment of hairpieces, prosthetics, and other devices to the body; Transdermal drug delivery
Silicone gel adhesives	Two-parts mixed coated onto a substrate and then heated to cure	Soft skin adhesive for wound and scar-care applications
Silicone film-in-place, fast-cure elastomers	Spreading or spraying onto surface; cures at ambient temperature	Spray-on wound dressings Drug-loaded lotions Topical analgesics

The addition of reinforcing fillers reduces the tackiness of the silicone, increases its hardness, and enhances its mechanical strength. Fillers might also be employed to affect other properties; for example, carbon black is added for electrical conductivity, or barium sulfate to increase radiopacity. These and other materials are used to pigment the otherwise colorless elastomer; however, care must be taken to select only pigments suitable for the processing temperatures and end-use application.

The most widely used reinforcement is obtained by using fumed silica, such as Cab-O-Sil, Aerosil, or Wacker HDK. Fumed silica is produced by the vapor phase hydrolysis of silicon tetrachloride vapor in a hydrogen/oxygen flame:

$$SiCl_4 + 2H_2 + O_2 \xrightarrow{1800^\circ C} SiO_2 + 4HCl$$

Unlike many naturally occurring forms of crystalline silica, fumed silica is amorphous. The very small spheroid silica particles (in the order of 10 nm in diameter) fuse irreversibly while still semimolten, creating aggregates. When cool, these aggregates become physically entangled to form agglomerates. Silica produced in this way possesses remarkably high surface area (100–400 m^2/g) (Noll, 1968; Cabot Corporation, 1990). Reinforcement occurs with polymer adsorption encouraged by the large surface area of the silica, and when hydroxyl groups on the filler surface lead to hydrogen bonds between the filler and the silicone polymer. In this way, reinforcing filler contributes to the high tensile strength and elongation capability of silicone rubber (Lynch, 1978).

The incorporation of silica filler into silicone polymers is accomplished prior to cross-linking, by mixing the silica into the silicone polymers. This addition increases the already high viscosity of the polymer, resulting in viscosities from 10,000 to well over 100,000 mPa s. The mixing, therefore, typically occurs on a two-roll mill, in a twin-screw extruder, or in a Z-blade mixer capable of processing materials with this rheology.

Chemical treatment of the silica filler with silanes enhances its incorporation in, and reinforcement of, the silicone elastomer, resulting in increased material strength and tear resistance (Fig. 1.3.2B.2).

Processing of Silicone Elastomers

After blending the silicone polymer with amorphous silica filler, an initiator and/or cross-linker, and catalyst are needed to cure the elastomer. To avoid premature cure these ingredients must be separated until use. Consequently, products for making silicone elastomers are generally supplied as two-component or two-part kits, for example, a base and a peroxide paste, or a kit made of part A containing polymer and catalyst, and part B containing polymer and cross-linker. These two components are mixed at a fixed ratio at the point of use and formed into the desired shape before cure.

Silicone elastomers are thermosetting materials. Unlike a thermoplastic, which can be remelted and formed again, a cured silicone elastomer part cannot be reprocessed. They must be formed into the appropriate shape and configuration prior to cross-linking. Suitable methods for shaping silicone elastomers include casting, extrusion, and molding. The process selected depends on the viscosity of the feedstock elastomer material and the shape of the desired cured elastomer part.

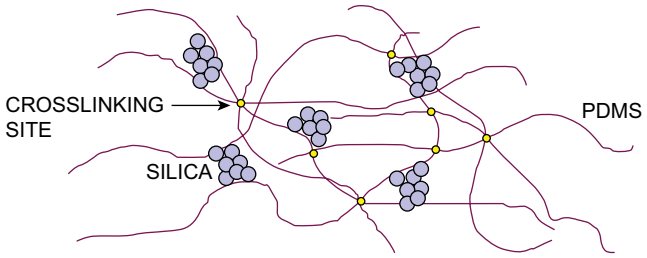
High Consistency Rubber (HCR). If very high-molecular-weight silicone polymers are used (silicone "gums" in the trade) to produce an elastomer, the resulting material is an HCR. These materials have high tear strengths and tensile elongations. Uncured HCRs are putty-like materials that require high shear equipment for processing. The most common technique for HCR processing is extrusion and is

TABLE 1.3.2B.6 Types of Cross-linking (Curing) of Silicone Materials

Crosslinking Scheme/ Mechanism	Usual Components	Main Reaction(s)	Typical Uses	Pros	Cons
• Radical Cross-linking • Free-radical polymerization	• Vinyl-containing polymers[a] • Organic peroxide initiator	$R^{\cdot} + CH_2=CH-Si\equiv \rightarrow R-CH_2-CH^{\cdot}-Si\equiv$ $RCH_2-CH^{\cdot}-Si\equiv + CH_3-Si\equiv$ $\rightarrow RCH_2-CH_2-Si\equiv + \equiv Si-CH_2^{\cdot}$ $\equiv Si-CH_2^{\cdot} + CH_2=CH-Si\equiv$ $\rightarrow \equiv Si-CH_2-CH_2-CH^{\cdot}-Si\equiv$ $\equiv Si-CH_2-CH_2-CH^{\cdot}-Si\equiv + CH_3-Si\equiv$ $\rightarrow \equiv Si-CH_2-CH_2-CH_2-Si\equiv + \equiv Si-CH_2^{\cdot}$ $2\equiv Si-CH_2^{\cdot} \rightarrow \equiv Si-CH_2-CH_2-Si\equiv$	High consistency silicone rubbers, such as those used in extrusion, compression, or injection molding	Can be used at high temperatures	• Depending on the peroxide initiator selected, voids can form due to volatile residues during processing • Post-cure may be needed to remove volatiles, which can catalyze depolymerization at high temperatures
• Condensation, one-part RTV (room-temperature vulcanization) • Moisture-initiated condensation reaction	• Hydroxy end-blocked polydimethyl siloxane • Methyl triacetoxysilane[b] • Tin-catalyst		Medical device bonding adhesives, encapsulants, and sealants	Cure at room temperature	• Acetic acid byproduct can be undesirable for certain applications[b] • Can take significant time for complete cure, ~24 h, because reaction proceeds from outside in as moisture diffuses into the material • Needs base levels of moisture to initiate and sustain cure • Can have limited shelf-life
• Condensation, two-part RTV • Condensation reaction initiated by component mixing	• Hydroxy end-blocked polydimethyl siloxane • Alkoxysilane, such as tetra-*n*-propoxysilane, $Si(OnPr)_4$ • Organotin salt catalyst		Medical device bonding adhesives, encapsulants and sealants	• Cure at room temperature • Cure byproduct is alcohol • Longer shelf-life than the corresponding one-part system	• Shrinkage can occur after cure at room temperature (0.5%–2% linear shrinkage). Not recommended for use in parts with precise tolerances • Organotin salt catalyst limits stability of resulting elastomer at high temperatures
• Addition-Cure • Platinum-catalyzed addition reaction	• Vinyl end-blocked polymers • Si–H groups carried by a functional oligomer • Pt "Karstedt" catalyst		• Molded silicone elastomer components • Silicone gel	• Can eliminate shrinkage issue in condensation reactions • No byproducts	• Two-part product, which will begin to react immediately upon mixing (unless an inhibitor is used) • Pt in the complex is easily rendered inactive, or "poisoned," if inadvertently bonded to electron-donating substances such as amine or organosulfur compounds

[a]Efficient cross-linking with radicals is achieved only when some vinyl groups are present on the polymer chains; using so-called vinyl-specific peroxides; however peroxide-initiated cross-linking of unsubstituted poly(dimethylsiloxane) can be practiced.

[b]The methyltriacetoxysilane can be replaced by oximosilane $RSi(ON=CR')_3$ or alkoxysilane $RSi(OR')_3$ to avoid acetic acid by-product.



• **Figure 1.3.2B.2** Silicone elastomer/silica network.

primarily used to produce tubing for bio-pharma processing (Colas et al., 2004). Less common processing techniques include compression, transfer, and injection molding.

Liquid Silicone Rubber (LSR). To obtain a liquid silicone rubber, lower molecular weight silicone polymers are blended with silica. The viscosity of the resulting LSR is correspondingly lowered as compared to an HCR. The LSRs are supplied as two-part kits, which can be pumped, metered, mixed, and directly injected into the molding cavity. Their processing is further eased by the shear-thinning effect that occurs during pumping and injection, reducing the viscosity and injection pressure of the LSR blend.

LSRs are particularly well-suited for long automated production runs as the pumping, metering, and injecting into the molding cavity can be both accomplished and precisely controlled with automation. This does incur higher up-front equipment costs and initial process development time to ensure proper mold temperature control, allowance for venting (air escape from mold cavity during injection), appropriate mold filling rate (to not over- or underfill the mold), prevention of premature curing, and complete product ejection after cure. This acquisition cost is usually justified for large production runs as they provide for more efficiency in terms of mold cycle time, overall processing time, and material usage (Sommer, 2003).

Room Temperature Vulcanizing (RTV) Elastomers. In addition to HCRs and LSRs, which are designed to cure by exposure to heat, other silicone elastomers, known as RTVs, are intended to be cured at room temperature. These materials rely on moisture in the air to cure via a condensation reaction (described in Table 1.3.2B.6), but can also be prepared using a platinum-catalyzed two-part addition reaction.

Typically, RTV elastomers are provided in two-part systems and can be viewed as a variation of LSR, but with lower viscosity and less inhibitor. They can be mixed either by hand or a simple lab mixer, de-aired, and then cast. They are commonly used in laboratory trials as a product development tool, but also have medical commercial applicability, e.g., for dental impression molding.

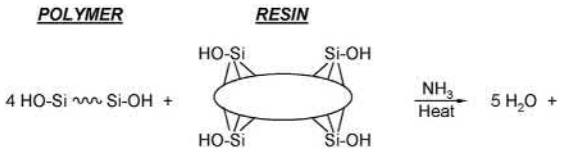
Silicone Gels

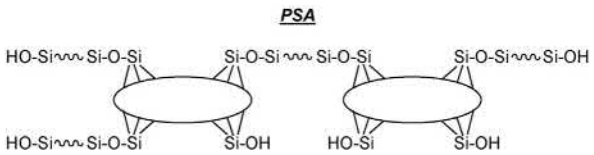
Silicone gels are typically composed of a very lightly cross-linked silicone elastomer whose polymer network has been swollen with silicone fluids or, less commonly, nonsilicone fluids, such as mineral oil. However, these gels contain no silica or other fillers. Silicone gel is often supplied in a two-part fluid system and cures via a platinum-catalyzed addition reaction. Parts A and B are mixed at a desired ratio and cured (usually by exposure to elevated temperature) to yield a sticky, but cohesive mass. The consistency of the material can be controlled by the degree of cross-linking and the type and quantity of swelling fluid. After mixing, but before cure, the mixture is still liquid and can be cast onto substrates or pushed through a large-gauge needle, enabling the filling of voids e.g., preformed shells, molds, or pouches.

Silicone Adhesives

Three basic types of silicone adhesives are used in medical applications: bonding, pressure-sensitive, and gel.

1. *Bonding adhesives.* Silicone bonding adhesives are used to attach components together and to seal seams and junctions. Electrical components can also be encapsulated and insulated using silicone bonding adhesive. Silicone bonding adhesives are most commonly formulated as one-part RTV elastomer systems that use a condensation cross-linking reaction, as described earlier in this chapter.
2. *Pressure-sensitive adhesives.* Silicone PSAs are typically formulated in solvent. Silanol end-blocked PDMS undergoes a polycondensation reaction with silicate resin in the presence of ammonia as catalyst. The ammonia is stripped with heat and usually the solvent is exchanged. For some applications, a hot-melt PSA can be used with no solvent.





The resulting materials, in addition to being adhesive to skin and other substrates, are highly flexible and permeable to moisture vapor, CO_2, and oxygen. An additional class of silicone PSAs has been developed by incorporating a subsequent reaction step that converts the pendant ≡SiOH groups into ≡SiOSi$(CH_3)_3$ groups via a reaction with hexamethyldisilazane.

3. *Gel adhesives.* Silicone gel adhesives are supplied in a solventless, two-part system and are cured via a platinum-catalyzed addition reaction run at elevated temperatures. The materials can be coated as a thin film onto a backing substrate such as polyurethane. These materials, also called soft-skin adhesives, have gentler and less traumatic removal from skin than the pressure-sensitive alternatives.

Silicone Film-in-Place, Fast-Cure Elastomers

In addition to the cured silicone elastomers in skin contact applications, in situ cure materials have been developed.

These materials form films when spread or sprayed on the skin, and then undergo RTV cure. The ability of silicone to spread and form films is related to its low surface tension as described in the Physicochemical Properties section above (Maxon et al., 2004).

Biocompatibility of Silicones

There has been much discussion regarding the various definitions of the term *biocompatibility.* We now take it to mean "the ability of a material to perform with an appropriate host response in a specific situation" (Black, 1992; Remes and Williams, 1992). The material properties of silicone, such as hydrophobicity, have been related to biocompatibility properties such as reduced hemolytic potential. Additionally, the relative purity of silicone, its high-molecular-weight polymeric nature, and its chemical structure provide a theoretical basis for its lack of toxicity. Historically it has been tacitly understood that silicone materials are intrinsically biocompatible, since they have been used successfully in so many healthcare applications. However, given the modern definition of the term, no material can be assumed to be universally biocompatible, since this implies that it is suitable for every conceivable healthcare application involving contact with the host patient.

Numerous silicone materials have undergone biocompatibility testing. Many have passed every bioqualification test; however, others have not. Several factors can affect the results of such testing, including the composition of the material. As described previously, the basic polydimethylsiloxane (PDMS) polymer can be modified by replacing the methyl groups with other functional groups. In some cases, those groups may be responsible for an untoward host response. There may be byproducts from the preparation of silicone materials that might trigger tissue reaction, e.g., acetic acid, peroxide initiator, etc.

Purity is another factor that can affect biotest results. Medical silicone materials, including fluids, gels, elastomers, and adhesives, are manufactured by several companies today. Some of these firms manufacture these medical materials following good manufacturing practice (GMP) principles in dedicated, registered, and inspected facilities. Others sell materials generated on their industrial production line into the healthcare market.

Selection of appropriate preclinical material bioqualification tests for their application is the responsibility of the medical device or pharmaceutical manufacturer. Several national, international, and governmental agencies have provided guidance or regulation. Several silicone manufacturers offer special grades of materials that have met these specific requirements. The buyer should carefully investigate the supplier's definition, since there are no universal special-grade definitions.

At DuPont, BioMedical Grade materials have been qualified to meet or exceed the requirements of ISO 10993-1, USP (United States Pharmacopeia) Class V Plastics tests (acute systemic toxicity and intracutaneous reactivity), hemolysis, cell culture, skin sensitization, mutagenicity, pyrogenicity, and 90-day implant testing. Other physicochemical qualification tests have been conducted, such as certain tests from the *European Pharmacopoeia*. Specific information regarding material biotesting can be found in other chapters of this text. Testing of the device in finished form should follow material bioqualification tests such as those described above.

Biodurability of Silicones

Traditionally we have thought of *biocompatibility* as the situation in which the biomaterial has minimal adverse impact on the host. Conversely, *biodurability* is where the host has a minimal adverse effect on the biomaterial. The biodurability of silicone in medical applications is likely related to its exceptional thermal and chemical stability.

Silicones are used in numerous applications requiring high temperature resistance (Noll, 1968; Stark et al., 1982). During thermogravimetric analysis and in the absence of impurities, poly-dimethylsiloxane degradation only starts at around 400°C. Thus, silicones remain essentially unaffected by repeated sterilization by autoclaving and they can usually also be dry-heat sterilized. Other sterilization methods can be used, such as ethylene oxide exposure and gamma and e-beam irradiation—although care must be taken to ensure complete sterilant outgassing in the former and that the dosage does not affect performance properties in the latter.

Although silicones can be chemically degraded, particularly at elevated temperatures, by substances capable of acting as depolymerization catalysts (Stark et al., 1982), their hydrophobic nature limits the extent of contact with many aqueous solutions. Typically, the biologic milieu does not present a particularly hostile chemical environment for silicone. A notable exception, however, is the stomach, which excretes large amounts of hydrochloric acid, capable of attacking PDMS if it remains there too long. Based on silicone elastomer performance in long-term implantation applications in other sites, its biodurability is generally considered excellent (Table 1.3.2B.7).

The chemical stability associated with silicones became so well-established that it has been formulated into other biomaterials, such as polyurethane, to enhance their biodurability (Pinchuk et al., 1988; Ward, 2000; Christenson et al., 2002; Ward et al., 2006a,b).

Notwithstanding the chemical stability of silicone, certain factors have been shown to affect its durability in terms of long-term in vivo performance. The hydrophobic elastomer is somewhat lipophilic and can be swollen by lipids or other nonpolar agents. Early experience with in vivo failure of silicone-containing heart valves was traced to elastomer absorption of lipids from the blood that resulted in significant dimensional swelling (McHenry et al., 1970). In most cases the absorption was low and failures did not occur, but in a small percentage of cases the silicone was absorbing quantities sufficient to affect valve performance. Researchers speculated that variations in silicone poppet manufacture, such as cure, might have been a factor (Carmen and Mutha, 1972). Absorption of lipids was a variable reported by Swanson and LeBeau (1974) and Langley and Swanson (1976). The work of Brandon et al. (2002, 2003) has shown that the shells of silicone gel-filled breast implants also absorb silicone fluid (from the gel), causing a minor diminution in mechanical properties, one that is reversed after extraction of the elastomer.

TABLE 1.3.2B.7 Biodurability Studies of Silicone Elastomer and Medical Implants

Year	Researchers	Synopsis
1960	Ames	Explant examination of a clinical silicone ventriculocisternostomy shunt used in the treatment of hydrocephalus showed "the silicone rubber tubing was unchanged by three years implantation in the tissues of the brain and in the cervical subarachnoid space." Similarly, after over 3 years implantation of silicone tubing in the peritoneal cavity of dogs, Ames wrote, "The physical properties of the tubing itself are apparently unchanged by prolonged contact with tissues."
1963	Sanislow and Zuidema	Silastic T-tubes were placed in the common ducts of dogs and explanted 9 months later. They were found to be free of bile-salt precipitation and completely patent. Four were tested for tensile strength and compared with a control sample from the same lot of elastomer. "These tests suggested that little physical change occurred in the Silastic as a result of prolonged contact with animal bile." The tensile strength after 9 months was reported as 1130 psi (7.8 MPa), the same value as reported for the nonimplanted control.
1964	Leininger et al.	The Battelle Memorial Institute examined the biodurability of five plastics by implanting films in dogs for 17 months' duration. The material's tensile strength and elongation were measured and compared with nonimplanted controls. Although sizable changes were seen in the tensile properties of polyethylene, Teflon, and nylon, the results for Mylar and Silastic remained essentially the same.
1974	Swanson and LeBeau	"Dog-bone"-shaped specimens of medical-grade silicone rubber were implanted subcutaneously in dogs. Tensile properties and lipid content were measured at 6 months and 2 years post-implantation. A slight but statistically significant decrease in measured ultimate tensile strength and elongation were observed, as well as a small weight increase attributed to lipid absorption.
1976	Langley and Swanson	Mechanical test specimens were implanted in dogs for 2 years. Tensile strength, elongation, and tear resistance showed no statistically significant changes. Lipid absorption into the elastomer ranged from 1.4% to 2.6%.
2000	Curtis et al.	Six silicone breast implants surgically excised after 13.8–19.3 years and 10 similar nonimplanted units were tested to determine shell tensile properties and molecular weight of silicone gel extracts. The "study observed only minor changes (less than the explant or implant lot-to-lot variation range) in the tensile strength of Dow Corning silicone breast implants after nearly twenty years of human implantation." The gel extract molecular weight was either unchanged by implantation or increased slightly.
2003	Brandon et al.	In the most comprehensive study of breast implant biodurability heretofore published, the authors reported their results of tensile, cross-link density, and percent extractable measurements made on 42 explants and 51 controls. The study included some of the oldest explants, with human implantation durations up to 32 years. The researchers also performed a literature search and plotted all published explant tensile modulus data against implantation duration, finding no temporal relationship. Neither was a relationship with implant time seen for the cross-link density results, supporting the biodurability of the silicone elastomer utilized in the implant shells. The researchers concluded, "There was little or no degradation of the base polydimethylsiloxane during in vivo aging in any of the implants we examined."
2008	Taylor et al.	Silicone biodurability after long-term implantation was examined by a highly sensitive NMR spectroscopy technique as well as NMR relaxometry measurements of explanted gel breast implants and matched nonimplanted controls. No evidence of chemical degradation of the cross-linked silicone matrix was observed in specimens explanted after as many as 32 years in vivo underscoring the biostability of the cross-linked silicone shell and gel.

Medical Applications

Silicones, with their unique set of material properties, have found widespread use in the healthcare field. These properties include hydrophobicity, low surface tension, and thermal and chemical stability, which enable both the biocompatibility and biodurability of silicones.

Siliconization

The hydrophobic character of silicone materials led to their consideration for blood coagulation prevention in the mid-1940s. Researchers from the Universities of Toronto and Manitoba obtained a methylchlorosilane from the Canadian General Electric Company and coated syringes, needles, and vials with the material. When rinsed with distilled water, the silane hydrolyzed, forming a silicone coating on the substrate. The researchers found that the silicone treatment "on glassware and needles gives a surface which preserves blood from clotting for many hours" (Jaques et al., 1946). According to researchers at the Mayo Clinic, silicone: "was the most practical of any known [substance] for coating needle, syringe and tube" (Margulies and Barker, 1949). They further demonstrated that leaving blood in silicone-coated syringes had no significant persistent effect on the blood as a measure of coagulation time after being dispensed. Soon the use of silicone precoating of needles, syringes, and blood collection vials became commonplace. In addition to the blood-preserving quality of silicone, it

was discovered that coated needles were less painful (Fig. 1.3.2B.3). Today most hypodermic needles, syringes, and other blood-collecting apparatus are coated or lubricated with silicone.

Silicone materials have also found uses in the medical laboratory, including silicone tubing for fluid transport between vessels, e.g., bio-pharma processing, and silicone impression materials for dentistry (Starke, 1975; Colas et al., 2004).

Extracorporeal Equipment

Silicone tubing and membranes have found applications in numerous extracorporeal machines, e.g., kidney dialysis, blood oxygenators, and heart bypass machines; silicone is particularly well suited for these applications due in large part to its hemocompatibility and gas-permeability properties. Blood compatibility was also a factor in the incorporation of silicone in several mechanical heart valves (Fig. 1.3.2B.4). The use of silicone in extracorporeal applications continues today.

Medical Inserts and Implants

Silicone implants are literally found from head-to-toe, as detailed in Table 1.3.2B.8 and shown in Fig. 1.3.2B.4. Their use ranges from silicone vitreous fluid replacement in the eye to encapsulation of the electronics on a cardiac pacemaker to finger and toe joint replacements. Material selection will depend on numerous factors including intended function, required mechanical integrity, length of residence in the body, location, etc.

Catheters, Drains, and Shunts

Silicone elastomers are widely used in female and male urinary catheters for intermittent and longer term usage. These include devices composed entirely of extruded silicone elastomers and devices composed of nonsilicone substrates that are subsequently coated to reduce the host reaction. For example, the Silastic Foley is a latex catheter whose interior and exterior are coated with a silicone elastomer (Fig. 1.3.2B.4). Depending on their construction, these silicone catheters can

TABLE 1.3.2B.8 Anatomic Placement of Example Silicone Implants

Head and Neck	
Brain	Hydrocephalus shunts
Skull	Burr hole covers
Eye	Scleral bands and buckles Vitreous fluid replacement Intraocular lenses Contact lenses
Ear	Elastomer tubes for ontological ventilation Cochlear implants (encased in silicone)
Throat	Voice-box prostheses, post-laryngectomy
Torso	
Cardiac	Pacemaker encapsulated and leads insulated with silicone Mechanical heart valves
Gastric	Gastric band implant (Lap-Band, Realize) Angelchik antireflux device
Urinary System	
Urinary tract	Silicone urological catheters Urethral stents Artificial urethra
Bladder	Suprapubic drainage systems
Skeletal Joints	
Hip	Silicone elastomer cement restrictor (bone plug) for total hip replacement
Knee	Shock-absorbing silicone bumper for knee replacement
Hand	Wrist, hand, and finger joint implants
Foot	Foot and toe joint implants
Other	
Breast	Breast implants for post-mastectomy reconstruction or aesthetic augmentation
Scrotum	Testicular implants for congenital defects or post-orchiectomy surgery

be used for temporary insertion or as long-term implants for urethra replacement (DeNicola, 1950).

A particularly notable early example of a silicone medical device was the hydrocephalus shunt, which is implanted in patients suffering a dangerous and often fatal buildup of cerebrospinal fluid (CSF) in the brain. This one-way valve, composed of Silastic brand silicone elastomer and tubing from Dow Corning, allowed excess cerebrospinal fluid (CSF) to drain from the brain into the heart when pressure began to build, but closed to prevent backflow once the pressure equalized (Baru et al., 2001). The silicone used in the shunt could be autoclaved without loss of performance and was stable during long-term implantation. This shunt, now known as the Holter valve, was developed by John Holter, a machinist, when his son, Casey, contracted meningitis and subsequently developed hydrocephalus (LaFay, 1957). It is still being made, almost unchanged, today. The Holter valve and more recent valve/shunt designs have helped save the lives of over one million patients worldwide (Aschoff et al., 1999) (Fig. 1.3.2B.4).

Aesthetic Implants

Silicones have been used extensively in aesthetic and reconstructive plastic surgery for over 50 years. Silicone elastomer is used in implanted prosthetics of numerous descriptions, including breast, scrotum, chin, nose, cheek, calf, and buttocks. Some of these devices may also employ silicone gel, which is a softer feeling substance, contained within a silicone elastomer shell. These are often used for breast, testicular, and chin implants. Surgeons implant these medical devices for aesthetic reasons, to correct congenital deformity, or during reconstructive surgery after trauma or cancer treatment.

The most prominent of these aesthetic implants is the silicone breast implant. Breast enlargement by surgical means has been practiced for over a century. In 1895, Czerny reported transplanting a lipoma to a breast in order to correct a defect resulting from the removal of a fibroadenoma (Czerny, 1895). The insertion of glass balls into the breasts was described by Schwartzmann in 1930 and again by Thorek in 1942. The Ivalon sponge, introduced by Pangman in 1951, was the first augmentation prosthesis to be implanted fairly consistently. This surgical sponge, formulated of poly(vinyl alcohol) cross-linked with formaldehyde, was initially hand-trimmed to the desired shape by the implanting surgeon, and later preformed by Clay Adams, Inc. There was some early recognition of the tendency for tissue growth into the open-cell foam, and in 1958 Pangman patented the concept of encapsulating the foam with an alloplastic (manmade) envelope. His patent also contemplated the use of other fill materials, such as silicone, in place of foam. The Polystan and Etheron polyurethane sponge implants began to be used as breast implants in 1959 and 1960, respectively. These sponge implants became popular in the early 1960s, later being supplanted by the Cronin-type silicone gel-filled breast implants.

With silicone materials and prototypes supplied free of charge from Dow Corning, Doctors Cronin and Gerow developed and tested their silicone gel-filled breast implant in 1961. They implanted the first pair in 1962 (Cronin and Gerow, 1963). Word of their success and the superiority of these silicone implants to the existing foam type led to the popularity of the silicone gel breast implant (Gerow, 1976).

Fig. 1.3.2B.4 shows the appearance of these implants in 1964. The shells of Cronin-type implants were vacuum-molded with anterior and posterior elastomer pieces sealed together, creating a seam around the perimeter of the base. The posterior shell had exposed loops of Dacron mesh attached. The surgeons believed that prosthesis fixation to the chest wall was necessary to prevent implant migration.

Since this early 1964 design, Dow Corning and numerous other companies made prosthesis design improvements, including elimination of the seam and realization that fixation is frequently unnecessary.

In the early 1990s, these popular devices became the subject of a torrent of contentious allegations regarding their safety. The controversy in the 1990s initially involved breast cancer, then evolved to autoimmune connective tissue disease, and continued to evolve to the frequency of local or surgical complications such as rupture, infection, or capsular contracture. Epidemiology studies have consistently found no association between breast implants and breast cancer (McLaughlin et al., 1998, 2007; Park et al., 1998; Brinton et al., 2000; Mellemkjær et al., 2000). In fact, some studies suggest that women with implants may have decreased risk of breast cancer (Brinton et al., 1996; Deapen et al., 1997). Reports of cancer at sites other than the breast are inconsistent or attributed to lifestyle factors (Herdman and Fahey, 2001). The epidemiologic research on autoimmune or connective-tissue disease has also been remarkably uniform, and concludes there is no causal association between breast implants and connective-tissue disease (Gabriel et al., 1994; Sánchez-Guerrero et al., 1995; Hennekens et al., 1996; Edworthy et al., 1998; Nyrén et al., 1998; Kjøller et al., 2001; McLaughlin et al., 2007).

It can be argued that, as a consequence of this examination into the safety of silicone breast implants, silicones are among the most thoroughly tested biomaterials available.

Conclusion

Polydimethylsiloxanes, often referred to as silicones, are a robust class of materials used in a variety of different industries and applications. The inorganic backbone can be functionalized with methyl or other organic groups, while introduction of tri- or tetrafunctional siloxane units leads to a wide range of possible structures. The polymers are easily cross-linked at room or elevated temperatures to form elastomers and other structures. The materials typically exhibit many advantageous properties, including chemical and thermal stability, low surface tension, hydrophobicity, and high gas permeability. These properties combine to result in a biodurable and biocompatible material utilized for medical applications, such as long-term implants, skin-contact adhesives, and transdermal drug delivery.

SIDEBAR 1—LIMITATIONS OF PRESENT-DAY SILICONE MATERIALS

However, versatile as they are, present-day silicone materials still have limitations. The mechanical properties of silicone elastomers, such as tensile strength or tear resistance, are somewhat lower than for other implantable elastomers such as polyurethanes (although generally speaking, polyurethanes are less biodurable). While resistant to a wide array of chemical environments, silicone elastomers are susceptible to degradation in very strongly basic or acidic conditions, such as those found in the stomach. Like all hydrophobic implant materials, silicones are quickly coated with proteins when placed in tissue contact; and a scar tissue capsule forms to surround an implant during wound healing, walling it off from the host. Additionally, silicone elastomers are thermosetting materials, requiring different processing from conventional thermoplastics, such as Teflon or polyetheretherketone (PEEK).

SIDEBAR 2—SURFACE ACTIVITY AND LOW INTERMOLECULAR INTERACTIONS OF SILICONE

The surface activity of silicones is evident in many ways (Owen, 1981):

- Polydimethylsiloxanes have low surface tension (20.4 mN/m) and are capable of wetting most surfaces. With the methyl groups facing outward, this configuration gives very hydrophobic films and a surface with good release properties, particularly if the film is cross-linked after application. Silicone surface tension resides in the range considered most promising for biocompatible elastomers (20–30 mN/m) (Baier, 1985).
- Silicones have a critical surface tension of wetting (24 mN/m), which is higher than their own surface tension. This means silicones are capable of wetting themselves, which promotes good film formation and surface coverage.
- Silicone organic copolymers can be prepared with surfactant properties, with the silicone acting as the hydrophobic part (i.e., in silicone glycol copolymers).

The low intermolecular interactions in silicones have other consequences (Owen, 1981):

- Glass transition temperatures are very low (i.e., 146 K for a polydimethylsiloxane compared to 200 K for polyisobutylene, the analog hydrocarbon).
- The presence of a high free volume compared to hydrocarbons explains the high solubility and high diffusion coefficient of gas into silicones. Silicones have a high permeability to oxygen, nitrogen, and water vapor, even though liquid water is not capable of wetting a silicone surface. As expected, silicone compressibility is also high.
- The viscous movement activation energy is very low for silicones. Their viscosity is less dependent on temperature compared to hydrocarbon polymers. Furthermore, chain entanglements are involved at higher temperature, and contribute to limit viscosity reduction (Stark et al., 1982).

SIDEBAR 3—FILLERS FOR SILICONE ELASTOMERS

Silicone elastomers for medical applications normally use fumed silica as filler, and, occasionally, appropriate pigments or barium sulfate. Because of their low glass transition temperatures, these compounded and cured silicone materials are elastomeric at room and body temperatures without the use of plasticizers, unlike other medical materials such as PVC.

SIDEBAR 4—CURE INHIBITION OF SILICONE ELASTOMERS

Fabricators of silicone elastomer parts should be aware that these LSRs and other addition-cure products contain an inhibitor, a substance that weakly bonds to the platinum catalyst to moderate its activity, permitting sufficient pot life by avoiding premature cure. If contamination occurs with substances capable of bonding more strongly to the platinum catalyst (e.g., amino or thio compounds), the catalyst (which is present in only minute quantities, typically about 10 ppm) may lose activity, resulting in inhibition of cure.

SIDEBAR 5—SILICONE BREAST IMPLANT SAFETY

Numerous systematic reviews (UK IEAG, 1993; France ANDEM, 1996; US IOM, 2000; Australia TDEC, 1997; Germany BgVV, 1998; UK IRG, 1998; EU EQUAM, 2000; US NSP/MDL926, 2001; Spain/EU STOA, 2003) commissioned by various governments have repeatedly and consistently borne out that the evidence fails to support a cause-and-effect relationship between silicone breast implants and systemic diseases. Following FDA approval action on November 17, 2006 making silicone gel breast implants widely available in the United States again, the controversy had diminished.

Recently, however, the controversy has been stoked by the identification of a new, albeit rare, condition called breast implant associated-anaplastic large cell lymphoma (BIA-ALCL). As the nomenclature indicates, the condition is associated with breast implants. The first case was reported in 1997 (Keech and Creech, 1997), the FDA indicated their preliminary interest in the condition in 2011 (US FDA CDRH, 2011), and the World Health Organization designated BIA-ALCL as a provisional disease diagnosis in 2016 (Swerdlow et al., 2016). BIA-ALCL presents as fluid accumulation and edema in the patient's breast implant capsule. Biopsy and serology usually confirm the differential diagnosis. ALCL patients have atypical, monoclonal T-cell proliferation with positive immunohistochemical results for CD30. Like other non-Hodgkin's lymphoma patients, they test negative for anaplastic lymphoma kinase (ALK) (Fleming et al., 2018). Of the estimated 35 million women globally who have received breast implants, there are just over 500 reported cases of BIA-ALCL and 12 associated deaths (Sieber et al., 2017).

Current epidemiology strongly suggests that this disease often has an indolent course, although most patients do undergo explantation and resection of the capsule around the implant. BIA-ALCL is not typically a cancer that will inevitably progress without treatment, in some cases spontaneous regression and resolution have been observed (Fleming et al., 2018).

As this chapter was being revised in late 2018, hypotheses regarding the etiology of BIA-ALCL focused mainly on chronic inflammation and biofilm infection with *Ralstonia* species (a Gram-negative bacilli in the *Burkholderiaceæ* family) (Hu et al., 2016). An extremely interesting factor in the development of this condition is that virtually all of the women diagnosed had implants with textured surfaces (Brody et al., 2010). While this disease has been observed in women with polyurethane foam-covered implants and in implants whose shells were imprinted with the negative texture of such foam, most BIA-ALCL patients had implants with very rough surfaces prepared through the use of a lost-salt process (Brody et al., 2010). In animal implantation studies of several implant surface textures, we observed intensities of inflammation that were consistent with the later clinical outcomes. It is evident that surface properties of alloplastic biomaterials can have a profound and determining effect on biocompatibility and that not all implants, nor implant textures, are created equal (Curtis and Klykken, 2015).

In addition to ALCL being associated almost exclusively with textured breast implants, it is also important to note that it has occurred with saline-filled as well as silicone gel-filled implant types. Material of composition does not appear to be related to the development of this condition as ALCLs have been observed adjacent to multiple implant types with varied materials of construction (Palraj, 2010).

Acknowledgments

A portion of this chapter (here updated) was authored by André Colas and originally published in *Chimie Nouvelle*, the journal of the Société Royale de Chimie (Belgium), Vol. 8 (30), 847 (1990) and is reproduced here with the permission of the editor.

The authors thank S. Hoshaw, Ph.D. and P. Klein, Ph.D. for their contributions regarding breast implant epidemiology.

Chapter Questions

1. Which material property was the basis for Charles Holter's selection of silicone rubber for the hydrocephalic shunt valve?
   a. Biostability
   b. Hemocompatibility
   c. Thermal stability
   d. Viscoelasticity
   e. All of the above
2. Among the following applications where silicones are still in use today, which was the first reported human implantation of a silicone elastomer medical device?
   a. Breast augmentation
   b. Bile duct repair
   c. Hydrocephalus shunt
   d. Urethra repair
3. What functions can fillers serve in silicone elastomers?
   a. Material extender to reduce bulk cost
   b. Reinforce the cross-linked polymer matrix
   c. Provide color pigmentation
   d. Enhance visibility on X-ray
   e. All of the above
4. Draw the molecular structure represented by the shorthand notation TM_2M^H. What is its chemical name?
5. What properties of silicones are responsible for their (a) biodurability and (b) biocompatibility?
6. For the following biomaterials design scenarios, select the preferred material and provide your assumptions and justifications for doing so.
   a. Your customer is designing a syringe. They want to select a material capable of lubricating the interior surface of the syringe to reduce the force required to depress the plunger. Would you select a silicone fluid or a silicone elastomer?
   b. You have two material options for designing an indwelling urinary catheter: (1) silicone elastomer or (2) thermoplastic polymer, e.g., polyvinyl chloride (PVC). Which would you select?
   c. You are designing a wound dressing. It is intended to be used on geriatric patients who are suffering from chronic wounds. The adhesive must be selected such that it provides secure attachment yet gentle release from the skin. Would you select an acrylic adhesive or a silicone tacky gel adhesive?
   d. An artificial tendon is being designed and is intended for implantation. You are primarily concerned about the tensile strength of the material. Would you select a silicone elastomer, a polyurethane elastomer, or PEEK (polyether ether ketone)?
7. Case Study: Sterilization of a silicone elastomer (Foley catheter, neonatal catheter, tubing).

   One of the most significant challenges to consider when designing a medical device is whether and how to sterilize it. Sterilization, which can help to ensure the safety of the device for implantation, can also drastically affect material properties and ultimate stability. Discuss each of the following topics as they would affect the sterilization of a silicone elastomer being used as a Foley catheter, neonatal catheter, tubing, etc.
   a. Would a standard manufacturing facility be sufficient for the production of the catheter or would either cGMP (good manufacturing practice) or clean room facilities be required? How would each process affect the bio-burden and subsequent sterilization required?
   b. What types of sterilization techniques can be used with silicone elastomers?
   c. What are the considerations for each sterilization technique?
   d. What are the consequences of selecting an inappropriate sterilization technique?
   e. How would the biomaterial or device be assessed post-sterilization? How do you guarantee sufficient sterilization?

Chapter Answers

Question 1

The most correct answer is c. While hemocompatibility, biostability, and viscoelastic properties are all related to silicone's successful application in shunts for the treatment of hydrocephalus, thermal stability was the basis for Holter to select silicone rubber for his valve. Steam sterilization deformed other rubbers he tried.

Question 2

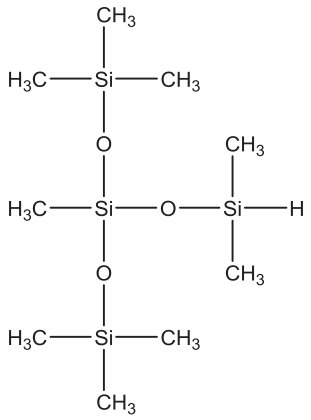
The correct answer is b. While many believe that Holter's silicone hydrocephalic shunts in 1956 were the earliest use, the first reported human implantation of a silicone elastomer medical device was actually a decade before. In April 1946, Dr. Frank Lahey used silicone elastomer materials from the experimental laboratory of General Electric Company called "bouncing clay" for bile duct repair. Silicone materials continue to be used in each of these applications today. The vast majority of today's breast implants still have shells made of silicone elastomer. Silicone stents and T-tubes remain in use for biliary repair. Valved hydrocephalus shunts of silicone—including the popular Pudenz-Schulte and Holter types—continue to save lives. Silicone tubes and catheters continue to find wide urologic use, including in the surgical repair of epi- and hypospadias.

Question 3

The correct answer is e, all of the above. Fillers such as fumed amorphous silica can be used to both extend the material and reinforce the cross-linked polymer matrix. Silicone-compatible dyes and pigments can modify the color of the elastomer. And additives such as barium sulfate increase radiopacity if necessary so implants are visible on X-ray.

Question 4

The long-hand name for TM_2M^H is 3-dimethylsiloxy-heptamethyltrisiloxane. Its structure is below:



Question 5

a. The biodurability of silicone materials is attributed to their tremendous thermal and chemical stability, afforded to them by three specific properties:
   (1) Silicon, when compared to carbon, has much lower electronegativity ($\chi^{Si} \approx 1.80$, $\chi^{C} \approx 2.55$). In the case of the Si–O bond, this electronegativity difference leads to a more polar bond with a high bond energy, which is highly resistant to homolytic scission. This provides improved stability over organic polymers with primarily C–C bonds.
   (2) The side methyl groups on the siloxane polymers shield the polar Si–O backbone from strong intermolecular interactions that could result in degradation.
   (3) Additionally, the Si–O bonds have a low barrier to rotation (3.3 kJ/mol around a Me_2Si–O bond, compared to 13.8 kJ/mol for an H_2C–CH_2 bond). This enables silicone polymers to adopt the most energetically favorable configuration.

b. The biocompatibility of silicones is also due to a combination of unique properties:
   (1) Due to its hydrophobic nature, any implanted silicone material undergoes rapid protein adsorption (opsonization) to its surface. This can limit the host response to the foreign material.
   (2) The cross-linked and/or long-chain silicone polymers used in medical materials will not leach over time in the relatively aqueous environments found within the body. This is due to their hydrolytic stability, which prevents the degradation of these larger silicone molecules into lower molecular weight silicones that would leach more readily. The one exception is in the acidic environment of the stomach, where the elevated level of hydrochloric acid is capable of attacking PDMS over long residence times.
   (3) Silicones have high permeability to oxygen, nitrogen, and water vapor due to their high free volume compared to hydrocarbons.
   (4) Silicones are widely considered to be hemocompatible, having very low hemolytic potential.
   (5) Finally, silicones are able to be manufactured with high levels of purity, with tight controls over the polydispersity of silicone polymers and over the resulting material properties.

Question 6

a. The correct answer is silicone fluid. Silicone elastomers, even when filled with silica that tends to reduce bulk adhesion, remain very tacky and sticky and would not impart a lubricious surface to the interior of a syringe. Silicone fluids, on the other hand, are able to readily form a film on the interior surface (e.g., barrel) of a syringe due to their critical surface tension of wetting being lower than their own surface tension. This leaves a lubricating surface on the syringe and, additionally, can help prevent blood coagulation.

b. The correct answer is the silicone elastomer. Although widely used in urinary catheters due to their low cost, PVC (and other thermoplastic) catheters are less flexible than their silicone counterparts and the plasticizers required to soften the material can have deleterious effects over long-term use. Silicone elastomer catheters have excellent biocompatibility, but can require lubrication to easily insert the catheter into the urinary tract.

c. The correct answer is the silicone tacky gel adhesive. In patients with compromised skin, such as the geriatric population, a silicone soft skin adhesive dressing will provide secure attachment of a wound dressing while maintaining a gentle release profile, which is less likely to further damage the skin. Acrylic adhesives are inexpensive, can be coated at low coat weights, and provide strong attachment to the skin. This strong attachment, coupled with acrylic adhesives potentially sensitizing skin over repeated exposures, makes it a less gentle alternative for wound dressings.

d. The correct answer is PEEK. The silicone elastomer, even at comparable durometers, will have significantly lower tensile strength than either polyurethane or PEEK. In an artificial tendon application, the implant must be able to match the tensile strength of a tendon to withstand the mechanical loads required in use without failure.

Question 7

a. The cleaner the manufacturing facility, the cleaner the surface of the material will be prior to sterilization. A cleaner surface will require less exposure to harsh sterilization conditions, which will limit the possibility of the sterilization process negatively impacting the robustness of the material/device. This needs to be balanced with the feasibility of manufacturing in these environments, e.g., cost, access.

b. Among the most common methods, ethylene oxide, dry heat, and autoclaving can be used to sterilize devices comprised of silicone elastomers. Depending on the material and other parameters, gamma sterilization and e-beam (also known as beta) sterilization can also be used with silicone materials.

c. What are the considerations for each sterilization technique?
   (1) Ethylene oxide. Exposure to ethylene oxide will successfully sterilize silicone elastomers. However, complete outgassing of the ethylene oxide gas must be verified. Any remaining EtO and/or byproducts of its reaction with water, e.g., ethylene glycol, can have significant and deleterious effects upon implantation. The device packaging, therefore, must be permeable to not only EtO, but those other byproducts.
   (2) Autoclave/Dry Heat. Due to the thermal and moisture resistance of silicone elastomers, autoclaving is generally considered a well-tolerated sterilization technique for these materials. Similarly, dry heat sterilization is used regularly with silicone elastomers due to their thermal resistance.
   (3) Gamma Sterilization/e-Beam. Although these techniques will sterilize the silicone elastomer, they can potentially further cross-link the material and change its mechanical properties. The dose will directly affect the extent of the change.

d. One needs to balance the sterilant dose that a material can withstand with the dose it receives. For polymers, in particular, you need to minimize the amount of radiation a material receives while still ensuring a sufficient sterilization effect. An inappropriate sterilization technique will not allow the user this balance, resulting in either an insufficiently sterilized material or a material whose properties have been negatively impacted and that can no longer perform as needed.

e. According to ISO 10993-1, a battery of biological evaluation tests shall be performed either on the final product, or representative samples from the final product, or materials processed in the same manner as the final product (including sterilization). This is important because the processing, especially sterilization, impacts these materials and their properties. The critical performance parameters should also be reevaluated with the sterilized material to ensure no significant change has occurred. The challenge is to balance sufficient sterilization with maintaining the material properties of the device. Sufficient sterilization ensures that the dosage exceeds the bioburden with adequate safety margin (overkill). Typically, sterilization assurance is performed by either dosimetric or parametric release or a combination of both. Dosimetric release is defined as the release of terminally sterilized batches or lots of sterile products based on physical data from the irradiation process instead of direct sterility testing. This includes appropriate process qualification to verify that the irradiation cycle provided the required minimum dose to the product. Parametric release is defined as the release of terminally sterilized batches or lots of sterile products based upon compliance with the defined critical parameters of sterilization without having to perform the requirements under pharmacopeial sterility tests, such as USP 〈71〉. Parametric release is a possibility when the mode of sterilization is very well understood, the physical parameters of processing are well defined, predictable, and measurable, and the lethality of the cycle has been microbiologically validated through the use of appropriate biological indicators or, in the case of ionizing radiation, the appropriate microbiological and dosimetric tests. The use of parametric release for sterilization processes requires prior FDA approval.

Introduction

Fluorinated biomaterials have a long history of biomedical device and biomaterials applications. These materials are generally carbon-based polymers, liquids, and gas precursors to films that all contain large amounts of chemically bonded fluorine (i.e., perfluorocarbons). Fluorinated materials can be solids, liquids, thin films, coatings, or gels, depending on their chemistry, processing, and mode of use. Fluoropolymers in general are thermoplastic polymers analogous to hydrocarbon-based polyethylene (PE), but highly fluorinated; some or all of the hydrogen atoms attached to the PE carbon polymer chain are replaced by fluorine (F) or fluorinated alkyl (perfluorocarbon) side groups. In some cases, other halogen atoms (e.g., chlorine, Cl) are also included with F to slightly modify polymer properties (Drobny, 2005). Notably, fluoropolymers show unique properties not achievable by other polymer materials, including chemical inertness, extreme hydrophobicity and solvent resistance, low coefficients of friction, high design tolerances for device fabrication, and temperature resistance (Drobny, 2005). These properties facilitate fluoropolymer use in specific technologies where most hydrocarbon-based materials do not perform well, either in device manufacturing or their applications. Nevertheless, as with all biomaterials, fluoropolymers perform best only in certain biomedical applications, and often carry a considerably greater cost than their hydrocarbon analogs into medical device designs.

Just 2 years after the first commercial launch of completely fluorinated polytetrafluoroethylene (PTFE), as DuPont's now well-known Teflon product, after World War II ended, this new polymer was implanted in animals for the first time (Leveen and Barberio, 1949). However, early PTFE materials processing difficulties limited device capabilities. In 1963, Japanese researchers reported a new process for expanding PTFE films to produce highly uniform, continuous fibrous porous structures that, after thermal processing, retained this microstructure with vastly improved mechanical strength (Oshige, 1967). In 1972, this expanded fibrous material was first used experimentally as a venous graft substitute (Soyer et al., 1972), and a year later as an arterial bypass implant (Matsumoto et al., 1973). Several years later (1976), expanded PTFE (ePTFE) was refined to production scales by Gore, allowing increased access and clinical use of this more versatile PTFE form in commercialized biomedical products (Gore, 1976). This enabled fluorinated biomaterials to be employed in biomedical applications both inside and outside the living host, facilitating entry as an important class of polymeric biomaterials that are seen in the field today.

Biomedical interest in fluorinated biomaterials focuses on several unique properties: lubricity; high sizing tolerances for device fabrication; and select aspects of reasonable biocompatibility resulting from both unique chemical and morphological properties. Understanding certain aspects of fluorinated chemistry is important to appreciate their material properties and broad utility in biomedical products.

Interesting Fluoropolymer Chemical and Physical Properties Derived From Their Polymer Chemistry, Molecular Structure, and Bonding

Replacing large amounts of hydrogen in C–H and C–C bonds in organic materials with fluorine as C–F chemistry, using several different chemical means, results in dramatic changes to the fluoromaterial's physical and chemical properties. Technologically desirable characteristics of perfluorinated materials are identified from how they interact distinctly with other media (e.g., heated fabrication machines and device-extruding dyes, as well as tissue, blood, proteins, and other polymers). Single fluorine bonds with carbon are the strongest carbon bonds, some 25 kcal/mol^{-1} stronger than C–Cl (Smart, 1994). Fluorination also strengthens adjacent aliphatic bonds: the CF_3–CF_3 bond is 10 kcal/mol^{-1} stronger than the CH_3–CH_3 bond (Smart, 1994). This makes alkyl fluorides 10^2–10^6 times more stable than

the corresponding alkyl chlorides in solvent and thermal reactions (Smart, 1994). Exceptional thermal and chemical stabilities observed for perfluorinated materials then result. Fluorine's high ionization potential energy and low polarizability provide relatively weak intermolecular forces, low interfacial energies, and low refractive indices in fluorinated materials. This is important to interfacial applications (see section on Surfaces Modified by Fluorination Treatments later). Fluorine's larger atomic radius compared to hydrogen provides a rational basis for the observed structural differences between perfluorocarbons and hydrocarbons; chain movement energies (i.e., C–C chain rotational barriers) for various fluorine-substituted bonds are significantly higher than barriers in analogous hydrocarbon systems (Smart, 1994). Partially fluorinated commercial polymers, polyvinylidene fluoride (PVDF), and ethylene-trifluoroethylene copolymer, have zigzag polymer chain conformations with different C–F dipole alignments along the chain (Smart, 1994), while perfluorocarbons with only C–F bonds (e.g., PTFE, see later) assume helical chain orientations with C–F dipoles distributed axially around the chain helix (Doeff and Lindner, 1989; Zhang et al., 1989; Sun et al., 1994a, 1994b; Kobayashi and Owen, 1995; Bar et al., 1997; Stone et al., 1998). PTFE, for example, as a model for high molecular weight perfluorocarbon chains, is known to have a rich phase diagram of several distinct helical solid phases (Scheirs, 1997). This polymer helix basically encases the inner carbon–carbon polymer backbone with a tight outer shell of fluorine groups, protecting the carbon bonds from reactants, and also contributing to unique chain–chain interactions in PTFE and helical fluorinated polymers. Although most fluoropolymers share unique properties (e.g., thermal and chemical stability, lubricity), their mechanical properties are slightly different, depending on whether they are fully fluorinated or contain a number of hydrogen atoms. Generally, partially hydrogenated fluoropolymers (e.g., PVDF, see later) exhibit higher stiffness than fully fluorinated polymers (i.e., perfluoropolymers). Perfluoropolymers exhibit greater elongation and higher maximum service temperatures that benefit device engineering and thermal processing.

Distinguishing the Different Fluoropolymers

Fluoropolymers can be classified into homopolymers and copolymers by the monomer(s) used in their polymerization. They are divided into either "partially fluorinated" or "perfluorinated" (i.e., 100% C–F bonds) based on the amounts of fluorine in the polymer chain. Fig. 1.3.2C.1 lists currently available commercial biomedical fluoropolymers. Polymer chemical composition affects the resulting materials' properties; only certain fluoropolymers exhibit properties attractive for biomedical products. As one selection criterion, Fig. 1.3.2C.2 (Scheirs, 1997) compares some selected mechanical properties for different biomedical fluoropolymers (Drobny, 2005).

Abbreviation	Generic polymer name	Structure
PTFE	Poly(tetrafluoroethylene)	PVDF	Poly(vinylidene fluoride)	FEP	Fluorinated ethylene-propylene

Polytetrafluoroethylene

PTFE (DuPont tradename Teflon) is perhaps the most commonly analyzed fluoropolymer. As described previously, fluorine's large size and mutual repulsion of adjacent fluorine atoms causes PTFE macromolecule chains to exhibit a twisting helix, comprising 13 CF_2 groups per 180-degree turn, distinct from the classic planar zigzag chain typical for PE (Bunn and Howells, 1954). Fig. 1.3.2C.3 shows this important conformational chain distinction that imparts certain unique physical properties to the fluoropolymer. Helical PTFE chains are often of very high molecular weight (>10^6) from their polymerization by reactive tetrafluoroethylene (TFE) gas. The helical polymer chains pack into solid

• BOX 1.3.2C.1 Sir John Charnley and the PTFE Replacement Hip Bearing

Convinced that hip joint repair could not use metal-on-metal bearings, Professor Sir John Charnley's early work on hip arthroplasty techniques in the early 1950s used a Teflon-on-Teflon solid bearing to resurface the arthritic femoral head and acetabulum. These Teflon-on-Teflon bearings failed within 2 years from mechanical creep and particulate issues. His further innovations created a femoral stem and metal head articulating against a Teflon cup socket inserted into the acetabulum. High Teflon wear occurred with joint articulation, producing severe osteolysis, loosening in the surrounding bone, and, as a result, requiring many revision surgeries. Teflon's poor performance in this articulating joint application prompted the adoption of high molecular weight polyethylene as a better bearing surface—an innovation that persists today.

crystallites like long, parallel, stiff molecular rods; individual PTFE polymer molecules can slip on each other as quasicylinders sliding under shear stress. Tight helical packing and chain–chain slip make PTFE the most lubricious polymer available, with a low coefficient of friction (0.1). This is a major selection criterion for manufacturing fluoropolymer tubing for catheters. Unfortunately, this also makes PTFE solids very susceptible to cold flow (creep) under stress—a major reason for their contraindication in mechanical applications (i.e., poor bearing and joint surfaces) (Box 1.3.2C.1). Mutual repulsive forces of adjacent fluorine atoms keep the PTFE chain backbone from bending. Low-energy barriers to chain–chain slip events result from low chain–chain interaction energies. PTFE's very high bulk solid fractional crystallinity means that it scatters most visible light wavelengths, resulting in its characteristic opaque white color. PTFE's high molecular weight and rigid helical chain conformation also produce high melt viscosities (e.g., 1012 Pa/s), ~6 times higher than most thermoplastic polymers. This viscosity is excessive for conventional melt processing fabrication methods for thermoplastic medical devices (e.g., extrusion and injection molding). This requires a high continuous service temperature (~260°C) for processing PTFE into devices. Therefore, as PTFE does not dissolve in any solvents, PTFE processing technologies are similar to those of powder metallurgy. This involves form casting of prepolymerized PTFE granulated powders or latex formulations, followed by mold compression and thermal sintering. PTFE's high thermal stability is key to success under the extreme processing conditions required for molded device parts (Drobny, 2005).

Fluorinated Ethylene Propylene

Fluorinated ethylene propylene (FEP) is a copolymer of TFE and hexafluoropropylene (HFP), first produced by DuPont in 1956 (Teflon FEP) to reduce PTFE's high crystallinity and melt viscosity. This improves FEP processing characteristics while maintaining high perfluorination. Bulky FEP perfluoromethyl groups produce defects in solid fluoropolymer crystallites, reducing polymer melting point, impeding chain slip, and reducing solid cold flow (Drobny, 2001).

FEP combines the unique mechanical and chemical properties of PTFE with the melt processability of more conventional polymers. FEP has a maximum service temperature of 204°C, and a slightly higher coefficient of friction than PTFE. It is used in biomedical devices in place of PTFE.

Polyvinylidene Fluoride

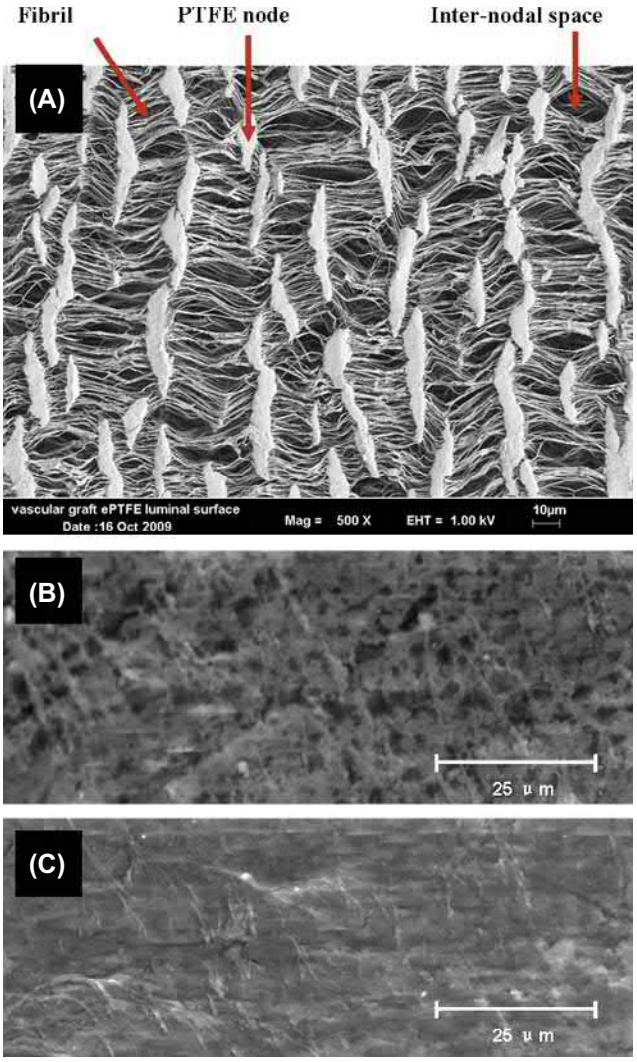
PVDF is a homopolymer of the vinylidene monomer (CH_2CF_2), and is sold as Kynar. PVDF has the highest flexural modulus of all fluoropolymers, due to the interpenetration of larger CF_2 groups crystallizing with adjacent smaller CH_2 groups on adjacent chains. Unlike other fluoropolymers, PVDF is soluble in highly polar solvents (dimethylformamide, tetrahydrofuran), acetone, and esters (Drobny, 2005). PVDF's unique high dielectric constant, high dielectric loss factor, and interesting piezoelectric behavior under certain conditions result from this chemistry and result in solid-state structures. Fluorine's shielding effects to all neighboring CH_2 groups provides PVDF with good chemical resistance and thermal stability (Scheirs, 1997; Drobny, 2001). These are all valuable properties sought in specific medical device applications.

Fluoropolymer Melt Processing

Because most perfluorinated polymers do not dissolve in many solvents, their biomedical products are often made by melt extrusion, where polymers develop flow upon melting in normal extrusion equipment. This technique, common to all polymer devices and chemistries, exposes fluoropolymers to very high temperatures to reduce their viscosity and improve flow characteristics for extended device production runs and product lengths. Fluoropolymers FEP and PVDF will readily melt flow when heated, typically above 260°C. This permits uninterrupted feed of fluoropolymer resin into the parts extruder to produce long continuous lengths of product (i.e., medical tubing). By contrast, PTFE extrusion is limited due to difficulties in its materials handling, size of the stock preforms, and tubing. However, PTFE's poor melt processing presents an important opportunity: PTFE tubing can be manufactured to very small dimensions, with wall thicknesses as small as 2.54×10^{-3} cm and tolerances of $\pm 1 \times 10^{-3}$ cm. This engineering benefit is largely due to PTFE's inability to melt flow, allowing more precise control over its use in small-dimensional, high-tolerance extrusion forms. This unique PTFE property is essential for producing medical products requiring tight size tolerances, such as small diameter and multilumen tubing with multiple precision passages for advanced catheters.

Original Gore-Tex and Generic Equivalents

PTFE film extrusion under anisotropic loading conditions produces expanded Teflon (ePTFE). Its microarchitecture exhibits pores axially aligned along the stretch direction, resulting in a unique fluoropolymer fabric material



• **Figure 1.3.2C.4** (A) Scanning electron micrograph (SEM) of expanded polytetrafluoroethylene (ePTFE) showing regular node–fiber open materials structure (scale bar, lower right corner = 10 microns) (B. Wagner, W. L. Gore & Associates, Flagstaff, USA, is acknowledged for ePTFE micrographs). (B) SEM of solid Teflon showing the cross-sectional porous structure resulting from the compressed sintering of PTFE particles (P. Hogrebe, SEM micrographs). (C) Dense continuous top surface (scale bar = 25 microns).

with an oriented microporous architecture. This was originally commercialized as the fabric-like Gore-Tex material (Gore, 1976). ePTFE's porous structure is characterized by regular PTFE nodes interconnected by PTFE fibrils (Fig. 1.3.2C.4A), distinct from solid PTFE shown in Fig. 1.3.2C.4B. In ePTFE, internodal spacing or distance (i.e., PTFE fibril length between solid PTFE nodes) is important to control device implant behavior (McClurken et al., 1986), and this can be controlled from 1 to 100 microns (Santiago et al., 1981) while retaining some properties similar to PTFE, e.g., biological adsorption, low tensile strength, low modulus of elasticity, water penetration control, and easy sterilizability. Porous ePTFE structures also allow important mechanical modulus-matching properties in tissue sites better than other polymers for many soft biological tissue applications (Mole, 1992). Porosity also importantly

encourages in-growth of tissue, and hence moderate levels of tissue mechanical fixation. Bulk PTFE does not exhibit this property. The micropores also present active sites for stable blood clotting, an important property for conditioning implanted vascular graft surfaces to limit their chronic blood coagulation.

Surfaces Modified by Fluorination Treatments (Grainger and Stewart, 2001)

Bulk perfluorinated materials' intrinsically higher costs and often substandard mechanical properties limit their applications. When only fluorinated polymer interfacial properties are desired, then fluorinated surface layers can be chemically deposited or coated over other mechanically superior substrates to impart fluorinated properties only at the surface. This surface application limits bulk fluorocarbon costs and their performance liabilities. As developed further later, fluorinated surfaces can be produced by plasma deposition of gaseous precursor monomers, direct solid powder or solution overcoating and casting/evaporation, and solution phase fluorinated component blooming. High surface fluorocarbonation produces unique interfacial properties, imparting specific, technologically attractive features, including low solid-state surface free energy (or low water wettability and permeability), surface lubricity, and chemical resistance and durability, to device surfaces. Table 1.3.2C.1 shows that perfluorinated polymer surfaces exhibit low interfacial energies (indicated by Zisman γ_c values), correlating directly with their utility as low-adhesion, low-water-wetting, and low-friction surfaces. Substituting either hydrogen or another halogen for fluorine along the polymer backbone results in significant increases in γ_c values (as seen in comparisons of PTFE with high-density polyethylene [HDPE]); PVDF:poly(CH_2CHF) has a $\gamma_c \sim 25$ mN/m, approaching that for polyethylene (HDPE, see Table 1.3.2C.1). Another important outcome of this low interfacial fluoromaterial energy is that fluorinated species thermodynamically prefer to coat a material's surface exposed to air. Hence fluorinated components will migrate from deep inside fluid coating mixtures to "bloom" and enrich as a coated overlayer at the solid–air interface.

Surface-enriched films of fluorinated components reside at surfaces even if fluorinated components are doped only at trace or minority components into bulk coating materials. Therefore fluorinated surfaces can be fabricated using minority fluorinated components added to a bulk material if they are allowed to move to that material's surface (e.g., from coating solutions), offsetting the intrinsically high costs of fluorinated materials. Emphasis on surface-fluorinated coatings and films has therefore increased as technological needs drive new, improved, and less expensive methods to put this chemistry over biomaterial surfaces. Several coating strategies have sought to create, organize, and orient $-CF_3$ and $-SF_5$ terminal groups from films over any surface to provide such properties. High surface density and organization of these groups is necessary to achieve their technological properties. Alignment of perfluorinated chains terminating in this $-CF_3$ or $-SF_5$ chemistry at the surface is required. Orienting the side chains in fluoroalkyl side chain acrylate and methacrylate films enriches surfaces with side chain-terminating $-CF_3$ groups (Bunn and Howells, 1954; Clark and Muus, 1962; Russell et al., 1986; Naselli et al., 1989), and lowers solid interfacial energies. Perfluoroalkyl-grafted polysiloxanes also exhibit side chain orientation of their perfluorinated chemistry, sometimes with spontaneous perfluorinated group organization as a film or coating (Hare et al., 1954; Pittman, 1972; Schneider et al., 1989; Tsao et al., 1997; Clark, 1999). Gas plasma-deposited thin fluorinated coatings are also well developed for this purpose (D'Agostino, 1990), representing a mature industry and biomedically relevant materials treatment (e.g., for vascular devices and intraocular lenses; Ratner, 1995).

Biomedical Applications

Biomedical applications of fluoropolymers, fluorocarbon coatings, and perfluorinated fluids and gels all include clinical interventional and luminal access devices (catheters in many forms), and more permanent implants (cardiovascular (Stanley, 1982), dental (Ratner, 1993), ocular (Legeais et al., 1998), craniofacial (Valdevit et al., 2000), urological (Reid et al., 1995), and abdominal (Grannis and Wagman, 1995) applications) as well as substantial nonimplanted medical tubing and biotechnology components (protein blotting and filtration membranes). Annually, millions of perfluorinated polymer components are used worldwide in biological milieu both in vitro and in vivo. PTFE (Teflon) and ePTFE (Gore-Tex) are widely used in medical tubing,

TABLE 1.3.2C.2 Fluorinated Biomaterials Biomedical Applications

Decade	Biomedical Applications
1970s	Implantable vascular grafts, peripheral catheters, and catheter introducers
1980s	Guiding catheters, protein blotting membranes, tissue meshes, tubing
1990s	Endoluminal stents, blood substitutes
2000s	Drug-eluting stents

advanced catheters, vascular grafts, meshes, sutures, and other medical implants. PVDF is used for biotechnology blotting/separation membranes. Table 1.3.2C.2 provides biomedical applications of more popular fluoropolymers. Clinically, ePTFE vascular grafts, including dialysis-access grafts, and Teflon-FEP catheter components are the most widely used fluorinated material medical devices. Other biomedical applications are described next.

Fluorinated Material Biological Response

Fluoropolymers are often regarded as chemically inert under most biological conditions. As noted earlier, they have some mechanical shortcomings under cyclic or continuous shear (creep). This makes applications in loadbearing situations (i.e., joint replacement, wear surfaces) difficult. Additionally, fluoropolymer surfaces are not inert to host biological reactions, including protein adsorption and blood clotting, either in vitro or in vivo. In fact, extremely tight binding of serum albumin to fluoroplasma-deposited surfaces (Kiaei et al., 1992), high levels of fibronectin and hemoglobin on PVDF (Paynter and Ratner, 1985) and various serum proteins (Dekker et al., 1991), including significant fibrinogen (Chandy et al., 2000), and high levels of both fibronectin and albumin (Grainger et al., 2003) on PTFE are observed in vitro. Importantly, protein adsorption to fluoropolymers is also observed in vivo (van Wachem et al., 1985; Roald et al., 1994), including fibrinogen activation, fibrin deposition, and platelet activation from blood, often deliberately promoted to stabilize blood reactivity on ePTFE vascular graft materials in vivo (Hoffman et al., 1986; Callow, 1988; Roald et al., 1994). Therefore nonspecific protein adsorption is significant, often irreversible, on fluoropolymer surfaces, leading to their desired utility as efficient protein-blotting membranes. But different proteins from different media (i.e., serum vs. plasma vs. blood) produce different interfacial reactions to fluorinated surfaces. From serum in vitro, for example, substantial amounts of albumin adsorption hinder serum-mediated cell attachment to fluoropolymers. This albumin passivation against further biological reactivity helps render the surface biofouling resistant. Clinical human cell-based vascular graft endothelialization to improve their blood compatibility is also generally poor on nonporous fluoropolymer chemistries (Kempczinski et al., 1985; Callow, 1988; Dekker et al., 1991; Schmidt et al., 1991; van Kooten et al., 1992; Roald et al., 1994; Legeais et al., 1998). This poor cell–fluoropolymer attachment has often been interpreted as "biological inertness," but results instead from substantial plasma protein adsorption on fluoropolymers (Baier et al., 1984) that does not support cell attachment and growth. Serum albumin, the most abundant protein in blood, blocks most cell attachment and other protein binding (Kesler et al., 1986; Zilla et al., 1989). Fibronectin, collagens, and other trace matricellular proteins (e.g., osteopontin, laminin, vitronectin) are cell-adhesive proteins. The observed general inability of nonporous fluoropolymers to support cell attachment has been related to excessive adsorption of albumin over cell-adhesive proteins (e.g., fibronectin) from serum—a medium lacking clot-forming fibrinogen (Grainger et al., 2003). Preadsorption of specific cell-adhesive proteins (e.g., collagen or fibronectin) to fluoropolymers is used to promote reliable cell adhesion (McClary et al., 2000; Koenig et al., 2003). Therefore little evidence suggests that fluoropolymers can be intrinsically "biologically inert." In fact, the opposite is true; solid fluoropolymers are intrinsically reactive and adsorptive to almost every protein studied, and the nature of what types of proteins are adsorbed dictates the fluoropolymer's biological reactivity. For example, porous fluoropolymers with 60–80 μm voids, including ePTFE, can facilitate rapid blood clotting and cell and bacterial in-growth in blood. These interactions occur by blood-based protein adsorption, clotting, and cell/bacterial adhesion, with additional physical integration and engagement into the ePTFE pores (Clark et al., 1974; Clowes et al., 1986).

PTFE (Teflon) Mesh and Fabric Vascular Implants

The innovation that enabled the spinning of PTFE paste into a fiber that could be woven or knitted into fabric or mesh produced a fabric-like fluorinated material (Berry, 1951). Attracted by solid PTFE's reported "blood compatibility" claimed in early animal acute in vivo studies, PTFE weaves were applied early in vascular grafts (Edwards, 1959). However, these early woven vascular grafts exhibited both high early failure rates and substantial late failure rates. Graft thrombosis was the most frequent early complication, accompanied by a high mortality rate (Boyd and Midell, 1971). Gore-Tex (ePTFE) vascular grafts supplanted these earlier PTFE weaves in this application and are discussed next. Thrombosis is a general property of fluoropolymer meshes and weaves in blood, passivating surfaces rapidly for acute short-term use, but limiting long-term blood-contacting applications.

ePTFE and Teflon Soft Tissue Repair Meshes

Teflon fibrous mesh has been used to repair abdominal wall defects (Ludington and Woodward, 1959) and hernias (Gibson and Stafford, 1964; Snijders, 1969; Kalsbeek,

• BOX 1.3.2C.2 ePTFE Hernial Mesh

Nearly a million hernial repairs are performed annually in the United States. Clinically, hernial repair meshes are implanted to bulk the abdominal wall at the herniated site. Tissue in-growth and organized fibrogenesis are deliberately promoted in these meshes to stabilize them in the abdominal tissue. ePTFE meshes and their combinations with polypropylene meshes are clinically available as a hernial repair product. However, ePTFE's lack of resistance to infection and inability to effectively engage tissue, promote on-growth, and organize fibrogenesis makes these meshes inferior to more popular polypropylene and polyester synthetic polymer meshes.

1974). However, it does not reliably integrate into body tissues, is not sufficiently infection resistant, and exhibits wound complication rates too high for routine hernia or abdominal repair use. ePTFE mesh is clinically used to repair hernias of many types (DeBord, 1998), reducing risks of several complications (DeGuzman et al., 1995; Lo Monte et al., 2009) (Box 1.3.2C.2). Infection and intestinal obstructions remain an issue for ePTFE mesh. However, they are better controlled with antibiotic therapies without mesh removal. ePTFE meshes have also been used as abdominal surgery barriers against surgical adhesions (Tulandi, 1997; Morris-Stiff and Hughes, 1998). ePTFE is also Food and Drug Administration (FDA) approved for many different plastic surgical facial defect reconstructions and augmentations, but is contraindicated in cosmetic lip augmentation, temporomandibular joint reconstruction, cardiovascular defects, and dermal placement (Levine and Berman, 1995). Nonetheless, commercial sources for these plastic surgery materials are discontinued.

ePTFE Vascular Implants

Because of abundant protein adsorption, ePTFE's porous inner surface is often claimed in vascular implants (blood) to clot blood rapidly to stabilize further surface coagulation and promote formation of a host "pseudointimal lining" that maintains blood compatibility under high-flow, high-shear applications. Its porous outer surface promotes perigraft cell and tissue infiltration that mechanically stabilizes the prosthesis in place, preventing kinking (White, 1988). Unlike most animal models, humans do not reliably form stable cellular "neointimal" endothelial cell linings in these grafts, limiting their success. ePTFE is currently used most widely to fabricate medium-sized (4–10 micron internode) vascular grafts for use in specific clinical blood vessel replacement indications (Kannan et al., 2005), including major vessels affected by disease or trauma, and arteriovenous hemodialysis grafts (Jenkins, 1976; Konner, 2005). ePTFE vascular prostheses are most clinically successful in high blood flow, low -resistance conditions (i.e., large peripheral arteries >5–6 mm diameter, such as the descending aorta). They are generally not suitable for smaller arterial reconstructions (e.g., coronary circulation and peripheral vascular placements) under high-resistance, low-flow conditions that allow continued clotting and loss of patency. Typically, ePTFE suffers from thrombosis, poor healing, lack of compliance, and excessive intimal and anastomotic hyperplasia leading to stenotic complications. Their routine placement in high-flow vascular environments allows them to remain patent despite their thrombus generation (Box 1.3.2C.3).

Arteriovenous ePTFE Grafts for Dialysis Access

Hemodialysis—essential for patients with end-stage renal disease—often requires regular, repeated (weekly) access to large blood vessels capable of producing high flow rates through an external artificial kidney device. Hemodialysis patients typically undergo cannula puncture of skin, underlying tissue, and vasculature to provide this access to the external artificial kidney. Repeated trauma to patient skin, tissue, and blood vessels from 13- to 17-gauge access needles produces notable complications, including hyperplasia, thrombosis, hematoma, occlusion, infection, and other morbidities. Vascular access complications remain the main reason for hemodialysis patient hospitalization. Synthetic ePTFE arteriovenous (A–V) grafts are surgically placed across the basilic vein and brachial artery to permit cannula access and reduce tissue trauma complications. A–V prosthetic graft failure rates are substantial (>50%), leading to increasing use of native fistulas and catheters (Li et al., 2008). However, synthetic grafts reliably provide high blood flow rates shortly after placement, as they do not require maturation before use. In A–V ePTFE grafts, stenosis occurs most commonly at the graft–venous anastomosis. Histologically, macrophages are seen in large numbers in the adventitial and medial layers in the anastomotic tissues from A–V ePTFE grafts (Kapadia et al., 2008) (Box 1.3.2C.4).

Multilumen Catheters

Fluoropolymers are important for biomedical tubing, and are central to advanced multilumen small-gauge medical-grade tubing required in many new minimally invasive catheters. These catheters permit surgeons to perform several invasive procedures through several lumens in a single inserted catheter device without removing one entire catheter to insert another. Catheter in vivo exposures are usually short term, typically using endoluminal access, and are increasingly minimally invasive. As described earlier, PTFE's unique properties and stable thermal processing methods allow PTFE multilumen tubing precision manufacture unlike any other material, and this is a very important fluoropolymer in this particular use.

Guiding Catheters

An important clinical device with a long track record, the guiding catheter helps the clinician deliver stents and other devices endoluminally. Central to the guiding catheter is a

• BOX 1.3.2C.3 Notable Clinical Success for Fluoropolymer Coatings on Cardiovascular Stents

Stent coatings comprising one or more polymers with a drug are widely used on coronary and peripheral DESs and deemed essential for producing controlled drug release kinetics to locally influence vascular site tissue healing, stent thrombogenicity, and stent patency. Among several patient factors, including health status, cardiovascular disease, and physiological factors, stent coating designs are known to influence stent blood compatibility, local tissue healing, and chronic inflammatory responses. Many durable and biodegradable polymers are used as coatings, combined with an equally diverse selection of drugs released from these polymers (Fig. 1.3.2C.5).

Two different fluoropolymer coatings are currently used in the majority of cardiovascular stents deployed clinically. Abbott Vascular's XIENCE family of endovascular coronary stents is the world's leading DES, with twice as many implants as any other DES. First introduced in 2006, this stent model has undergone several design changes and product improvements to now represent four different XIENCE stents. Each XIENCE stent employs polymers PBMA as a primer layer and PVDF-HFP overlayers in conformal wire stent coatings (6–7 microns thick). PBMA base primer over the metallic stent metal wires (struts) adheres the stent to the overlying fluoropolymer polymer-drug coating. PVDF-HFP is employed in the drug matrix layer to hold the drug everolimus on the stent and control its release, as well as ease its release from the deploying catheter expansion balloon.

PVDF-HFP is a semicrystalline fluorinated copolymer of vinylidene fluoride and hexafluoropropylene monomers (Fig. 1.3.2C.6).

• BOX 1.3.2C.3 Notable Clinical Success for Fluoropolymer Coatings on Cardiovascular Stents—cont'd

The PVDF-HFP copolymer backbone is comprised of entirely saturated carbon–carbon single bonds, >50% of which are fluorinated, resulting in unusual $–CF_2$ main chain and $–CF_3$ side group polymer dipole properties and polymer hydrophobicity. Significantly, the PVDF-HFP copolymer exhibits high elasticity and fatigue resistance attributed to its low glass transition temperature, T_g (–29°C), and semicrystallinity. It is considered a durable coating as it is resistant to hydrolytic, oxidative, or enzymatic breakdown. Introduction of the HFP comonomer to the PVDF polymer chains restricts polymer crystal content, forming nano-sized crystalline domains that alter polymer interchain distances and dipolar mobility, and reducing the polymer T_g. This allows this fluoropolymer the requisite mechanical properties (polymer elongation 600%–750%) to expand as the metallic stent is expanded in vivo, retaining a conformal, adherent, and defect-resistant coating character important to its biocompatibility. XIENCE's drug is everolimus (Fig. 1.3.2C.2B; 100 μg/cm^2 stent surface area loading on-stent). The PVDF-HFP copolymer drug matrix controls drug release to 80% in 1 month.

Like many other blood-contacting polymers, fluoropolymer surfaces are hydrophobic. They are recognized to elicit a unique biological response in contact with plasma or blood known as "fluoropassivation," reducing fibrin deposition, platelet reactivity, thrombogenicity, and inflammatory responses, and enhancing more rapid, reliable vascular neointimal healing (Lavery et al., 2017; Xie et al., 2010; Chin-Quee et al., 2010; Garfinkle et al., 1984; Kiaei, 1988; Massa et al., 2007; Lin et al., 2000). Preferential affinity of fluorinated surfaces for albumin, with respect to fibrin, fibrinogen, or fibronectin, and the inhibitory effect of materials fluorination on platelet adhesion/activation or leukocyte recruitment while encouraging more rapid neointima formation and endothelialization, are proposed mechanisms to explain this consistently observed phenomenon (Grainger et al., 2003; Szott et al., 2016).

Commercially available (currently only in CE-mark countries) fluoropolymer-based peripheral stents (FP-PESs, Eluvia) are now sold by Boston Scientific. The Eluvia FP-PES uses the same dual-layer polymer coating as XIENCE, comprising the primer layer PBMA to promote adhesion to the stent of an active polymer layer comprising a combination of drug, paclitaxel (concentration is 167 μg/cm^2 stent surface area), and PVDF-HFP, controlling drug release for 12 months upon deployment (Gasoir et al., 2017).

Another fluoropolymer stent coating, Polyzene-F (PzF; CeloNova BioSciences, Inc., TX, USA) is a formulation of poly[bis(trifluoroethoxy) phosphazene], an inorganic hydrophobic polymer possessing a backbone of alternating nitrogen and phosphorus atoms bearing trifluoroethoxy side groups. The COBRA-PzF (CeloNova BioScience, Inc.) coronary stent system is a cobalt chromium metallic stent design using this Polyzene-F polymer coating without drug, and was recently approved by the FDA for clinical use (Richter and Stampfl, 2005; Hiroyoshi et al., 2018).

Importantly, as stents undergo substantial mechanical manipulations, structural change, and deformation during expansion and deployment in vivo, coatings must adapt to the stent deformations with structural integrity and reliable metal–polymer adhesion. Select fluoropolymers seem to exhibit superiority in this regard, withstanding mechanical deformations required for stent assembly, deployment, expansion, and placement without any adverse effect on the mechanical and biological functionality of the coated device. The majority of struts on the XIENCE PVDF-HFP fluoropolymer coating lacked coating defects after stent in vivo explantation at 180 days. This coating also has been shown to remain intact at maximum stent postdilatation without exhibiting any mechanical constraints on stent final dimensions (Yazdani et al., 2016). The ability of the fluoropolymer coating to remain intact without defects, exhibit reliable fluoropassivation in blood, and deliver drug is a clear stent performance advantage. Recent metaanalyses have established that durable fluoropolymer (PVDF-HFP)-coated everolimus-eluting stents (FP-EESs) have lower rates of stent thrombosis and target vessel revascularization than bare metal stents (BMSs) or thick-strut biodegradable polymer drug-eluting stents (BP-DESs). Additionally, preclinical ex vivo porcine shunt data confirmed superior acute thromboresistance for FP-EES versus BMS and BP-DES (Otsuka et al., 2015; Torri et al., 2018).

PTFE inner liner with its superior lubricity and low friction coefficient that slides within an outer lumen. Lubricity is so critical to this device function that FEP, as the second-most lubricious material available, is insufficient as a catheter liner. During catheter construction, PTFE is chemically bonded onto the tube's outer diameter to enable slip. Bonding is accomplished by using an FEP heat-shrinkable fusing sleeve. After depositing PTFE over the liner the FEP mold is removed from the device, leaving a smooth outer PTFE jacket on the liner within the catheter outer liner.

PTFE Catheter Introducers

Now over three decades old, the PTFE "introducer" facilitates catheter insertion into a patient's vein, taking full advantage of PTFE's endoluminal lubricity and precision tubing processing. Once the catheter is inserted, the PTFE outer sheath can be removed from the patient, leaving the implanted catheter behind. The introducer exploits PTFE processing that molecularly orients the fluoropolymer material in the tubing-based sleeve over the catheter. This allows PTFE tubing to be readily split and torn longitudinally from the catheter in situ, enabling the surgeon to remove a PTFE introducer from a patient while the primary catheter remains in place.

Perfluorocarbon Liquids and Emulsions as Oxygen-Carrying Blood Substitutes

Low molecular weight perfluoro-fluids can be aspirated into the lungs directly or injected as submicron-sized emulsion droplets into the blood to facilitate oxygen transport, exploiting their high oxygen-carrying capacities (Winslow, 2005). Liquid perfluorocarbons in the lung eliminate the gas–lung interface, acting to reduce tension in the lung alveolus, and reducing mechanical work required to breathe during respiratory distress and lung surfactant deficiency. Emulsions made from dispersing perfluoro-fluids into water using interfacial droplet stabilizers (emulsifiers) create submicron perfluoro-droplets, much smaller than red blood cells. This provides

• BOX 1.3.2C.4 The ePTFE Vascular Graft and a Bizarre and Costly Patent Dispute

The 1974 patent filing from W. L. Gore & Associates, Inc. for the invention of the vascular graft resulted in the eruption of one of the most expensive and notorious medical device patent disputes in history. To challenge Gore's patent validity, a competing company started from former Gore employees and consultants—International Medical Prosthetics Research Associates, Inc. (IMPRA)—filed their own competing patent based on work from a pediatric heart surgeon, Dr. Goldfarb, investigating ePTFE at Arizona State University. IMPRA also agreed to fund Goldfarb's research in exchange for exclusive rights to Goldfarb's patent. But, after an extended period without IMPRA support, Goldfarb dissolved his IMPRA ties. Eventually, IMPRA returned patent rights to the doctor, but not without a nasty struggle. Goldfarb then licensed his still-pending patent to the C. R. Bard medical device company, seeking to obtain a piece of the vascular graft market from Gore and IMPRA. In 1995, the US Patent and Trade Office Interference Board declared that the Goldfarb patent (still pending) invalidated the Gore patent on the vascular graft—a decision upheld twice in the US appeals court. Goldfarb was finally awarded his patent in 2002, still licensed to C. R. Bard, invalidating the Gore patent. But Gore continued to sell its ePTFE vascular grafts until Bard filed suit in 2003. The trial, first "settled" in 2007, found Goldfarb to be the rightful graft inventor, that his patent was valid, and that Gore had willfully infringed the patent in its vascular products. But it was not over yet: in 2009, Gore's claims of inequitable conduct against Bard were denied, and damages against Gore were increased to a total of $410 million. Gore then appealed this verdict (Frankel, 2009). In 2012, citing "substantial evidence" that Gore infringed a patent for vascular grafts, the US Court of Appeals upheld assessed penalties on Gore for past interest, royalties, and fees. Resolution of the case was estimated to have yielded about $1 billion for Bard from Gore, and is among one of the largest settlements in patent litigation history. Interestingly, the judgment also allowed Gore to keep selling their products on the markets as it was in the public interest to allow competition in the medical device arena.

enormous oxygen-carrying capacity in blood to supplement normal oxygenation in microcirculation. Several commercial products have been clinically available, most recently Oxygent (Alliance Pharmaceutical, USA), consisting of two different perfluorocarbon fluids stabilized as a microemulsion using egg phospholipids. The product is eliminated from the blood after injection by macrophage/monocyte clearance, and is exhaled eventually from the lung.

Fluorinated Liquids in the Eye as Experimental Vitreous Substitutes

Detached retinal repair and other ophthalmic surgeries require oxygen-permeable viscous liquid vitreous substitutes. Perfluorinated oils and polymers have intrinsic high oxygen permeabilities and solubilities with suitable viscosity control. Perfluoropolyethers, perfluorinated alkanes, and perfluorinated silicone oils have all been studied in ocular vitreous applications, but still lack convincing safety, toxicity, or efficacy to date to produce an approved product in this context.

Fluorinated (Meth)Acrylates and (Meth) Acrylated Perfluoroalkyl Silicones as Cross-Linked Polymer Cores for Soft Contact Lenses

Exploiting the intrinsic high oxygen permeability well known for perfluorinated materials, rigid gas permeable contact lenses (RGPs) have used many variations on cross-linked perfluorinated acrylates and perfluorinated polyether silicone gels as lens cores to improve extended-wear contact lens on-eye performance. Increased ocular acuity under high-throughput inexpensive but precise lens fabrication methods, with high lens oxygen transport, is sought. Many patents describe many fluorinated polymer gels in this regard, with most major lens manufacturers developing these lens core materials.

Fluorinated Materials as Antifouling Coatings for Intraocular Lenses

General cellular reactions to implanted polymer intraocular lenses (IOLs) replacing cataracts can result in cell migration onto, and adhesion to, the lens, with optical interference (clouding) requiring IOL replacement. To prevent cells from migrating onto and coating the IOL's optical lens surface (typically a thermoplastic), thin optically transparent plasma-deposited fluorocarbon films or layers of other fluorinated polymers are deposited on the IOL rear surface. Several patents describe this approach and application.

PTFE Paste Injectable Bulking Agent

Teflon particles formulated as an injectable paste have been reported for the treatment of vesicoureteric reflux (VUR) (Puri, 1995), corrected by subureteric injection of a PTFE paste (Puri and O'Donnell, 1984). Subureteric paste injection by endoscopy has successfully addressed primary and secondary VUR in children for nearly two decades (Le Guillou et al., 1984; Dodat and Paulhac, 1987; Puri, 2000). Similarly, PTFE paste was introduced nearly four decades ago to treat female stress urinary incontinence (Beckingham et al., 1992; Politano, 1992; Meschia et al., 2002). However, this device does not have regulatory approval, due to high risks for PTFE microparticle migration and granuloma induction, especially in lymph nodes, kidneys, lungs, and brain (Aaronson et al., 1993). Applications of Teflon paste injection are still reported (Harrison et al., 1993; Lopez et al., 1993; Herschorn and Glazer, 2000), but its side effect concerns limit clinical use.

Ligament Replacement

The Gore-Tex ligament prosthesis comprises a single long fiber of ePTFE woven into loops. Mechanical testing shows that the resulting ultimate tensile strength is ~3 times that of the human anterior cruciate ligament (ACL). Creep and bending fatigue testing validate this ePTFE device as a strong synthetic ACL replacement material (Bolton and Bruchman, 1985). The Gore-Tex ACL prosthesis is

currently FDA approved for use in patients with failed autogenous intraarticular graft procedures (Mascarenhas and Macdonald, 2008). However, while acute performance shows promising stability in the knee, extended use and implant time produce significant ligament loosening, and other knee stability problems.

Sutures

PTFE also finds limited use as a suture fiber in various forms. Both PTFE monofilament and ePTFE fibers are surgically proven, with clinically accepted surgeon-handling and lubricity properties. Additionally, PTFE is blended into other common surgical sutures used for myocardial heart valve prostheses fixation. Poly(ethylene terephthalate) (polyester)-braided sutures are impregnated with PTFE polymer to limit wrinkling of the braid and consequent swelling. PTFE hydrophobic properties likely help protect the polyester braid from water uptake and hydrolysis (Bhat, 2002).

The Money Joint

Most biomaterials used for jaw joint reconstruction were introduced to markets prior to the 1976 Medical Devices Amendment Act that required device manufacturers to prove that their devices were safe and effective. A legal loophole that required manufacturers only to prove that their devices were "substantially equivalent" to a pre-Amendment device allowed temporal mandibular joint (TMJ) implants marketed soon after 1976 to enter the market without testing. Two designs widely used as TMJ replacement surfaces were Dow Corning's Silastic and Vitek's Proplast-Teflon product. Vitek developed and sold Proplast sheeting (Teflon FEP film laminated with a porous composite material of PTFE and carbon) in the 1970s. Implants modified in the 1980s comprised Teflon film laminated to PTFE and aluminum oxide. These implants, ~1 cm^2 in size, were cut from sheets in the operating room and sutured into the TMJ joint. In 1983, the FDA allowed Vitek to market a precut disc because, under the law, the company needed only to convince the FDA that its device was "substantially equivalent" to Dow's Silastic disc marketed years earlier. In 1986, several reports of catastrophic biomechanical failure of the PTFE implant were linked to a giant cell reaction leading to bone resorption and pain. Further analysis documented device failure rates of 10%–25%. By 1992, implant success rates below 20% were reported. Animal studies performed only after failures in humans began showed complete erosion of the TMJ implant within a "few months." In early 1990, with implant failures increasing, the FDA recalled Vitek's products. Predictably, Vitek declared bankruptcy with its rising product litigation costs, but continued to market their TMJ implants. Surgeons continued to implant them until eventually the FDA seized all products from Vitek, as well as its subsidiaries.

Summary

Due to their unique chemistry, fluorinated materials, primarily fluoropolymers, have attractive properties of biomaterials interest, including chemical stability, low adhesion/friction, nonwetting, high protein adsorption, high oxygen permeability, and precision tubing manufacturing. Low cell adhesion in serum and high intrinsic blood coagulation in plasma and blood both result from distinct media-dependent protein adsorption treatments and the physical form of the material. Expanded PTFE provides fabric-like properties with controlled pores and high surface area to alter device-related mechanics, processing, and tissue responses, while promoting rapid blood clotting. Solid fluoropolymers also have attractive precision-engineering and device-processing properties essential to producing several medical device classes where fine dimensional tolerances and biocompatibility are required. This enables fabrication of multilumen, high-tolerance, small-dimensional tubing for advanced catheters.

Glossary

Blooming a term used to describe the spontaneous enrichment of certain chemistries at the surface of a bulk matrix, usually associated with surface enrichment by low surface energy chemistry-like fluorinated materials. This phenomenon is used to promote a surface enriched in trace components like expensive added fluorinated chemistry by allowing them to spontaneously diffuse from the bulk material to the surface.

Blotting membrane a thin, porous, hydrophobic, high protein-binding capacity polymer membrane (e.g., PVDF) used to transfer proteins from a gel electrophoresis separation process for further probing with antibodies to identify the proteins as a blot or spot.

Drug-eluting stent small mesh tubes inserted into arteries to maintain patency after a procedure called angioplasty. The mesh is coated with a polymer/drug combination that deploys with the stent placement and elutes drug to the vascular bed adjacent to the stent for weeks to months.

ePTFE expanded polytetrafluoroethylene, produced from PTFE films under anisotropic stretching to yield a unique node–fibril microporous morphology in a fabric-like sheet form deemed important to biomedical utility in implanted biomaterials.

Fluorinated biomaterial a material intended for a biomedical application made from a base material that contains significant amounts of chemically bonded fluorine.

Fluoropolymer fluorinated polymer, also perfluoropolymer, usually thermoplastic, with high content of fluorine atoms replacing hydrogen atoms along the carbon-based polymer chain.

Perfluorinated material a material wherein all hydrogen atoms are replaced with fluorine, generally making C–F bonds.

PTFE polytetrafluoroethylene, a high molecular weight, highly crystalline perfluoropolymer solid also known as Teflon, discovered at DuPont in 1938, with unique solid properties and processing requirements.

Chapter Exercises

1. Fluoropolymers are commonly considered "inert." Teflon PTFE for example does not dissolve in any known solvents. Are fluoropolymers biologically inert? Explain.
   Answer: Fluoropolymers of all types and chemistries are well recognized to interact actively with all biological components: proteins, platelets, bacteria, fungus, algae, cells. Tight protein adsorption to fluoropolymer surfaces from different fluids (e.g., serum, plasma, blood, simple buffered protein solutions) is reported. Blood coagulation and complement activation are well documented. In fact, some fluorinated implants (e.g., ePTFE vascular grafts) are preclotted in patient fluids (e.g., whole blood) to passivate them prior to implantation. Cells and bacteria also adhere and proliferate under both in vitro and in vivo conditions. Fluoropolymers are not biologically inert. They do, however, appear to prefer to adsorb certain proteins from mixtures that then bias their subsequent interactions with other biological components. PVDF protein blotting membranes are passivated with various masking proteins (e.g., casein) to prevent adsorption of other proteins during protein blotting and transfers. Additionally, many fluorinated surfaces will adsorb high amounts of serum albumin from blood, plasma fractions, and mammalian sera. This "albumin passivation" renders these surfaces resistant to other protein adsorption, cell and platelet adhesion, and blood coagulation activation.
2. PTFE under mechanical loading suffers from creep: describe this problem and its impact on implant applications where durable mechanical properties under compression or cyclic loading are essential.
   Answer: Creep and cold flow are classic problems for PTFE polymers under continuous loading that result in deformation. PTFE failures in certain biomechanical applications experiencing loading (e.g., temporal mandibular knee hip joint bearing surfaces) are notable examples. Despite low coefficients of friction that make PTFE attractive in loadbearing surfaces, PTFE implant experiences to date in mechanical loading have not been promising (witness the early Charnley hip bearing and TMJ joint failures).
3. RGP contact lens materials based on glassy polymethylmethacrylates have included fluorinated copolymers with either silicone polymers or as perfluorohydrocarbons. What is the functional advantage for including fluorinated materials in these contact lenses?
   Answer: Due to their polymer chemistry, RGP lenses do not contain significant amounts of water, affecting their mechanical properties, comfort, and oxygen through-lens transmissibility. RGP lenses rely instead on microscopic pores in the lens to transmit oxygen to the cornea. But RGP lenses exhibit limited oxygen permeability, compromising several contact lens properties. As highly fluorinated materials have intrinsically high oxygen permeability, fluorinated lenses provide an alternative transport mechanism to improve oxygen permeability through the lens compared to the aqueous phase in conventional soft lens materials. Additionally, fluorine content in an RGP lens influences lens flexibility, lipid/protein deposition properties, and cost considerations.

The Organic Matrix of Restorative Composites and Adhesives

JACK L. FERRACANE[1], CARMEM S. PFEIFER[2]

[1]Department of Restorative Dentistry, Oregon Health & Science University, Portland, Oregon

[2]Biomaterials and Biomechanics, Oregon Health & Science University, Portland, Oregon

Introduction—Historical Perspective

The use of polymeric materials to build directly-placed dental restorations dates to the 1950s (Fig. 1.3.2D.1) (Bayne, 2005). The first materials relied on polymethyl methacrylate as the organic matrix, which confined their use to small, nonload-bearing applications. Owing to low mechanical properties and high volumetric shrinkage, and in the absence of an adhesive system, these materials were found to be unsuitable for most dental restorations (Anusavice et al., 2013). In the early 1960s, Dr. Rafael Bowen synthesized a dimethacrylate monomer referred to as Bis-GMA (bisphenol A diglycidyl dimethacrylate) that revolutionized restorative composites (Bowen, 1956, 1939, 1962) and is still used in the majority of currently available commercial materials (Anusavice et al., 2013). The fillers used in the early "macrofill" composites were comprised of quartz, ground into particles of 10–100 μm. Though the mechanical properties were significantly increased in comparison to the polymethyl methacrylate-based materials, early formulations exhibited severe wear due to the large particle size (Lee et al., 1975, 1974). Clinical use of dental composites became well accepted for anterior teeth in the early 1970s when the mechanism of adhesion to enamel through phosphoric acid etching was popularized, based on the technique first described by Dr. Michael Buonocore in the late 1950s (Bayne, 2005; Anusavice et al., 2013; Zero, 2013; Buonocore, 1955). Early adhesives consisted of a resin of BisGMA and TEGDMA, and were very hydrophobic compared to the modern formulations (Bowen and Molineaux, 1969). The concept of "total etching," now known as "etch-and-rinse," in which phosphoric acid was applied to both the dentin and enamel surfaces, was only introduced 10–15 years later, and it was not until the 1980s that Nakabayashi first described the potential formation of a "hybrid layer" of resin-reinforced dentin with the use of an etch-and-rinse technique (Nakabayashi et al., 1982; Nakabayashi, 1985).

The first composite materials were self-cured, requiring the mixing of two pastes containing appropriate amine and peroxide catalysts to produce polymerization within minutes. The concept of "on command" polymerization led to the replacement of the two-paste system with a single paste polymerized via a photocatalyzed redox reaction (Lee et al., 1976). The initial materials employed UV-mediated photocuring, which was later replaced by visible light photocuring based on camphorquinone/amine initiator systems (Bassiouny and Grant, 1980).

Thus, the beginning of the development of dental composites experienced three major ground-breaking discoveries that facilitated their acceptance by the profession: the introduction of BisGMA as a base monomer for the composite, the acquisition of adhesion to dentin through the hybrid layer formation, and the advent of visible light-mediated, on-command photocuring (Fig. 1.3.2D.1). Subsequently, composites underwent dramatic development in the inorganic portion, primarily to produce heavily filled materials with small filler sizes. Some current materials employ nanotechnology that allows for the incorporation of up to 80% by weight of nanometer-sized fillers (Chen, 2010).

Interestingly, however, the chemistry used in the organic matrix continues to rely on methacrylates, and it is only in the past 10 years that attempts have been made to replace these monomers. Dental composite restorations may last on average less than 10 years in service, with the main causes for restoration replacement being secondary caries and fracture (Demarco et al., 2015, 2012). New alternatives being investigated aim at overcoming the drawbacks of ester bond hydrolysis, high polymerization stress, and gap formation, which combined lead to instability at the tooth–restoration interface and loss of mechanical integrity (Fugolin et al., 2019; Gonzalez-Bonet et al., 2015; Podgorski et al., 2015). Novel materials also aim at not being merely inert (not cytotoxic/allergenic), but rather capable of eliciting desirable biological responses, such as remineralization and antimicrobial activity.

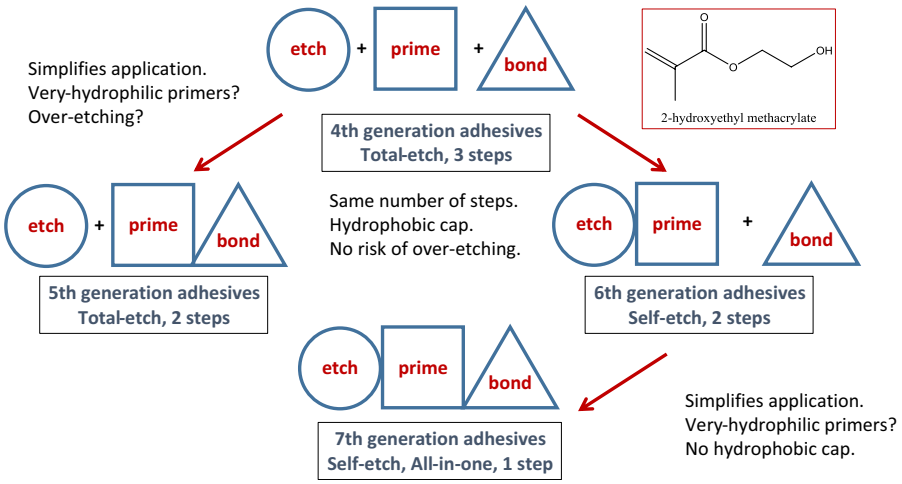
The Monomer Matrix—Conventional Systems

Dimethacrylates (Base and Diluent Monomers) Used in Commercial Composites

BisGMA remains the most common dimethacrylate monomer used in dental composites and adhesives (Fig. 1.3.2D.2). The success of this monomer is related to a combination of properties afforded by BisGMA's structure: a rigid BPA (bisphenol A) core, strong hydrogen bonding potential imparted by the two hydroxyl groups in the backbone, and the potential to form cross-linked networks by virtue of two methacrylate functionalities per molecule (Asmussen and Peutzfeldt, 1998). The strong hydrogen bonding in BisGMA imparts intermolecular reinforcement, but also results in high viscosity (1200 MPa/s) (Lemon et al., 2007). The high viscosity, in turn, hinders the addition of a high volume of inorganic filler particles, which are the component mainly responsible for producing high mechanical properties (El-Safty et al., 2012; Ilie and Hickel, 2009). In addition, the low mobility of BisGMA in a polymerizing medium also means that diffusion-controlled acceleration takes place early in conversion (Odian, 2004), leading to low conversion for the homopolymer (Gajewski et al., 2012). To allow for the incorporation of larger amounts of filler and also to adjust clinical handling properties, so-called "diluent" monomers are combined with BisGMA (Froes-Salgado et al., 2015). The most commonly used diluent monomer is triethyleneglycol dimethacrylate (TEGDMA), which has



• **Figure 1.3.2D.3** Representation of the different generations of dental adhesives. The structure of 2-hydroxyethyl methacrylate (HEMA) is shown at the top right corner.

a much lower viscosity [0.1 MPa s (Gajewski et al., 2012)] and lower molecular weight (286 g/mol) compared to Bis-GMA (512 g/mol). TEGDMA has a flexible ethylene glycol unit backbone, with the homopolymer reaching around 100 MPa in flexural strength and 1.8 GPa in flexural modulus (Gajewski et al., 2012). The lower viscosity and greater molecular flexibility leads to delayed diffusional limitations to conversion when combined with BisGMA, in a well-documented synergistic effect (Asmussen and Peutzfeldt, 1998). The molar shrinkage coefficient of TEGDMA is also much higher than that of BisGMA, due to the lower molecular weight of the former (Patel et al., 1987). Therefore, when combined with BisGMA, TEGDMA's lower viscosity allows for the incorporation of larger amounts of particles and for increased conversion; however its smaller size, flexible backbone, and lack of strong intermolecular interactions increase shrinkage and decrease mechanical properties (Froes-Salgado et al., 2015; Goncalves et al., 2010). For this reason, other dimethacrylates have been used as diluents, including urethane dimethacrylate (UDMA) and ethoxylated bisphenol A dimethacrylate (BisEMA). UDMA and BisEMA have molecular weights (470 and 512 g/mol, respectively) comparable to BisGMA, but have much lower viscosity (23 and 0.9 MPa s, respectively) (Gajewski et al., 2012; Goncalves et al., 2009). Though lower than for BisGMA, UDMA has a significant hydrogen bonding potential via intermolecular interaction on the imino group, which reinforces the network (Bowen and Molineaux, 1969). BisEMA only has hydrogen bonding acceptor capability via ethylene glycol units, but still presents a stiff BPA core. With recent concerns over the potential exposure to BPA upon degradation of these materials, alternatives have been developed (Fig. 1.3.2D.2), such as the dimethacrylate monomer known as TCD-urethane used in one specific commercial material (Venus Diamond, Kerr). This monomer also has a stiff core based on a ring moiety, and relatively high molecular weight (507 g/mol). Another example is the dimethacrylate monomer DX-511, patented by Dupont and used in Kalore from GC Corporation. Its molecular weight is 895 g/mol.

The commercial materials containing conventional and alternative monomers have been extensively characterized in vitro and in clinical studies. The rationale for their development was to produce low-viscosity diluents for high filler loading that have higher molecular weights, thus producing much lower shrinkage than TEGDMA. Indeed, the volumetric shrinkage of some of the new materials was lower than conventional materials at the same filler level (Boaro et al., 2010), but the correlation with polymerization stress and the consequent interfacial gap formation is more complex. Polymerization stress is complex, resulting from a combination of shrinkage, final conversion, and elastic modulus (Goncalves et al., 2008; Pfeifer et al., 2008). In fact, some of the "low-shrinking" materials have not shown reduced stress (Boaro et al., 2010). In addition, controlled clinical trials have failed to demonstrate improved performance and longevity of restorations made with these materials compared with their conventional counterparts (Baracco et al., 2016; Kruly et al., 2018; Magno et al., 2016; Mahmoud et al., 2014; Schmidt et al., 2015).

Adhesive Monomers

Most modern adhesives are composed of a combination of a dimethacrylate monomer (generally BisGMA) that provides cross-linking and increased polymer stability, and one or more monomethacrylate monomers with hydrophilic characteristics (Cadenaro et al., 2019). The most common example is hydroxyethyl methacrylate (HEMA), whose complete miscibility with water allowed for "wet bonding" to be performed on the dentin substrate via the formation of a hybrid layer (Nakabayashi et al., 1982). HEMA is used mostly in fourth and fifth generation, etch-and-rinse adhesives, but can also be present in sixth and seventh generation, self-etching compositions, including the most recent "universal" adhesives (Fig. 1.3.2D.3). The rationale for the different generations of adhesives is to simplify the technique-sensitive application of fourth generation, three-step, etch-and-rinse adhesives (Lane et al., 2016) by either combining the primer and bond steps (two-step, etch-and-rinse, or fifth-generation adhesives), or by using self-etching (acidic) monomers that eliminate the

need for a separate etching step. These self-etch adhesives have either a separate final resin bond step (self-etch, two-step, or sixth-generation adhesives) or without a separate bond step (all-in-one, or seventh-generation adhesives). In the early 2000s, the concept of very hydrophilic adhesives started to be investigated, with the phenomenon of adhesive layer degradation by water percolation being described and the term "water-treeing" being coined (Tay and Pashley, 2003). Water treeing describes the seepage of water through adhesives, especially those where the hydrophilic primer step is combined with the hydrophobic bond step (fifth and seventh generations), resulting in an adhesive layer that serves as a semipermeable membrane (Chersoni et al., 2004; Tay et al., 2004, 2003). The adhesive polymer network is intrinsically less cross-linked than that of composites, and also much more prone to water sorption (Cadenaro et al., 2019). This means that the hydrolysis-prone ester bonds in methacrylates are exposed to degradative conditions. In fact, some studies have shown that the adhesive layer can be severely compromised after only 6 months (Tay and Pashley, 2003), especially for materials where the bond step is not separate from the primer application.

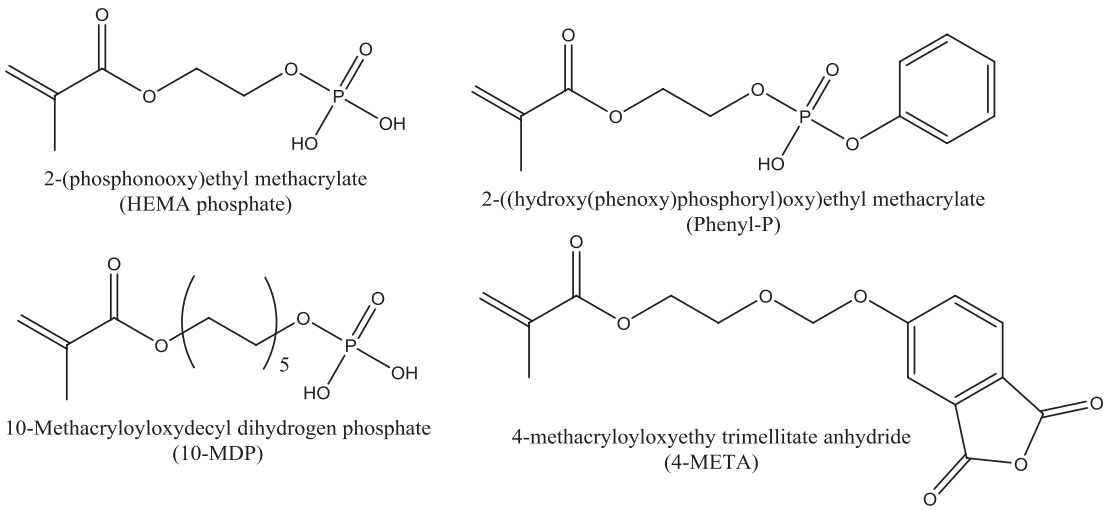
Self-etching has the potential to decrease dentin permeability because the dentinal tubules do not become completely exposed during demineralization, as is the case when phosphoric acid is applied to dentin. Because there is no acid rinsing step, the demineralized dentin material becomes incorporated within the bonding layer with self-etch adhesives. Therefore, the hybrid layer is much thinner, and primer and adhesive more easily penetrate the full depth of the demineralization. In contrast, for the etch-and-rinse systems, there is potential for a band of collagen to remain exposed and not penetrated by the adhesive (Cadenaro et al., 2019), which increases the likelihood of water permeability. Self-etching monomers present a pKa of 1.7–2.5 (Salz et al., 2006), and rely either on carboxylic acid or phosphonic acid moieties (Fig. 1.3.2D.4). Several different monomer structures have been investigated, with 10-MDP (10-methacryloyloxydecyl dihydrogen phosphate) showing the best overall results (Feitosa et al., 2014; Yoshihara et al., 2013) and now being used in most commercial universal dental adhesives (since the expiration of the original patent by Kuraray Inc.).

The Monomer Matrix—Novel Systems

Lower Stress Resin Systems

Low-Shrinkage Materials

As composites undergo polymerization, bonding to the cavity wall causes the shrinkage inherent in the process to take place under confinement (Feilzer et al., 1987). Being unable to accommodate all of the change in volume, the polymerizing material transfers stress to the bonded interface (Feilzer et al., 1987). If the bond strengths are insufficient, a gap opens at the interface, potentially leading to staining, bacterial infiltration, and ultimately recurring decay (Peutzfeldt and Asmussen, 2004). The management of polymerization stress is complex, since many factors affect the magnitude of the forces transferred to the interface, including the size of the cavity preparation and the free surface area (Goncalves et al., 2008), as well as the interplay between conversion, shrinkage, and modulus development (Pfeifer et al., 2008). Any strategy aiming at reducing stress should not jeopardize conversion or elastic modulus, so tackling the shrinkage was the first approach used in stress management. In the 2000s, novel materials claiming to produce less polymerization shrinkage and stress were marketed using monomers with higher molecular weight or those polymerizing via a ring-opening mechanism. In either case, the rationale was to reduce the molar shrinkage coefficient of the material (Patel et al., 1987). In other words, the loss in free volume among polymerizing chains is expected to be diminished for monomers that either occupy more space initially (higher molecular weight) or that polymerize by expansion of a ring-opening system, such as in the case of epoxides (Patel and Braden, 1989). Examples of higher molecular weight monomers are shown in Fig. 1.3.2D.2, along with the only commercial dental composite example of a ring-opening monomer.



• **Figure 1.3.2D.4** Molecular structures of common acidic monomethacrylate monomers used in the formulation of self-etching adhesives.

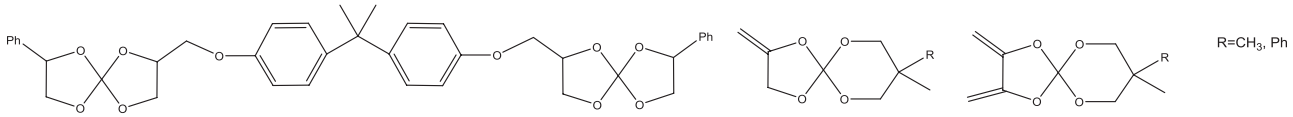
In vitro studies indeed demonstrated reduced polymerization shrinkage and stress with these materials, albeit at times correlated to reduced conversion and/or mechanical properties (Boaro et al., 2010). Other ring-opening systems based on spiro-ortho carbonates (Stansbury, 1992) have also been proposed (Fig. 1.3.2D.5). The main advantage of ring-opening systems is their reduced shrinkage (Yoo and Kim, 2010), but they are also ester-free and generally more hydrophobic than methacrylate-based systems, which explains their reduced water sorption and solubility (Gonzalez-Bonet et al., 2015). Complications associated with these systems include the cationic polymerization mechanism which requires specialized initiator and adhesive systems that are sensitive to moisture and pH (Vitale et al., 2014).

Polyhedral oligomeric silsesquioxanes (POSS) have also been proposed to improve the properties of dental composites (Chen, 2010; Schreck et al., 2011; Fong et al., 2005). These molecules are comprised of distinctive nanocage structures, with an inner inorganic framework of silicon and oxygen atoms, and an outer shell of organic functional groups (Ghanbari et al., 2011). They were at first designed to reduce polymerization shrinkage in dental composites due to their high molecular weight (Fong et al., 2005). Early reports indicated that the mechanical properties of composites are reduced with the addition of even modest concentrations of these oligomers (Fong et al., 2005). More recent reports indicate the potential use of POSS additives to reinforce other classes of polymeric materials, such as those used in maxillofacial applications (Mohammad et al., 2010).

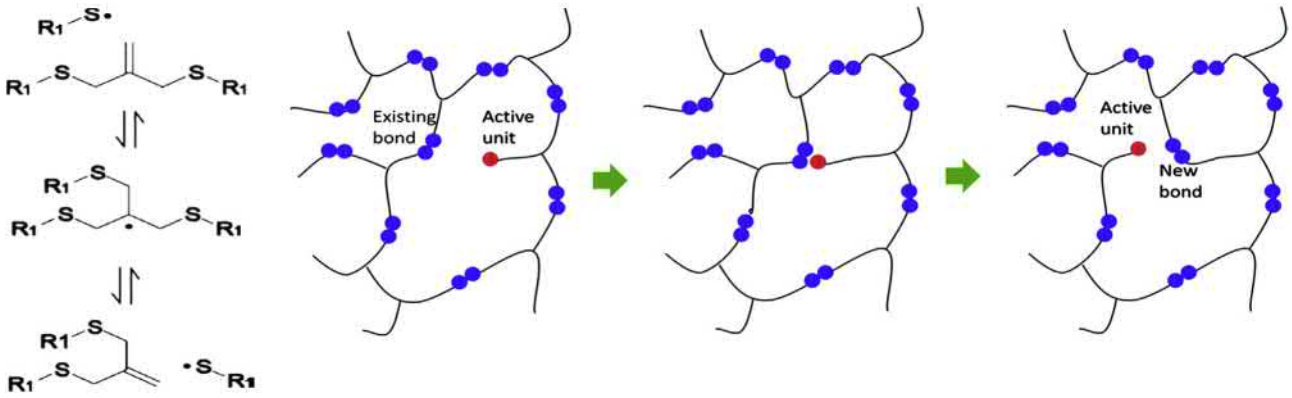
The inclusion of prepolymerized resin particles has been proposed to reduce polymerization shrinkage and stress in dental composites, and more recent examples have included nanogels (Moraes et al., 2011; D'Ovidio et al., 2018; Liu et al., 2012) and other oligomers (Carioscia et al., 2005; Bacchi et al., 2014; Bacchi et al., 2016; Bacchi and Pfeifer, 2016). In the case of nanogels, prepolymerized particles of around 230–650 kDa are synthesized in solution (Dailing et al., 2014), producing a cross-linked network bearing different functional groups, such as methacrylates. These networks are swollen by the secondary monomer matrix they are added to and as the polymerization progresses, become covalently attached to the newly forming polymer (Moraes et al., 2011). Studies have demonstrated reduced polymerization shrinkage and stress without compromising conversion and mechanical properties (Moraes et al., 2011). These materials have also been successfully used in adhesives having increased longevity of the bonded interface (Gotti et al., 2016; Moraes et al., 2012). Stress reductions have also been shown with the addition of thiol-ene and thiourethane oligomers, through reduced shrinkage, but more closely related to network rearrangement, as explained in detail in the next section.

Network Modulation

Apart from decreasing shrinkage, polymerization stress reduction can also be achieved by controlling network formation. One specific approach is to delay the time in conversion at which modulus develops rapidly (Cramer et al., 2010). One study demonstrated that in cross-linked methacrylates, most of the stresses develop after the material achieves approximately 60% conversion (Lu et al., 2004a,b). At that point in conversion, diffusional limitations and network formation have progressed sufficiently to inhibit significant stress relaxation within the material (Odian, 2004), leading to the buildup of stress and an overall limited conversion (Odian, 2004; Lovell et al., 1999). Another study demonstrated that the gel point in methacrylates occurs at around 5% conversion and that the modulus presents a significant increase at around 60% conversion (Pfeifer et al., 2011), coinciding with the most significant increase in stress reported by Lu et al. (Lu et al., 2004a, b). This is typical of methacrylates, which undergo polymerization via a chain-growth mechanism. In contrast, the gelation/vitrification in polymers formed via step-growth mechanisms only takes place at very high conversions (Odian, 2004). One example of step-growth polymers is thiol-enes, which are not generally useful for dental material applications when used alone due to their intrinsically low mechanical properties (Shin et al., 2009). However, hybrid systems based on combined chain-growth (methacrylates) and step-growth (thiol-containing) polymers have been developed, showing significantly reduced polymerization stress with similar (Cramer et al., 2010; Boulden et al., 2011; Ye et al., 2011) or improved (Bacchi et al., 2015) conversion and mechanical properties. Chain transfer reactions of the thiol functionality to the vinyl-containing monomer during polymerization are responsible for delaying the development of diffusional limitations to termination and propagation until higher levels of conversion have been reached (Berchtold et al., 2001; Lovell et al., 2001). As a consequence, final conversion is increased and the overall polymerization stress is decreased (Cramer et al., 2010). There is a chance for reduced cross-linking and, consequently, reduced mechanical properties, since chain-transfer events are chain breaking (Berchtold et al., 2001). Indeed, in some ternary thiol-ene-methacrylate systems the flexural strength and modulus may be compromised in comparison to the neat methacrylate control, in spite of increased conversion (Cramer et al., 2010a,b). However, the toughness and fracture toughness increase due



• **Figure 1.3.2D.5** Molecular structure of a few examples of monomers based on spiro-orthocarbonate chemistry (Stansbury, 1992; Yoo and Kim, 2010; Stansbury, 1990). (Adapted from Figure 6 in "Dental Composites — Chemistry and Composition" [Pfeifer, CS. Chapter 11 in *Dental Biomaterials* (Pfeifer, 2017)]).



• **Figure 1.3.2D.6** Mechanistic step of the chain-transfer reactions that take place in allyl disulfide networks (left) and cartoon illustration of the bond forming/breaking events within a cross-linked network. (Adapted from Yang, H., Yu, K., Mu, X., Shi, X., Wei, Y., Guo, Y., et al., 2015. A molecular dynamics study of bond exchange reactions in covalent adaptable networks. Soft Matter. 11, 6305–6317. and Park, H.Y., Kloxin, C.J., Scott, T.F., Bowman, C.N., 2010. Covalent adaptable networks as dental restorative resins: stress relaxation by addition-fragmentation chain transfer in allyl sulfide-containing resins. Dent. Mater. 26, 1010–1016).

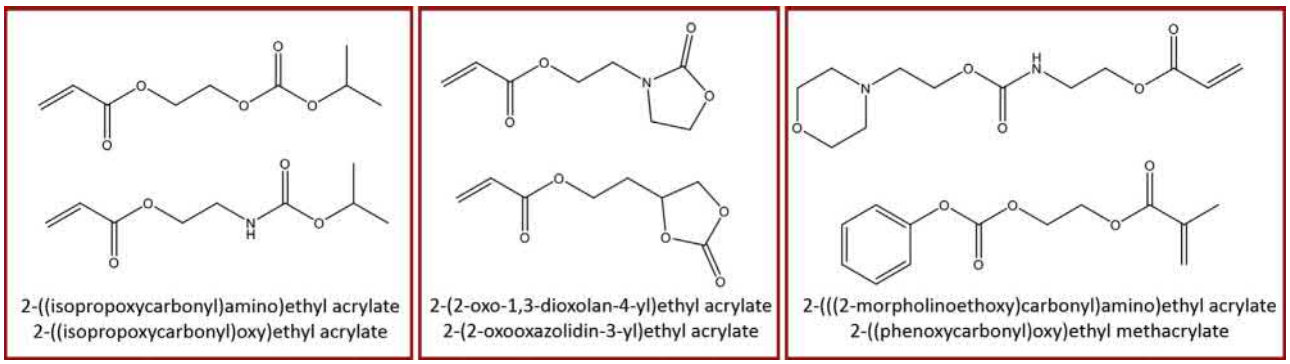
to enhanced stress relaxation and crack arrest mechanisms, owing to the low Tg (glass transition temperature) afforded by thiol-carbon bonds (Cramer et al., 2010). The use of multifunctional thiols (Cramer et al., 2010) and multithiol oligomers (Carioscia et al., 2005) alleviates concerns over decreased cross-linking. In addition, the use of thiol-functionalized thiourethane oligomers has been shown to reduce polymerization stress via the same chain-transfer reactions, but at the same time to significantly increase fracture toughness via the presence of tough thio-carbamate bonds within the oligomer network (Bacchi et al., 2016).

Another approach to control network formation is to use allyl disulfide-based monomers, capable of network rearrangement via covalently adaptable networks (CANs) (Yang et al., 2015). The cross-links in CANs are capable of undergoing reversible rearrangement reactions, as illustrated in Fig. 1.3.2D.6. The chain-breaking/chain-forming reactions provide a mechanism for macroscopic flow and stress relaxation that are initiated at the molecular level, and activated by an external stimulus to the cured polymer (Kloxin and Bowman, 2013). In addition, during the polymerization reaction, the cross-linking chain strand rearrangements actively work to delay or at least partially offset diffusional limitations to conversion, ultimately reducing the overall polymerization stress without reducing the cross-linking density (Bowman and Kloxin, 2012). These monomers have been proposed for use in dental materials in combination with multithiol and dimethacrylate monomers, with the advantages of reducing stress while producing supra-ambient Tg networks ("glassy networks") (Park et al., 2010). This technology has been translated into a commercial material (Filtek Bulk-Fill Posterior, 3M-ESPE), incorporating the addition-fragmentation moiety directly into the backbone of a proprietary dimethacrylate monomer (http://multimedia.3m.com/mws/media/976634O/filtek-bulk-fill-posterior-restorative-technical-product-profile.pdf). In vitro studies demonstrated that this material leads to a reduction in polymerization stress and an increase in depth of cure compared to a conventional methacrylate control (Fronza et al., 2015), while a 1-year clinical evaluation did not show a difference in performance compared to conventional materials (Bayraktar et al., 2017).

Finally, polymerization-induced phase-separation and interpenetrating network formation have also been proposed as means to control polymerization stress in dimethacrylate networks (Pfeifer et al., 2014). In such systems, two distinct but interconnected phases are formed as the material polymerizes, and the differential in stiffness among the several formed domains is leveraged to accommodate the change in volume, and alleviate part of the stresses being generated (Li and Lee, 2000; Li and Lee, 2000). This can be accomplished by using "low-profile additives" (prepolymerized particles, commonly PMMA) (Szczepanski et al., 2012), metastable mixtures of monomers (Pfeifer et al., 2014), or a combination of monomers in which each polymerizes via a different mechanism (Cook et al., 2006). One example of phase-separating monomer [dimer acid dimethacrylate, Mw = 849 g/mol, Fig. 1.3.2D.2 (Trujillo-Lemon et al., 2006)] is used in the composition of a commercial material (N'Durance, Septodont), which in theory provides a reduction in shrinkage via polymerization-induced phase separation, and also due to the high molecular weight of the monomer (Bracho-Troconis et al., 1995; Lu et al., 2010).

Fast Polymerizing Monomers

In several applications, including in dentistry, the speed of polymerization is almost equally as important as other physicochemical properties of the polymer. Faster reacting monomers allow for high conversions to be achieved with shorter light exposure times, lower light intensities, and/or lower initiator concentrations. A few examples of monomers with ultra-fast polymerizations have been developed and showed increased degrees of conversions and improved mechanical properties (Lu et al., 2005; Berchtold et al., 2004), including when used to replace TEGDMA in a BisGMA/TEGDMA



• **Figure 1.3.2D.7** Examples of fast polymerizing methacrylate-based monomers. The top and bottom IUPAC names in each box correspond to the top and bottom molecules, respectively.

system (Lu et al., 2005). These monomers (Fig. 1.3.2D.7) are based on carbamates, carbonates, and oxazolidones (Decker and Moussa, 1991), among others. The mechanism for faster polymerization has been correlated to efficient chain-transfer reactions involving labile hydrogens from the functional groups (Decker and Moussa, 1991), and/or potentially inefficient termination reactions (Decker and Moussa, 1990). Hydrogen bonding has also been hypothesized to play a role in preorganizing monomer molecules (and thus increasing the polymerization rate), which may also explain the increased stiffness observed with these materials (Jansen et al., 2003). No commercial example exists for dental applications.

Antimicrobial Resins

Secondary decay is one of the leading causes for composite restoration replacement (van de Sande et al., 2013; Neshchadin et al., 2013). Caries formation at the interface may be promoted by gap formation due to polymerization stress and/or material degradation through hydrolysis (Cenci et al., 2009; Kuper et al., 2014; Maske et al., 2019). Bacterial recolonization in those areas may lead to the formation of acidogenic biofilms that demineralize the tooth structure and lead to marginal breakdown (Maske et al., 2018). More recently, the role of the biofilm itself on material degradation has been described, with bacteria-derived esterases potentially being responsible for the breakdown of ester-containing methacrylates into by-products which, in turn, can upregulate the function of the bacteria (Stewart and Finer, 2019). Therefore, the development of materials that can avoid the recolonization of the surface and interface with the tooth by caries-forming bacteria has gained interest in recent years (Stewart and Finer, 2019; Zhou et al., 2019).

Quaternary ammonium is the most commonly studied antimicrobial moiety attached to polymerizable methacrylates, with several studies demonstrating its efficacy in impeding biofilm formation (Zhou et al., 2019; Han et al., 2017). Quaternary ammonium methacrylates (QAMs) are positively charged monomers characterized as broad-spectrum antibiotics (Wang et al., 2018). The concentration of such monomers into composite systems is limited by their hydrophilicity, which may lead to decreased mechanical properties due to excessive water sorption (Zhang et al., 2015). However, even at relatively low concentrations (up to 10 wt.%), they have shown efficacy in reducing biofilm formation, with the bacterial content on the surface decreasing linearly with the surface charge (Zhang et al., 2015). The length of the side chain on the quaternized nitrogen has also been correlated with the antibacterial potential against *S. mutans* (Zhang et al., 2016). The optimal chain length has been demonstrated to be between 12 and 16 carbons, and the proposed killing mechanism has been described as the positive charge attracting the bacteria to the surface while the side chain interacts with the thick bacterial wall, leading to its rupture (Zhang et al., 2016). However, no study has confirmed this proposed mechanism. Drawbacks of this system include: (1) the contact–kill mechanism limits their potency to the very first layer of bacteria, with little effect on the bulk of the biofilm; (2) since the QAMs are generally monofunctional ester-containing monomers, they are likely to either leach out as unreacted monomers or as degradation products, which poses toxicity concerns; and (3) QAMs are not selective to dysbiotic bacteria, and instead also eliminate protective (commensal) early colonizers such as *S. sanguinis* (Cheng et al., 2017). Other compounds, such as imidazolium, have also been made polymerizable by functionalization with methacrylates, with encouraging results in terms of antimicrobial activity (Hwang et al., 2017). However, they also rely on broad-spectrum antibiotics, acting via contact–kill mechanisms.

Enhanced Chemical Stability

Material degradation in the harsh conditions of the oral environment is likely one of the causes for marginal breakdown and bulk fracture of the composite. The oral environment experiences variations in temperature, pH, and mechanical loading throughout the day, and in conjunction with the individual's oral microbiome, creates significant challenges for polymeric materials. The vast majority of all adhesives and composites currently in use are based on methacrylates, which contain hydrolyzable ester bonds. To various degrees, the different methacrylate-based materials are prone to water sorption and solubility, with leachates from materials comprising unreacted monomers, oligomers, and degradation products (Finer and Santerre, 2004). Common degradation

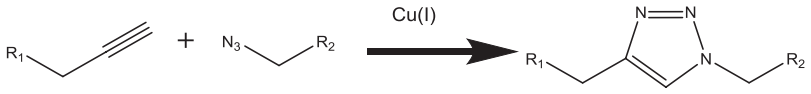
products include methacrylic acid, BisHPP (2,2-bis[4(2,3-hydroxypropoxy)phenyl]propane), ethylene glycol, and ethylene glycol monomethacrylate, among others (Finer and Santerre, 2004). BPA has also been detected in the oral cavity after placement of certain orthodontic resins and pit and fissure sealants (Deviot et al., 2018; Eliades et al., 2011; Kloukos et al., 2013). The hydrolysis of the ester bonds has been demonstrated to be catalyzed by several esterases present in the saliva (Finer and Santerre, 2004) and produced by oral bacteria (Marashdeh et al., 2018; Huang et al., 2018).

In an attempt to reduce material degradation in the oral environment, research efforts have focused on designing alternative monomers to methacrylates that have fewer or no ester linkages. Examples of ester-free monomers include acrylamides (Fugolin et al., 2019; Moszner et al., 2006), vinyl ethers (Gonzalez-Bonet et al., 2015), alkyne-azides (Zajdowicz et al., 2018), and thiol-vinyl sulfones (Podgórski et al., 2014), all of which are very distinct in their properties and polymerization schemes (Fig. 1.3.2D.8).

Acrylamides and methacrylamides are chemically very similar to methacrylates, with the exception that the oxygen in the ester bond is replaced by a nitrogen atom in the amide bond. The presence of the lone electron pair in nitrogen provides resonance stabilization to the bond, and the trigonal planar conformation about the nitrogen–carbon shortens the bonds in comparison with the conformation in methacrylates, both of which make hydrolysis of the amide bond less likely than that of the ester in methacrylates (Bruice, 2016). However, the carbon–carbon double bonds on some of these monomers are also less prone to attack by free-radicals, which explains the lower reactivity and lower overall conversion observed (Tauscher et al., 2017). These monomers are also intrinsically more hydrophilic than methacrylates, and this greatly limits their usefulness in the formulation of dental composites. However, they may be well suited for use in adhesives where hydrophilicity is an asset (Salz and Bock, 2010), and in fact, commercial examples exist (AdheSE One F, Ivoclar-Vivadent; Xeno V, Dentsply Sirona). More recent iterations have shown significantly improved bond strengths, and maintenance of the integrity of the bonded interface for up to 6 months (Fugolin et al., 2019; Rodrigues et al., 2018). The slower reactivity may conceivably be circumvented by the addition of more reactive initiator systems containing iodonium salts and/or others based on germanium initiators (Moszner et al., 2008; Bouzrati-Zerelli et al., 2016), but this yet to be demonstrated. One clear concern with acrylamides is the potential for cytotoxicity (Sahinturk et al., 2018), something that needs to be thoroughly investigated before new materials are brought to the marketplace.

Vinyl ethers are another ester-free alternative to methacrylates. They have been shown to reach reasonably high conversion levels and produce extremely stable materials, even after being subjected to low pH storage and biofilm challenges (Gonzalez-Bonet et al., 2015). However, their polymerization progresses via a cationic mechanism that can be sensitive to moisture and produces networks with low Tg (Kirschbaum et al., 2015). When combined with methacrylates, these monomers produce stable composites with similar elastic modulus and Knoop hardness, and up to 30% greater conversion and fracture toughness compared to a BisGMA/TEGDMA control (Wang et al., 2018).

Thiol-vinyl sulfones and alkyne-azide polymerizations are both examples of materials that polymerize via click reactions (Adzima and Bowman, 2012), as well as being free of hydrolyzable ester bonds. The recent development of photo-base generators has allowed for thiol-vinyl sulfones to be photopolymerized on command, making them attractive for use in dental applications (Claudino et al., 2016). These materials present mechanical properties that are similar or better than methacrylate controls, with the advantage of increased conversion



General reaction scheme for alkyne-azides, catalyzed by copper I. Copper I is reduced from copper II either by reaction with sodium ascorbate or in the presence of a photoinitiator.

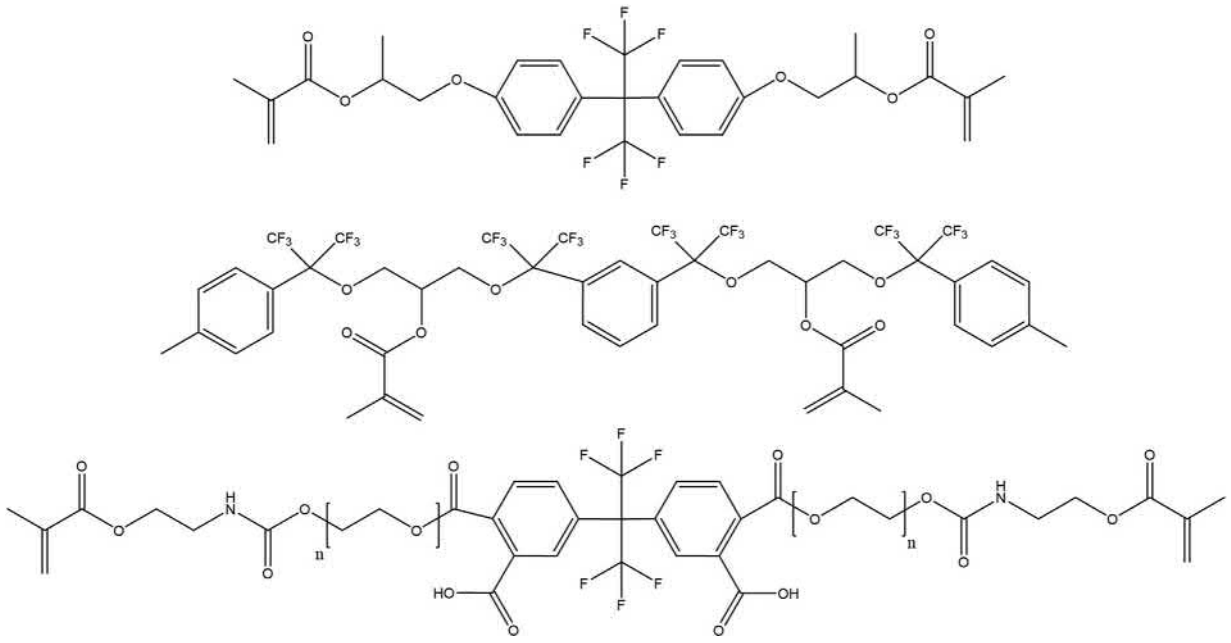
and improved resistance to degradation, as well as significantly reduced polymerization stress (Podgorski et al., 2015; Podgórski et al., 2014). Alkyne-azides rely on copper-catalyzed click-reactions (Demko and Sharpless, 2002). Photoactivated copper reduction has been recently demonstrated (Gong et al., 2013) and proposed for use in dental materials. Its advantages include low water sorption and solubility (very stable materials), potential antibacterial properties, reduced polymerization stress, and increased energy absorption (Zajdowicz et al., 2018; Song et al., 2016; Song et al., 2017). Potential disadvantages include a lower Tg compared to methacrylates, poorer color stability, and potential biocompatibility concerns due to the presence of the reduced copper catalyst (Song et al., 2016).

Enhanced Toughness

Historically, the most common strategy to increase the mechanical properties of composites has been to maximize filler content (Finer and Santerre, 2007; Rodriguez et al., 2019). Recently, modifications to the organic matrix have been proposed, such as the use of toughening additives (Bacchi et al., 2016; Fugolin et al., 2019). One example of such additives is thiourethane oligomers, produced through a thiol-isocyanate click reaction, and resulting in a preformed network with lower Tg that can then be added into a methacrylate matrix (Bacchi et al., 2014). The use of such networks has been described for applications where increased toughness and impact resistance are necessary (Li et al., 2009), including in dental materials (Bacchi et al., 2014; Bacchi et al., 2016; Fugolin et al., 2019). Along with a twofold increase in fracture toughness, these materials also result in lower polymerization stress (Bacchi and Pfeifer, 2016). The increase in toughness is in part explained by the low Tg of the oligomer. In addition, the flexible thiocarbamate bonds have been demonstrated to produce more homogeneous networks compared to urethane counterparts, as evidenced by narrowing tan delta peaks observed with dynamic mechanical analysis (Li et al., 2009). These characteristics likely impart some type of crack arrest capability, but it can also be hypothesized that active strand behavior is at play, similar to what is observed in other carbamate-containing materials (Kuhl et al., 2018), in covalent adaptable networks (Bowman and Kloxin, 2012), and in other urethane-containing materials (Zheng et al., 2016).

Hydrophobic Resins

Enhancing the hydrophobicity of the cured polymer would be an advantage in the oral environment. Fluorine-containing materials are intrinsically hydrophobic, with many examples in the literature demonstrating significantly reduced water sorption and solubility, increased contact angle, and similar to reduced mechanical properties compared to conventional methacrylates (Stansbury and Antonucci, 1999; Liu et al., 2018; Luo et al., 2016). Potential miscibility issues with other monomers could explain the reduction in properties, and in fact studies evaluating the effect of the addition of moderate amounts of solvents (aldehydes and ketones) (Prakki et al., 2009; Prakki et al., 2007), as well as the use of urethane-derived formulations (Liu et al., 2018; Luo et al., 2016), have demonstrated improved mechanical performance. Hydrophobic monofunctional monomers have also been synthesized with this chemistry to produce less water-permeable dental adhesives (Buruiana et al., 2016). Examples of these molecules are shown in Fig. 1.3.2D.9, but no commercial examples exist.



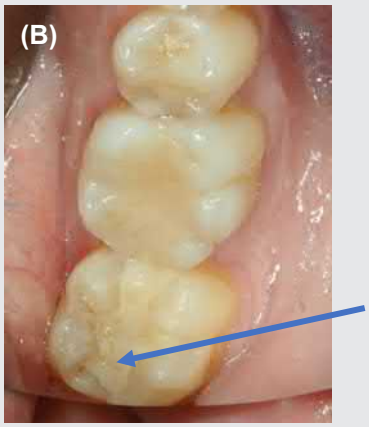
• **Figure 1.3.2D.9** Molecular structure of a few examples of fluorinated monomers proposed for dental applications (Stansbury and Antonucci, 1999; Prakki et al., 2009; Buruiana et al., 2016). (Adapted from Figure 11 in "Dental Composites — Chemistry and Composition" [Pfeifer, CS. Chapter 11 in *Dental Biomaterials* (Pfeifer, 2017)]).

CASE STUDIES I AND II

Describe the chemical characteristics and properties that would be most ideal for a dental resin-based restorative to be used in the following applications.

Case 1: A patient visits the dental office and complains to the dentist that one of their teeth is very sensitive when they drink cold liquids. The tooth is in the front of the mouth (see Fig. A) in their maxilla (upper jaw), and upon inspection the dentist notices that the surface of the tooth is eroded near the gum line. Blowing of light air from the dental unit onto the tooth elicits a rapid pain response. The dentist makes the choice to restore the tooth lesion (defect) with an adhesively bonded composite restorative material. What specific things should the dentist consider when choosing a material to restore this tooth? (Hint: Consider the importance of the following characteristics/properties for this application: high mechanical properties, high wear resistance, excellent esthetics, strong adhesion to dentin and enamel, high color stability, fast polymerization reaction, and resistance to degradation by moisture, enzymes, and bacteria.)

Case 2: A patient visits the dental office and complains to the dentist that one of their teeth is sore and it is hard to chew on that side of their mouth. The tooth is a second molar (see Fig. B) in their mandible (lower jaw), and upon inspection the dentist notices that the tooth already has a composite restoration but suspects that a new lesion is present. The dentist takes an X-ray and sees obvious evidence of a large lesion, not limited to the occlusal surface, but also extending to the distal portion of the tooth. The dentist decides to restore the tooth with an adhesively bonded composite restorative material that will replace the occlusal and distal parts of the tooth, and will extend all the way down to the gum line. What specific things should the dentist consider when choosing a material to restore this tooth? (Hint: Consider the importance of the following characteristics/properties for this application: high mechanical properties, high wear resistance, excellent esthetics, strong adhesion to dentin and enamel, high color stability, fast polymerization reaction, and resistance to degradation by moisture, enzymes, and bacteria.)



Silane Coupling Agents

The coupling between the organic matrix and the inorganic filler phase in dental composites is accomplished with the functionalization of the surface of silica-containing particles with a silane agent (Bowen, 1962). The majority of the currently available commercial materials use 3-(trimethoxysilyl) propyl methacrylate (TMPS), which provides a chemical bond with the filler via the hydrolysis of its methoxysilane groups, and provides covalent attachment to the organic matrix via copolymerization with the methacrylate (Matinlinna et al., 2011). TMPS is a small molecule, which likely forms close to a monolayer on the filler surface (Sideridou and Karabela, 2009), and this is enough to improve mechanical properties in resin composites. Without the silane coupling, the filler particles essentially behave as voids in the material, providing a facile path for crack propagation (Condon and Ferracane, 1998; Condon and Ferracane, 2002). The caveat of silanization, however, is the potential for stress concentration at the filler–matrix interface, given that the shrinkage inherent to the polymerization of the resin is constrained by the bond to the stiff inorganic particle (Condon and Ferracane, 1998; Condon and Ferracane, 2002). Other silane coupling agents have been proposed, bearing thiol functionalities that would help alleviate part of the stress via chain-transfer reactions between the thiol and the methacrylate in the organic matrix (Matinlinna et al., 2011). More recently, the use of prepolymerized species has been proposed to harness potential stress relaxation (Fugolin et al., 2019; Faria et al., 2018) and crack arrest mechanisms (Fugolin et al., 2019; Fronza et al., 2019; Ye et al., 2012) specifically at this vulnerable interface. This is hypothesized to be accomplished by functionalizing the surface with thicker layers of more compliant compounds, such as hyperbranched oligomers (Ye et al., 2012), thiourethane oligomers (Fugolin et al., 2019), or nanogels (Fronza et al., 2019).

Chapter Exercises

1. Identify the major milestones in the evolution of dental composite restorative materials and predict what future modifications may be forthcoming to produce more ideal formulations.
2. Describe the chemistry involved in the initiation and propagation of the polymerization of dimethacrylate monomers and explain the importance of maximizing the extent of the curing reaction.
3. Describe the origin of polymerization stress in dental composite restorations, and explain what chemical modifications to current formulations have been attempted to mitigate it.
4. Identify the chemical difference between the monomers used in self-adhesive and etch-and-rinse dental adhesive formulations, and explain the mechanism of adhesion of each to dentin and enamel tissues.
5. Explain what clinical benefit may be derived from the incorporation of an antimicrobial monomer in a dental resin, and discuss how such monomers demonstrate their activity.
6. Discuss how the monomers used in dental composite and adhesive formulations can be chemically and physically degraded within the oral cavity, and identify potential changes in formulation that can protect the polymerized resin and make it more degradation resistant.
7. Explain chemical approaches to enhance the toughness of dental resins used for composite restorations, as well as the need for improved toughness.

1.3.2E Hydrogels

NICHOLAS A. PEPPAS[1], ALLAN S. HOFFMAN[2]

[1]Department of Chemical Engineering and Biomedical Engineering, Pediatrics, Surgery and Molecular Pharmaceutics and Drug Delivery, The University of Texas, Austin, TX, United States

Introduction

Hydrogels have received significant attention because of their high-water contents and related potential for many biomedical applications. Hydrogels are polymeric structures held together as water-swollen gels by: (1) primary covalent cross-links; (2) ionic forces; (3) hydrogen bonds; (4) affinity or "bio-recognition" interactions; (5) hydrophobic interactions; (6) polymer crystallites; (7) physical entanglements of individual polymer chains; or (8) a combination of two or more of the above interactions.

Early work on hydrogels was initiated in the mid 1930s, mostly in Germany, with studies on kinetics of cross-linked polymers. In the 1940s, the research of 1094 Nobel laureate Paul Flory lead to a detailed, fundamental understanding of the hydrogels' cross-linked structure, their swelling/syneresis characteristics and the small and large deformation behavior in pure water and physiological fluids. The pioneering book by Andrade (1976) offered some of the early work that was available prior to 1975. Since then, numerous reviews and several books have addressed the preparation, structure, characterization, and applications of hydrogels (e.g., Peppas, 1987, 2001; Brannon-Peppas and Harland, 1990; Lee and Mooney, 2001; Qiu and Park, 2001; Hennink and van Nostrum, 2002; Jeong et al., 2002; Miyata et al., 2002; Drury and Mooney, 2003; Patterson et al., 2010).

Here, we focus on the preparation and characterization of the structure, and chemical and physical properties of *synthetic* hydrogels. Many natural polymers such as collagen, gelatin, fibrin, hyaluronic acid, heparin, alginates, pectins, chitosan, and others can be used to form hydrogels, and some of these gels have been used in biomedical applications. Details on these types of materials can be found throughout this textbook in other chapters.

Classification and Basic Structures of Hydrogels

Depending on their method of preparation, ionic charge, or physical structure features, hydrogels may be classified in several categories. Based on the method of preparation, they may be: (1) *homopolymer hydrogels*; (2) *copolymer hydrogels*; (3) *multipolymer hydrogels*; and (4) *interpenetrating network* (*IPN*) *hydrogels. Homopolymer hydrogels* are cross-linked networks of one type of hydrophilic monomer unit, whereas *copolymer hydrogels* are produced by cross-linking of chains composed of two comonomer units, at least one of which must be hydrophilic to render them water-swellable. *Multipolymer hydrogels* are produced from three or more comonomers reacting together (e.g., Lowman and Peppas, 1997, 1999). Finally, *interpenetrating network* (*IPN*) *hydrogels* are produced by two methods, one within a preformed network and the other in solution; the most common method is to polymerize one monomer within a different cross-linked hydrogel network. The monomer polymerizes to form a polymer or a second cross-linked network that is intermeshed with the first network.

There are several other ways that hydrogels may be classified. *Ionic hydrogels*, with ionic charges on the backbone polymers, may be classified as: (1) *neutral hydrogels* (uncharged); (2) *anionic hydrogels* (having negative charges only); (3) *cationic hydrogels* (having positive charges only); or (4) *ampholytic hydrogels* (having both positive and negative charges). These last gels may end up with a net negative, positive, or neutral charge.

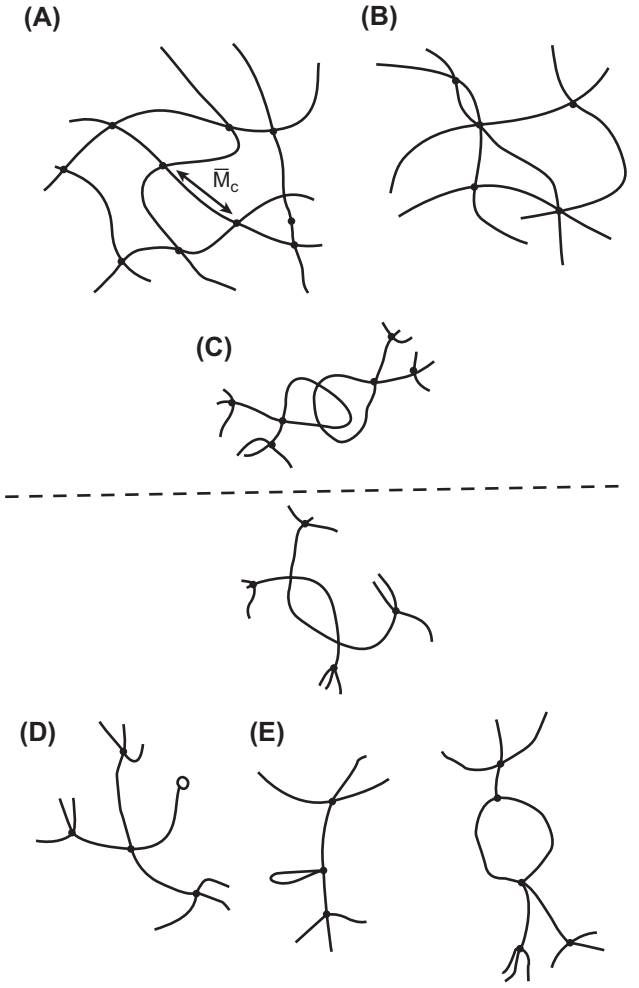
Based on physicochemical structural features of the network, hydrogels may also be classified as: (1) *amorphous hydrogels* (having covalent cross-links); or (2) *semicrystalline hydrogels* (may or may not have covalent cross-links). In amorphous hydrogels, the macromolecular chains are arranged randomly.

Semicrystalline hydrogels are characterized by self-assembled regions of ordered macromolecular chains (crystallites).

Another type of classification of hydrogels includes the "*complexation*" *hydrogels*, which are held together by specific types of secondary forces. These include hydrogen bonds, hydrophobic group associations, and affinity "complexes" [e.g., (1) heterodimers (peptide/peptide interactions called "coil–coil"); (2) biotin/streptavidin; (3) antibody/antigen; (4) conA/glucose; (5) poly(D-lactic acid)/poly(L-lactic acid) (PDLA/PLLA) stereocomplexes; and (6) cyclodextrin (CD) inclusion complexes]. The physical properties of the gels held together by such secondary associations are critically dependent on the network density of these interactions, as well as on the many environmental conditions that can affect them. Hydrogels may also be classified as stable or degradable, with the latter further categorized as hydrolytically or enzymatically degradable.

Structural evaluation of hydrogels reveals that ideal networks are only rarely observed. Fig. 1.3.2E.1A shows an ideal macromolecular network (hydrogel) indicating tetrafunctional cross-links (junctions) produced by covalent bonds. However, in real networks it is possible to encounter multifunctional junctions (Fig. 1.3.2E.1B) or physical molecular entanglements (Fig. 1.3.2E.1C) playing the role of semipermanent junctions. Hydrogels with molecular defects are always possible. Fig. 1.3.2E.1D and E indicate two such effects: unreacted functionalities with partial entanglements (Fig. 1.3.2E.1D) and chain loops (Fig. 1.3.2E.1E).

The terms "cross-link," "junction," or "tie-point" (shown by an open circle symbol in Fig. 1.3.2E.1D) indicate the covalent or secondary connection points of several chains. In the case of covalent linkages, these junctions may be carbon atoms, but they are usually small chemical bridges [e.g., an acetal bridge in cross-linked poly(vinyl alcohol), or an ethylene glycol diester bridge in the polyHEMA contact lens gel] with molecular weights much smaller than those of the cross-linked polymer chains. In other situations, a junction may be crystallites or other secondary interactions, such as described above, of a permanent or semipermanent nature. Thus, in reality, the junctions should never be considered as points without volume, which is the usual assumption made when developing theoretical models for prediction of the properties of cross-linked hydrogels (Flory, 1953). Instead, they have a finite size and contribute to the physical properties during biomedical applications.

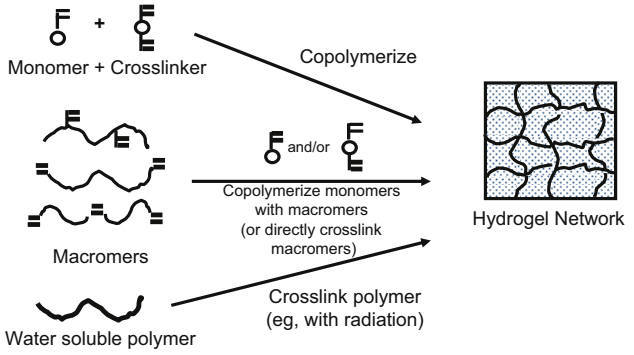


• **Figure 1.3.2E.1** (A) Ideal macromolecular network of a hydrogel; (B) network with multifunctional junctions; (C) physical entanglements in a hydrogel; (D) unreacted functionality in a hydrogel; (E) chain loops in a hydrogel.

Synthesis of Hydrogels

Covalently cross-linked hydrogels are usually prepared by bringing together small multifunctional molecules such as monomers and oligomers, and reacting to form a network structure. Sometimes large polymer molecules may be cross-linked with the same small multifunctional molecules. Such cross-linking may be achieved by reaction of two chemical groups on two different molecules, which can be initiated by catalysts, by photo-polymerization, or by radiation cross-linking (see reviews by Peppas et al., 2000; Hoffman, 2002; Ottenbrite et al., 2010; Jin and Dijkstra, 2010).

Several methods for forming cross-linked hydrogels are based on free radical reactions. The first involves a copolymerization-cross-linking reaction between one or more monomers and one multifunctional monomer that are present in relatively small quantities. In a related method, two water-soluble polymers may be cross-linked together by formation of free radicals on both polymer molecules, which combine to form the cross-link (Fig. 1.3.2E.2). These

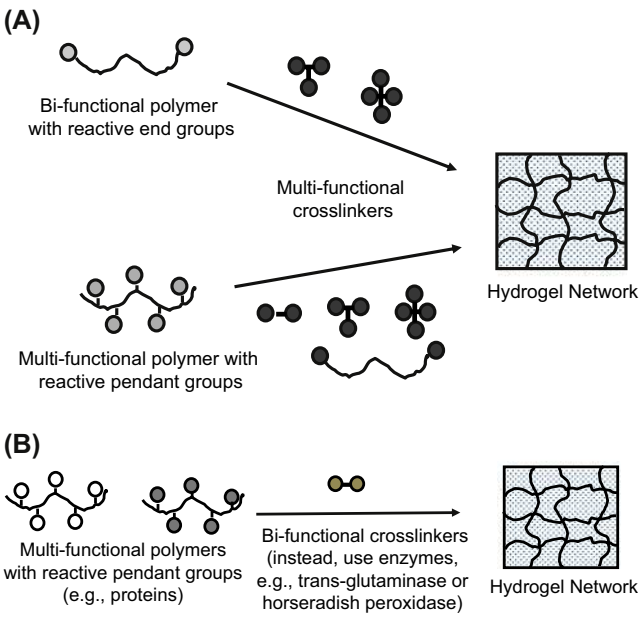


• **Figure 1.3.2E.2** Synthesis of hydrogels by free radical polymerization reactions and cross-linking reactions (Hoffman, 2002).

reactions are free radical polymerization or cross-linking reactions, and such processes for synthesis of cross-linked hydrogels can be initiated by decomposition of peroxides or azo compounds, or by using ionizing radiation or UV light. Ionizing radiation methods utilize electron beams, gamma rays, or X-rays to excite a polymer and produce a cross-linked structure via free radical reactions (e.g., Chapiro, 1962). Such free radical reactions can lead to rapid formation of a three-dimensional network, and are usually carried out in the absence of oxygen or air (note: some polymers are degraded by radiation, especially in air).

In another method, chemical cross-linking calls for direct reaction of a linear or branched polymer with a difunctional or multifunctional, low-molecular-weight, cross-linking agent. This agent usually links two higher-molecular-weight chains through its di- or multifunctional groups (Fig. 1.3.2E.3A). There are a number of well-known reactions that can be used for linking hydrophilic polymers together with each other or with cross-linkers to form hydrogels, including some recent methods with growing popularity, such as the Michael addition of dithiol compounds with divinyl compounds (e.g., see Schoenmakers et al., 2004; van de Wetering et al., 2005) and the reaction of alkynes plus azides to form triazoles (click reaction; see Kolb et al., 2001). The reader is referred to the excellent, comprehensive book detailing such chemistries, *Bioconjugate Techniques* (Hermanson, 2008).

A similar method involves the reaction of a small bifunctional molecule and linear polymeric chains having pendant or terminal reactive groups such as –OH, $–NH_2$, NCO, or –COOH that are cross-linked by the bifunctional molecule (Fig. 1.3.2E.3B). Natural polymers such as proteins can also be cross-linked in a similar way using enzymes. For example,



• **Figure 1.3.2E.3** (A) Synthesis of hydrogels by cross-linking reactive polymers with multifunctional cross-linkers (Hoffman, 2002). (B) Synthesis of hydrogels by cross-linking of multifunctional polymers with small bifunctional molecules (Hoffman, 2002).

transglutaminase catalyzes the reaction of protein glutamine amide groups with lysine amino groups (or with pendant or terminal amine groups on a synthetic polymer backbone) (Sperinde and Griffith, 1997, 2000). This reaction is:

$$-(CH_2)_3-CONH_2+-(CH_2)_4-NH_2+ \text{transglutaminase} \rightarrow -(CH_2)_3-CONH-(CH_2)_4-^{+N}H_3$$

In another enzyme-catalyzed cross-linking reaction, hydroxyphenylpropionic acid (tyramine) was conjugated to gelatin and cross-linked to form a hydrogel by the horseradish peroxidase (HRP)-catalyzed oxidation reaction with hydrogen peroxide (H_2O_2) (Wang et al., 2010; Jin and Dijkstra, 2010).

The formation of hydrogel networks may also result from physicochemical interactions, and some examples are highlighted below.

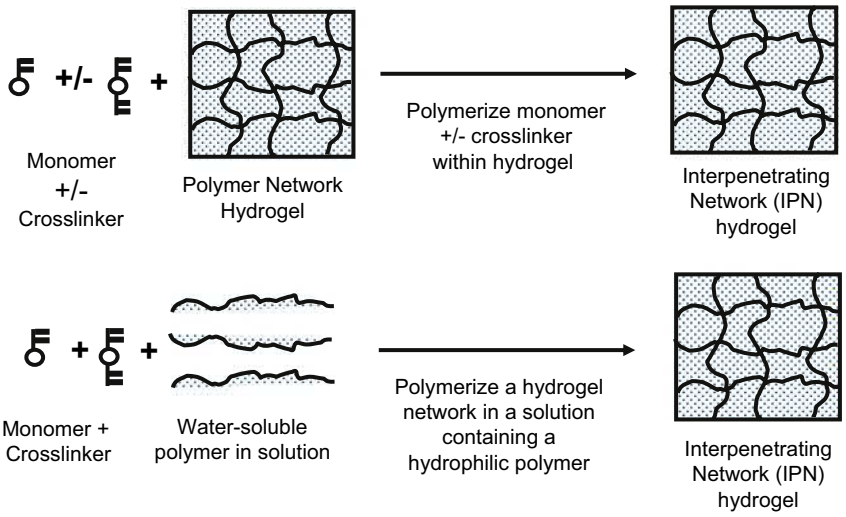
Poly(ethylene glycol) (PEG) molecules or block polymers containing PEG can "thread" through cyclodextrins (CDs), and sequences of CDs threaded on different PEG molecules can then self-associate, helping to hold together the hydrogel that is formed (Harada et al., 1992; Li et al., 2001, 2003a,b, 2006). Heterodimer peptide sequences that are conjugated as pendant groups on different polymer chains can complex together in "coil–coil" associations, and thereby "tie" chains together to form hydrogels (Yang et al., 2006; Xu and Kopecek, 2008). Stereocomplexes can form between D and L forms of poly(lactic acid) (known as PDLA/PLLA stereocomplexes); this complexation can lead to hydrogel formation if block copolymers that contain both PDLA and PLLA blocks, along with hydrophilic blocks as PEG, are mixed together (Jin and Dijkstra, 2010).

Fig. 1.3.2E.4 shows the formation of interpenetrating network (IPN) hydrogels. Fig. 1.3.2E.5 shows how hydrogels can be formed by ionic interactions. Fig. 1.3.2E.6A and B show how hydrogels can be formed by affinity recognition reactions (see also Miyata, 2010, for more on the formation of affinity recognition hydrogels).

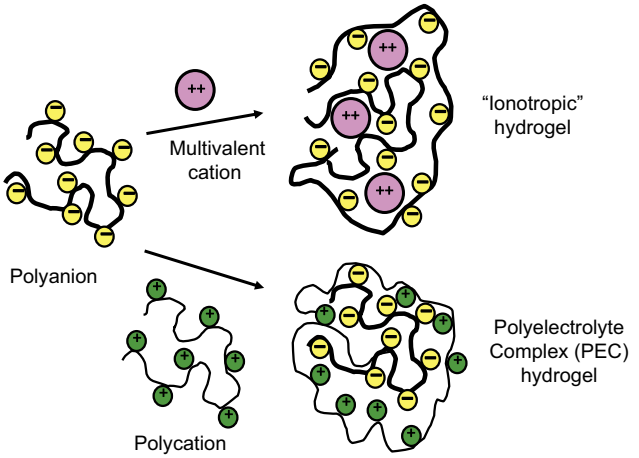
Swelling Behavior of Hydrogels

The physical behavior of biomedical hydrogels is dependent on their dynamic swelling and equilibrium in water and in aqueous solutions. Much of the water within swollen hydrogels may be bound to the polymer chains by either polar or hydrophobic interactions (e.g., Ilavsky, 1982). Many solutes can diffuse into and through hydrogels only within unbound or "free" water channels. Solutes that are chaotropic may diffuse into and through hydrogels by destructuring such bound water layers around the polymer chains.

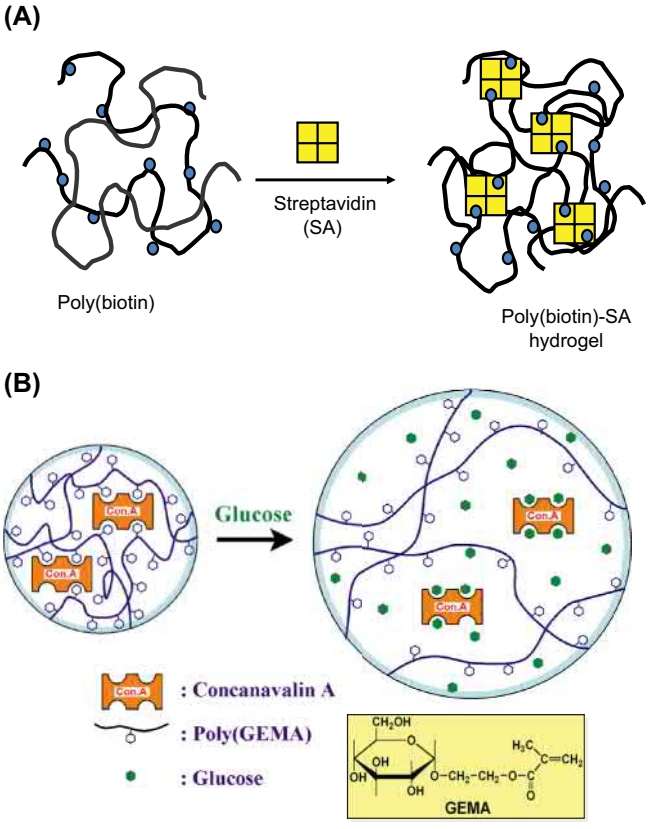
The Flory–Huggins theory is an ideal thermodynamic description of polymer solutions, and it does not consider network imperfections or the real, finite volumes of network chains and cross-links, and in the case of aqueous solutions it does not consider the presence of "bound" (vs. "free") water around the network chains. It can be used to calculate thermodynamic quantities related to that mixing process.



• **Figure 1.3.2E.4** Two methods for formation of an interpenetrating network (IPN) hydrogel (Hoffman, 2002).



• **Figure 1.3.2E.5** Formation of ionic hydrogels (Hoffman, 2002).



• **Figure 1.3.2E.6** (A) Formation of an affinity hydrogel between polybiotin and streptavidin (Morris et al., 1993). (B) Glucose-responsive hydrogel swells when free glucose competes with polymeric glucose groups in a ConA-cross-linked GEMA hydrogel (Miyata et al., 1996).

Flory (1953) developed the initial theory of the swelling of cross-linked polymer gels using a Gaussian distribution of the polymer chains. His model describing the equilibrium degree of cross-linked polymers postulated that the degree to which a polymer network swelled was governed by the elastic retractive forces of the polymer chains and the thermodynamic compatibility of the polymer and the solvent molecules. In terms of the free energy of the system, the total free energy change upon swelling was written as:

$$\Delta G = \Delta G_{\text{elastic}} + \Delta G_{\text{mix}} \qquad \textbf{(1.3.2E.1)}$$

Here, $\Delta G_{\text{elastic}}$ is the contribution due to the elastic retractive forces and ΔG_{mix} represents the thermodynamic compatibility of the polymer and the swelling agent (water).

Upon differentiation of Eq. (1.3.2E.1) with respect to the water molecules in the system, an expression can be derived for the chemical potential change of water in terms of the elastic and mixing contributions due to swelling.

$$\mu_1 - \mu_{1,0} = \Delta \mu_{\text{elastic}} + \Delta \mu_{\text{mix}} \qquad \textbf{(1.3.2E.2)}$$

Here, μ_1 is the chemical potential of water within the gel and $\mu_{1,0}$ is the chemical potential of pure water.

At equilibrium, the chemical potentials of water inside and outside of the gel must be equal. Therefore, the elastic

and mixing contributions to the chemical potential will balance one another at equilibrium. The chemical potential change upon mixing can be determined from the heat of mixing and the entropy of mixing. Using the Flory–Huggins theory, the chemical potential of mixing can be expressed as:

$$\Delta \mu_{mix} = RT\left(\ln\left(1-\upsilon_{2,s}\right) + \upsilon_{2,s} + x_1\upsilon_{2,s}^2\right) \quad \textbf{(1.3.2E.3)}$$

where χ_1 is the polymer–water interaction parameter, $\upsilon_{2,s}$ is the polymer volume fraction of the gel, T is absolute temperature, and R is the gas constant.

This thermodynamic swelling contribution is counterbalanced by the retractive elastic contribution of the cross-linked structure. The latter is usually described by the rubber elasticity theory and its variations (Peppas, 1987). Equilibrium is attained in a particular solvent at a particular temperature when the two forces become equal. The volume degree of swelling, Q (i.e., the ratio of the actual volume of a sample in the swollen state divided by its volume in the dry state) can then be determined from Eq. (1.3.2E.4).

$$\Delta \mu_{mix} = RT\left(\ln\left(1-\upsilon_{2,s}\right) + \upsilon_{2,s} + x_1\upsilon_{2,s}^2\right) \quad \textbf{(1.3.2E.4)}$$

Researchers working with hydrogels for biomedical applications prefer to use other parameters in order to define the equilibrium-swelling behavior. For example, Yasuda et al. (1969) introduced the use of the so-called hydration ratio, H, which has been accepted by those researchers who use hydrogels for contact lens applications (Peppas and Yang, 1981). Another definition is that of the weight degree of swelling, q, which is the ratio of the weight of the swollen sample over that of the dry sample.

In general, highly water-swollen hydrogels include those of cellulose derivatives, poly(vinyl alcohol), poly(N-vinyl 2-pyrrolidone) (PNVP), and poly(ethylene glycol), among others. Moderately and poorly swollen hydrogels are those of poly(hydroxyethyl methacrylate) (PHEMA) and many of its copolymers. In general, a basic hydrophilic monomer can be copolymerized with other more or less hydrophilic monomers to achieve desired swelling properties. Such processes have led to a wide range of swellable hydrogels, as Gregonis et al. (1976), Peppas (1987, 1997), and others have noted. Park and co-workers have developed a family of high water content, rapid swelling hydrogels (Omidian and Park, 2010), and superabsorbent hydrogels (Mun et al., 2010). Knowledge of the swelling characteristics of a polymer is of utmost importance in biomedical and pharmaceutical applications since the equilibrium degree of swelling influences: (1) the solute diffusion coefficient through these hydrogels; (2) the surface properties and surface molecule mobility; (3) the optical properties, especially in relation to contact lens applications; and (4) the mechanical properties.

Determination of Structural Characteristics

The parameter that describes the basic structure of the hydrogel is the molecular weight between cross-links, $\dot{M}_c$ (as shown in Fig. 1.3.2E.1A). This parameter defines the average molecular size between two consecutive junctions regardless of the nature of those junctions and can be calculated by Eq. (1.3.2E.5).

$$\frac{1}{\dot{M}_c} = \frac{2}{\dot{M}_n} - \frac{(\upsilon / V_1)\left[\ln\left(1-\upsilon_{2,s}\right) + \upsilon_{2,s} + x_1\upsilon_{2,s}^2\right]}{\left(\upsilon_{2,s}^{1/3} - \frac{\upsilon_{2,s}}{2}\right)} \quad \textbf{(1.3.2E.5)}$$

An additional parameter of importance in structural analysis of hydrogels is the cross-linking density, ϱ_x, which is defined by Eq. (1.3.2E.6).

$$\rho_x = \frac{1}{\dot{\upsilon}\dot{M}_c} \quad \textbf{(1.3.2E.6)}$$

In these equations, υ is the specific volume of the polymer (i.e., the reciprocal of the amorphous density of the polymer), and $\dot{M}_n$ is the initial molecular weight of the uncross-linked polymer.

Biomedical Hydrogels

Acrylic Hydrogels

Hydrogels with desired physical or chemical properties for a specific biomedical application may be "molecularly engineered" by choosing among the many types of acrylic monomers and cross-linkers available. This has led to many publications, describing a large family of acrylic hydrogels (e.g., Peppas et al., 2000; Peppas, 2001; Ottenbrite et al., 2010).

The most widely used hydrogel is water-swollen, cross-linked PHEMA, which was introduced as a biological material by Wichterle and Lim (1960). The hydrogel is inert to normal biological processes, shows resistance to degradation, is permeable to metabolites, is not absorbed by the body, is biocompatible, withstands heat sterilization without damage, and can be prepared in a variety of shapes and forms. The swelling, mechanical, diffusional, and biomedical characteristics of PHEMA gels have been studied extensively. The properties of these hydrogels are dependent upon their method of preparation, polymer volume fraction, degree of cross-linking, temperature, and swelling agent (Michalek et al., 2010).

Other acrylic hydrogels of biomedical interest include polyacrylamides and their derivatives. Tanaka (1979) has carried out extensive studies on the abrupt swelling and deswelling of partially hydrolyzed acrylamide gels with changes in swelling agent composition, curing time, degree of cross-linking, degree of hydrolysis, and temperature.

These studies have shown that the ionic groups produced in an acrylamide gel upon hydrolysis give the gel a structure that shows a discrete transition in equilibrium-swollen volume with environmental changes.

Discontinuous swelling in partially hydrolyzed polyacrylamide gels has been studied by Gehrke et al. (1986). Copolymers of HEMA and acrylamides with methacrylic acid (MAA) and methyl methacrylate (MMA) have proven useful as hydrogels in biomedical applications (see below).

Small amounts of MAA as a comonomer have been shown to dramatically increase the swelling of PHEMA polymers. Owing to the hydrophobic nature of MMA, copolymers of MMA and HEMA have a lower degree of swelling than pure PHEMA (Brannon-Peppas and Peppas, 1991a). One particularly interesting IPN is the double network (DN) hydrogel of Gong and Murosaki (Murosaki and Gong, 2010). These DN hydrogels are composed of two interpenetrating cross-linked networks of PAAm and PAMPS, and exhibit the unusual combination of exceptionally strong mechanical properties and high water contents. All of these materials have potential uses in advanced technology applications, including biomedical separations, drug-delivery devices, and as scaffolds for tissue engineering (Neves et al., 2017).

Poly(Vinyl Alcohol) (PVA) Hydrogels

Another hydrophilic polymer that has received much attention is poly(vinyl alcohol). This material holds great promise as a biological drug-delivery matrix because it is nontoxic. Two methods exist for the preparation of PVA gels. In the first method, linear PVA chains are cross-linked using glyoxal, glutaraldehyde, or borate. In the second method, semicrystalline gels are prepared by exposing aqueous solutions of PVA to repeated freezing and thawing (Peppas and Hassan, 2000). The freezing and thawing induces crystal formation in the materials and allows for the formation of a network structure cross-linked with the quasipermanent crystallites. The latter method is the preferred method for preparation as it allows for the formation of a "pure" network without the need to add cross-linking agents. Ficek and Peppas (1993) used PVA gels for the release of bovine serum albumin using novel PVA microparticles.

Poly(Ethylene Glycol) (PEG) Hydrogels

Hydrogels of poly(ethylene oxide) (PEO) and poly(ethylene glycol) (PEG) have received increasing attention recently for biomedical applications because of the nontoxic behavior of PEG, and its wide use in PEGylation of nanoscale drug carriers (e.g., Graham, 1992; Harris, 1992; Griffith and Lopina, 1995; Kofinas et al., 1996; Lee and He, 2010; Oishi and Nagasaki, 2010).

Three major techniques exist for the preparation of PEG networks: (1) chemical cross-linking between PEG chains, such as reaction of difunctional PEGs and multifunctional cross-linking agents; (2) radiation cross-linking of PEG chains to each other; and (3) physical interactions of hydrophobic blocks of triblock copolymers containing both hydrophobic blocks and PEG blocks (e.g., see Jeong et al., 2002, and Lee and He, 2010 for detailed discussion of pioneering work by S.W. Kim and co-workers on such block copolymer hydrogels. See also discussions of PEG hydrogels in the sections on Degradable Hydrogels and Temperature-Sensitive Hydrogels in this chapter).

The advantage of using radiation-cross-linked PEG networks is that no toxic cross-linking agents are required. However, it is difficult to control the network structure of these materials. Stringer and Peppas (1996) prepared PEG hydrogels by radiation cross-linking. In this work, they analyzed the network structure in detail. Additionally, they investigated the diffusional behavior of lower-molecular-weight drugs, such as theophylline, in these gels. Kofinas et al. (1996) have prepared PEG hydrogels by a similar technique. In this work, they studied the diffusional behavior of various macromolecules in these gels. They noted an interesting, yet previously unreported, dependence between the cross-link density and protein diffusion coefficient, and the initial molecular weight of the linear PEGs.

Lowman et al. (1997) described a method for the preparation of PEG gels with controllable structures. In this work, highly cross-linked and tethered PEG gels were prepared from PEG-dimethacrylates and PEG-monomethacrylates. The diffusional behavior of diltiazem and theophylline in these networks was studied. The technique described in this work has been used for the development of a new class of functionalized PEG-containing gels that are used for a variety of drug-release applications.

Degradable Hydrogels

Hydrogels may degrade and dissolve by either of two mechanisms: hydrolysis or enzymolysis of main chain, side chain, or cross-linker bonds (e.g., Gombotz and Pettit, 1995). Degradable hydrogels have mainly been designed and synthesized for applications in drug delivery and, more recently, as tissue engineering scaffolds (e.g., Park, 1993; Atzet et al., 2008; Garcia et al., 2010).

Hydrolytically degradable hydrogels have been synthesized from triblock copolymers of A–B–A structure that form hydrogels held together by hydrophobic forces, where A (or B) may be PLA, PLGA, or other hydrophobic polyesters that form hydrophobic blocks, and B (or A) is PEG, a hydrophilic block. These polyester hydrogels degrade into natural, endogenous metabolites such as lactic or glycolic acids, and the PEG block is then excreted through the kidneys (e.g., Lee and He, 2010; Jeong et al., 2002). A variation of this type of degradable hydrogel is formed by an A–B–A triblock copolymer composed of PEG-degradable polyester-PEG blocks mixed with cyclodextrin (CD) molecules, which thread onto the PEG blocks, after which the CDs self-assemble, forming the hydrogel [e.g., see the work of Harada et al., 1992; Li et al., 2001, 2003(a,b), 2006; Li, 2009].

Polymerizable, cross-linked, and degradable PEG gels have been prepared from acrylate- or methacrylate-terminated block copolymers that include PEG as a hydrophilic block (see the work of Hubbell and co-workers, e.g., Sawhney et al., 1993; Schoenmakers et al., 2004; van de Wetering et al., 2005; Lutolf and Hubbell, 2005; Raeber et al., 2005; Patterson et al., 2010; Patterson and Hubbell, 2010). These gels may have the simple A–B–A triblock structure of (methacrylate)–PEG–methacrylate which is photo-polymerized and later degrades by hydrolysis of the ester bonds linking PEG to the methacrylate cross-links. Another gel was formed with a more elaborate structure, (methacrylate–oligolactide–PEG–oligolactide–methacrylate), which is photo-polymerized, and later degrades and dissolves mainly by hydrolysis of the PLA in the main chains (see also Atzet et al., 2008; Kloxin et al., 2009). A third type of PEG gel may include a fibrin peptide cross-linking block, where the peptide is sequenced from fibrin that is a substrate for a naturally occurring, fibrinolytic enzyme. The peptide block reacts by thiol addition of HS–peptide–SH to the acrylate vinyl groups, cross-linking the (acrylate)–PEG–acrylate triblock, to form: {–peptide–S–acrylate–PEG–acrylate–S–peptide–}, which then degrades and dissolves by proteolysis of the peptide by a natural, endogenous fibrinolytic enzyme.

Star Polymer and Dendrimer Hydrogels

Dendrimers and star polymers (Dvornik and Tomalia, 1996; Oral and Peppas, 2004) are exciting new materials because of the large number of functional groups available in a very small molecular volume. Such systems could have great promise in drug-targeting applications. In 1993 Merrill published an exceptional review of PEO star polymers and applications of such systems in the biomedical and pharmaceutical fields. Griffith and Lopina (1995) prepared gels of controlled structure and large biological functionality by irradiation of PEO star polymers. Such structures could have particularly promising drug-delivery applications when combined with emerging new technologies such as molecular imprinting.

Self-Assembled Hydrogel Structures

Recently there have been new, creative methods of preparation of novel hydrophilic polymers and hydrogels that may have significant drug-delivery applications in the future [e.g., Li et al., 2001, 2003(a,b); Yang et al., 2006; Jin and Dijkstra, 2010; Wang et al., 2010; Miyata, 2010]. In one unusual example, Stupp et al. (1997) synthesized self-assembled triblock copolymer nanogels having well-defined molecular architectures.

Hydrogels usually exhibit swelling behavior dependent on the external environment. Over the last 30 years there has been a significant interest in the development and analysis of environmentally responsive hydrogels. These types of gels show large and significant changes in their swelling ratio due to small changes in environmental conditions, such as pH, temperature, ionic strength, nature, and composition of the swelling agent (including affinity solutes), light (visible vs. UV), electrical, and magnetic stimuli (e.g., Peppas, 1991; 1993; Hoffman, 1997; Hoffman et al., 2000; Yoshida and Okano, 2010). In most responsive networks, a critical point exists at which this transition occurs. These gels are sometimes referred to as "smart" or "intelligent" hydrogels.

"Smart" or "Intelligent," Stimuli-Responsive Hydrogels and Their Applications

An interesting characteristic of numerous stimuli-responsive "smart" gels is that the mechanism causing the network structural changes can be entirely reversible in nature (Koetting et al., 2015). The ability of pH- or temperature-responsive gels to exhibit rapid changes in their swelling behavior and pore structure in response to changes in environmental conditions lends these materials favorable characteristics as carriers for delivery of drugs, including peptides and proteins. This type of behavior may also allow these materials to serve as self-regulated, pulsatile, or oscillating drug-delivery systems (Yoshida and Okano, 2010).

pH-Sensitive Hydrogels

One of the most widely studied types of physiologically responsive hydrogels is pH-responsive hydrogels. These hydrogels are swollen ionic networks containing either acidic or basic pendant groups. In aqueous media of appropriate pH and ionic strength, the pendant groups can ionize and develop fixed charges on the gel, leading to rapid swelling. All ionic hydrogels exhibit both pH and ionic strength sensitivity, especially around the pK of the pH-sensitive group. These gels typically contain ionizable pendant groups such as carboxylic acids or amine groups. The most commonly studied ionic polymers include poly(acrylic acid) (PAA), poly(methacrylic acid) (PMAA), poly(diethylaminoethyl methacrylate) (PDEAEMA), and poly(dimethylaminoethyl methacrylate) (PDMAEMA). The swelling and drug-delivery characteristics of anionic copolymers of PMAA and PHEMA (PHEMA–co–MAA) have been investigated (Koetting et al., 2015). In acidic media, the gels did not swell significantly; however, in neutral or basic media, the gels swelled to a high degree due to ionization of the pendant acid group (this is similar behavior to that of polymers used as enteric coatings). Brannon-Peppas and Peppas (1991b) have also studied the oscillatory swelling behavior of these gels.

One interesting example of pH-responsive "smart" polymers with great sensitivity to pK is the behavior of two poly(alkylacrylic acids): poly(ethylacrylic acid) (PEAA) (Tirrell et al., 1985) and poly(propylacrylic acid) (PPAA) (Cheung et al., 2001). These polymers phase separate sharply as pH is lowered below their pK, and this can lead to lipid bilayer membrane disruption in acidic liposome solutions or within the acidic environments of endosomes and

lysosomes of cells, where the membranes of those vesicles contain proton pumps. This behavior makes such polymers very useful for endosomal escape and cytosolic delivery of biomolecular drugs such as protein and nucleic acid drugs (Stayton and Hoffman, 2008).

The swelling forces developed in pH-responsive gels are significantly increased over nonionic hydrogels. This increase in swelling is due to the presence of mobile counter-ions (such as Na^+) that electrostatically balance the fixed charges on the polymer backbone. The concentration of such counter-ions will be dependent on the concentration of the fixed polymer charges, which in turn will be dependent on the composition of the network polymer and the pH. As a result, the water content and mesh size of an ionic polymeric network can change significantly with small changes in pH, as the osmotic pressure of the counter-ions within the gel changes.

pH-Responsive Complexation Hydrogels

Another promising class of hydrogels that exhibits responsive behavior is complexing hydrogels. Bell and Peppas (1995) have discussed a class of graft copolymer gels of PMAAc grafted with PEG: poly(MAAc–g–EG). These gels exhibited pH-dependent swelling behavior due to the presence of acidic pendant groups and the formation of interpolymer H-bonded complexes at low pH between the ether groups on the graft chains and protonated pendant groups. In these covalently cross-linked, complexing poly(MAA–g–EG) hydrogels, complexation resulted in the formation of temporary physical cross-links due to hydrogen bonding between the PEG grafts and the pendant and protonated –COOH groups in PMAAc. The physical cross-links were reversible in nature and dependent on the pH and ionic strength of the environment. As a result, these complexing hydrogels exhibit drastic changes in their mesh size in response to small changes of pH, which could be useful for drug delivery in varying pH environments in the body, such as in the GI tract, mouth, and vagina, and on the skin.

In another study of complexation hydrogels, Hayashi et al. (2007) formed gels from PEGylated papain and PAAc at low pH. They showed how the molecular weight of the PEG and the addition of free PEG significantly affected the release rate of the PEGylated protein from the gel. A complexation gel formed as a result of H-bonding between PAAc and PAAm chains at low pH. It was unusual in that it exhibited temperature-responsive behavior, and went from a gel to a solution state as temperature rose above 30°C (Katono et al., 1991).

Temperature-Sensitive Hydrogels

Another class of environmentally sensitive gels exhibits sharp temperature-sensitive swelling–deswelling behavior due to a change in the polymer/swelling agent compatibility over the temperature range of interest. Temperature-sensitive polymers typically exhibit a lower critical solution temperature (LCST), below which the polymer is soluble. Above this temperature, the polymers may lose their hydrophobically bound water, and phase separate, causing the gel to collapse. Below the LCST, the cross-linked gel reswells to significantly higher degrees because of the increased hydrophobic bonding with water. Poly(N-isopropyl acrylamide) (PNIPAAm) has been the most widely studied temperature-responsive polymer and hydrogel, with an LCST of around 32–34°C (Dong and Hoffman, 1986; Park and Hoffman, 1990; 1992; Kim, 1996; Hoffman et al., 2000; Yoshida and Okano, 2010).

Some of the earliest work with PNIPAAm hydrogels was carried out by Dong and Hoffman (1986). They immobilized an enzyme in copolymer hydrogels of NIPAAm and AAm, and observed a maximum in the specific activity of the enzyme in each hydrogel as the temperature was raised. They concluded that above the maximum the gel collapsed as the copolymer LCST was surpassed, and the collapse blocked substrate diffusion into, and product out of, the gel. As the ratio of AAm/NIPAAm increased, the maximum shifted to higher temperatures due to the increasing hydrophilicity, which caused an increase in the LCST of the copolymer hydrogel. Most interesting was the fact that the curves were reversible up to the maximum reached for the highest AAm/NIPAAm ratio; above that LCST the enzyme was denatured due to the high temperature.

In another early work, Hirotsu et al. (1987) synthesized cross-linked PNIPAAm gels and determined that the LCST of the gels was 34.3°C; below this transition temperature significant gel swelling occurred. They noted that the deswelling–swelling above and below the LCST was reversible. Similar to Dong and Hoffman (1986), they also noted that the transition temperature was raised by copolymerizing PNIPAAm with small amounts of hydrophilic ionic monomers. Dong and Hoffman (1991) prepared heterogeneous PNIPAAm gels containing silicone polymer regions; these unusual gels collapsed at significantly faster rates than homopolymers of PNIPAAm. Park and Hoffman (1990, 1992) studied the effect of temperature cycling on the efficiency of enzyme turnover in a temperature-controlled packed bed of PNIPAAm hydrogel microparticles containing the enzyme. They noted a significant increase in the productivity of the reactor with thermal cycling of temperatures from above to below the LCST, where the increased efficiency was due to the collapse of the gel particles above the LCST, "squeezing" out the product followed by reswelling of the gel below the LCST, enhancing uptake of substrate.

Yoshida et al. (1995) and Kaneko et al. (1996) developed an ingenious method to prepare comb-type graft hydrogels of PNIPAAm chains grafted to a PNIPAAm hydrogel network. Under conditions of gel collapse (above the LCST), hydrophobic regions were developed in the pores of the gel by the collapse of the grafted chains, drawing the network chains together with the collapsing grafted chains, resulting in very rapid collapse of the gel. These materials had the ability to collapse from a fully swollen conformation in less than 20 min, while comparable gels that did not contain

graft chains required up to a month to fully collapse. Such systems show promise for rapid or oscillatory release of drugs such as peptides and proteins.

There is a whole class of thermally sensitive hydrogels based on physical interactions of hydrophobic blocks of triblock copolymers that also contain PEG blocks. Pluronic block polymers (e.g., PPO–PEO–PPO) form such gels, but they are not degradable. The most interesting block copolymers for biomedical applications are hydrolytically degradable since they contain blocks of PLA or PLGA (e.g., PLGA–PEG–PLGA or PEG–PLA–PEG), which hydrolyze and release PEG chains that can be eliminated through the kidneys. These thermally gelling block copolymers form in situ gels when injected subcutaneously, and act as drug-delivery depots, releasing entrapped drugs as they degrade (e.g., see Jeong et al., 2002, and Lee and He, 2010 for detailed discussion of pioneering work by S. W. Kim and co-workers on such block copolymer hydrogels). One very interesting class of such degradable block copolymer hydrogels is formed by stereocomplexation of the two stereoisomers of PLA in PLLA–PEG and PDLA–PEG block copolymers (Fujiwara et al., 2010; Gaharwar et al., 2014).

Affinity Hydrogels

Some hydrogels may exhibit environmental sensitivity due to the formation of complexes between chains that hold them together as a gel. Polymer complexes are macromolecular structures formed by the noncovalent association of groups on multifunctional molecules or on polymer chains that exhibit affinity for different groups on another polymer molecule. Sometimes this complexation is due to affinity recognition interactions, such as between streptavidin, with four binding sites for biotin, and a polymer with multiple pendant biotins (see Fig. 1.3.2E.7A and Morris et al., 1993), or concanavalin A with four binding sites for glucose and a polymer with multiple pendant glucose units (see Fig. 1.3.2E.7B and Miyata et al., 1996), or an antibody with two binding sites for its antigens (Miyata, 2010). The complexes may form by association of repeating units on different chains (interpolymer complexes) or on separate regions of the same chain (intrapolymer complexes). The stability of these affinity hydrogels is dependent on such factors as the affinity constant of the association, the concentration of a competing, mobile affinity agent, temperature, pH, ionic strength, network composition, and structure, especially the length of the network polymer chains between association points. In these types of hydrogel, complex formation results in the formation of physical cross-links in the gel. As the degree of such physical cross-linking is increased, the network mesh size and degree of swelling will be significantly reduced. As a result, if such hydrogels are used as drug carriers, the rate of drug release will decrease dramatically upon the formation of interpolymer complexes.

The hydrophilic character of hydrogels makes them attractive for a variety of biomedical and pharmaceutical applications. Because of their normally high water contents, hydrogels have been useful for delivering drugs from ingested tablets and osmotic pumps. Further, they have been successful as contact lenses applied to the eye, or as drug-releasing coatings on mucosal, skin, or open-wound surfaces. They have also been applied as nonfouling coatings on implants and devices that may contact blood, such as catheters. More recently they are being developed as scaffolds for tissue engineering implants.

Biomedical Applications of Hydrogels

Contact Lenses

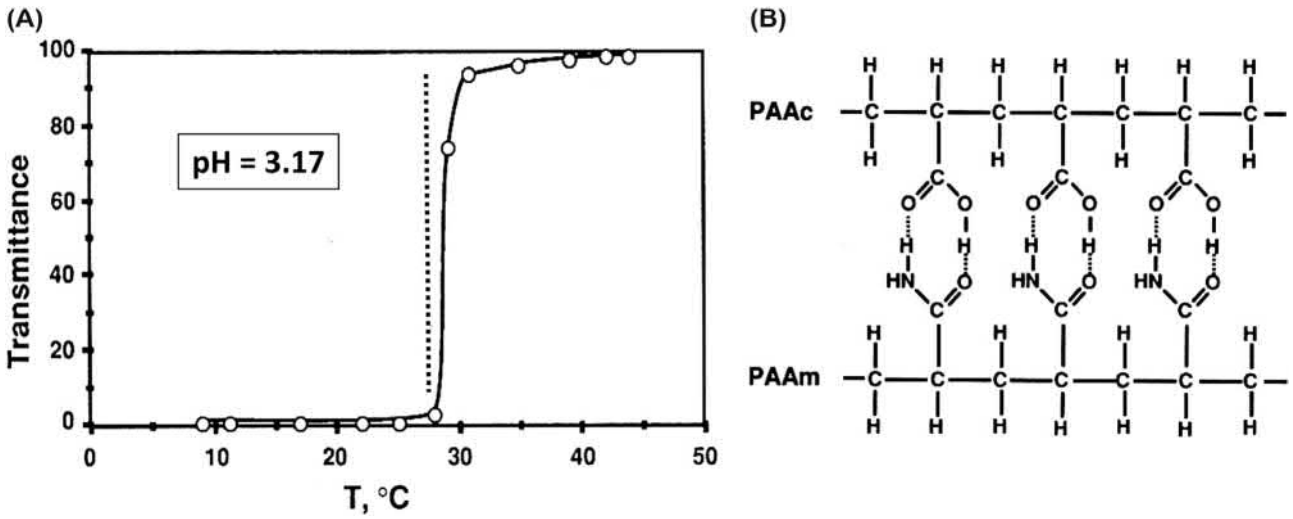
One of the earliest biomedical applications of hydrogels was the use of PHEMA hydrogels in contact lenses (Wichterle and Lim, 1960). Hydrogels are particularly useful as contact lenses because of their relatively good mechanical stability and favorable refractive index (see also Tighe, 1976; Peppas and Yang, 1981; Michalek et al., 2010). More recently, extended-wear contact lenses have been fabricated from an IPN composed of PNVP chains entrapped within a silicone hydrogel network. In this system, silicone monomers and cross-linkers are polymerized in a solution containing PNVP, and an IPN hydrogel is formed. The PNVP acts to lubricate the surface of the lens against the cornea, and the silicone hydrogel provides high oxygen transport to the cornea, as well as enhanced permeability of small nutrient molecules and ions.

Blood-Contacting Hydrogels

Hydrogels also exhibit properties that make them desirable candidates for blood-contacting biomaterials (Merrill et al., 1987). Nonionic hydrogels have been prepared from poly(vinyl alcohol), polyacrylamides, PNVP, PHEMA, and poly(ethylene oxide) (PEO, sometimes also referred to as PEG) (Peppas et al., 1999). Heparinized polymer hydrogels (Sefton, 1987) and heparin-based hydrogels (Tae et al., 2007) also show promise as materials for blood-contacting applications.

Drug Delivery From Hydrogels

Applications of hydrogels in controlled drug-delivery systems (DDS) have become very popular in recent years. They include equilibrium-swollen hydrogels, i.e., matrices that have a drug incorporated in them and are swollen to equilibrium, releasing the drug. This category of *solvent-activated*, matrix-type, controlled-release devices comprises two important types of systems: *(1) rapidly swelling, diffusion-controlled devices*; and *(2) slowly swelling, swelling-controlled devices*. In general, a drug-loaded hydrogel may be prepared by swelling the hydrogel to equilibrium in a drug solution, and carefully drying it. In the dry state it becomes a glassy polymer that can be swollen when brought in contact with water or simulated biological fluids. This swelling process may or may not be the controlling mechanism for



• **Figure 1.3.2E.7** Temperature dependence of light transmission for two H-bonded polymers, PAAc [poly(acrylic acid)] and PAAm (polyacrylamide) at pH 3.17; (A) shows the temperature dependence of light transmission and (B) shows the hypothetical H-bonded structure that would exist at low pH and at temperatures below 30°C, where the COOH groups are protonated and the polymer chains are complexed. The H-bonding is disrupted as temperature rises above 30°C. Data are for an aqueous solution at pH 3.17 (adjusted by HCl). Polymer concentration (wt.%): PAAc, 0.5%; PAAm, 0.5%. (Katono et al. (1991).

diffusional release, depending on the relative rates of the macromolecular relaxation of the polymer and drug diffusion from the gel.

In swelling-controlled release systems, the bioactive agent is dispersed into the polymer to form nonporous films, disks, or spheres. Upon contact with an aqueous dissolution medium, a distinct front (interface) is observed that corresponds to the water penetration front into the polymer and separates the glassy from the rubbery (gel-like) state of the material. Under these conditions, the macromolecular relaxation of the polymer influences the diffusion mechanism of the drug through the rubbery state. This water uptake can lead to considerable swelling of the polymer, with a thickness that depends on time. The swelling process proceeds toward equilibrium at a rate determined by the water activity in the system and the structure of the polymer. If the polymer is cross-linked, or if it is of sufficiently high molecular weight (so that chain entanglements can maintain structural integrity), the equilibrium state is a water-swollen gel. The equilibrium water content of such hydrogels can vary from ~30% to over 90%. If the dry hydrogel contains a water-soluble drug, the drug is essentially immobile in the glassy matrix, but begins to diffuse out as the polymer swells with water. Drug release thus depends on the simultaneous rate processes of water migration into the device, polymer chain hydration and relaxation, followed by drug dissolution and diffusion outward through the swollen gel. An initial burst effect is frequently observed in matrix devices, especially if the drying process brings a higher concentration of drug to the surface. The continued swelling of the matrix causes the drug to diffuse increasingly easily, mitigating the slow tailing off of the release curve. The net effect of the swelling process is to prolong and "linearize" the release curve. Details of the process of drug delivery from hydrogels have been presented by Korsmeyer and Peppas (1981) for poly(vinyl alcohol) systems, and by Reinhart et al. (1981) for PHEMA systems and their copolymers. One of numerous examples of such swelling-controlled systems was reported by Franson and Peppas (1983) who prepared cross-linked copolymer gels of poly(HEMA–co–MAA) of varying compositions. Theophylline release was studied and it was found that near zero-order release could be achieved using copolymers containing 90% PHEMA. For sensing devices see also Snelling Van Blarcom and Peppas (2011).

Targeted Drug Delivery From Hydrogels

Promising new methods for the delivery of chemotherapeutic agents using hydrogels have been recently reported. Novel bio-recognizable sugar-containing copolymers have been investigated for use in targeted delivery of anticancer drugs. For example, Peterson et al. (1996) have used poly(N-2-hydroxypropyl methacrylamide) carriers for the treatment of ovarian cancer. Sharpe et al. (2014) used hydrogels for advanced drug-delivery release.

Tissue Engineering Scaffolds From Hydrogels

This is an application area that continues to expand. It is driven by the same attractive properties that drive the use of hydrogels for drug-delivery applications: high water content gels that may be synthesized with degradable backbone polymers, with an added advantage of being able to attach cell adhesion ligands to the network polymer chains. There are a number of natural polymer-based hydrogel scaffolds that have been studied (e.g., collagen, gelatin, alginates, hyaluronic acid, chitosan, etc.) and the reader is referred to three chapters in this text (see Chapters 1.3.6A, 1.3.6B and 2.6.3)

and some excellent review articles (Lee and Mooney, 2001; Lutolf and Hubbell, 2005; Jin and Dijkstra, 2010).

One very interesting observation with hydrogels that has recently been reported is that they may stimulate stem cell differentiation; that is, when stem cells are deposited on some hydrogel surfaces, depending on the composition and/or mechanical stiffness of the surface, differentiation of the stem cells into certain phenotypes may occur (e.g., Liu et al., 2010; Nguyen et al., 2011). An important recent review of hydrogel design for regenerative medicine applications can be found in Annabi et al. (2014).

Miscellaneous Biomedical Applications of Hydrogels

Other potential applications of hydrogels mentioned in the literature include artificial tendon materials, wound-healing bio-adhesives, artificial kidney membranes, articular cartilage, artificial skin, maxillofacial and sexual organ reconstruction materials, and vocal cord replacement materials (Byrne et al., 2002a,b).

Introduction

Degradable polymers offer many advantages when used in biomaterial applications (e.g., temporary implants, degradable sutures, or drug delivery platforms), because of their ability to degrade in different environments, over different time scales, and without the production of toxic by-products (Piskin, 1995; Shalaby and Burg, 2003). Degradation is often desirable, as it can circumvent the need for additional surgeries to remove nondegradable medical implants/sutures, and hence reduce recovery time and risk of infection, as well as lower healthcare costs. Applications of degradable polymers are not limited to short-term applications, as tailoring polymer properties allows for controlled degradation rates to enable long-term support for tissue regeneration and sustained drug delivery over a defined period of time. Although degradable polymers offer a range of benefits, one must also consider the biocompatibility of the degradation products in addition to the polymer itself. Furthermore, uncontrolled or accelerated polymer degradation rates can lead to premature implant failure or side effects from depositing high concentrations of an encapsulated therapeutic. However, with careful consideration of polymer design, chemistry, and function, degradable biomaterials can be synthesized with precise and relevant degradation timescales, producing nontoxic, and in some cases functional, degradation products (e.g., release of a drug) (He and Benson, 2017).

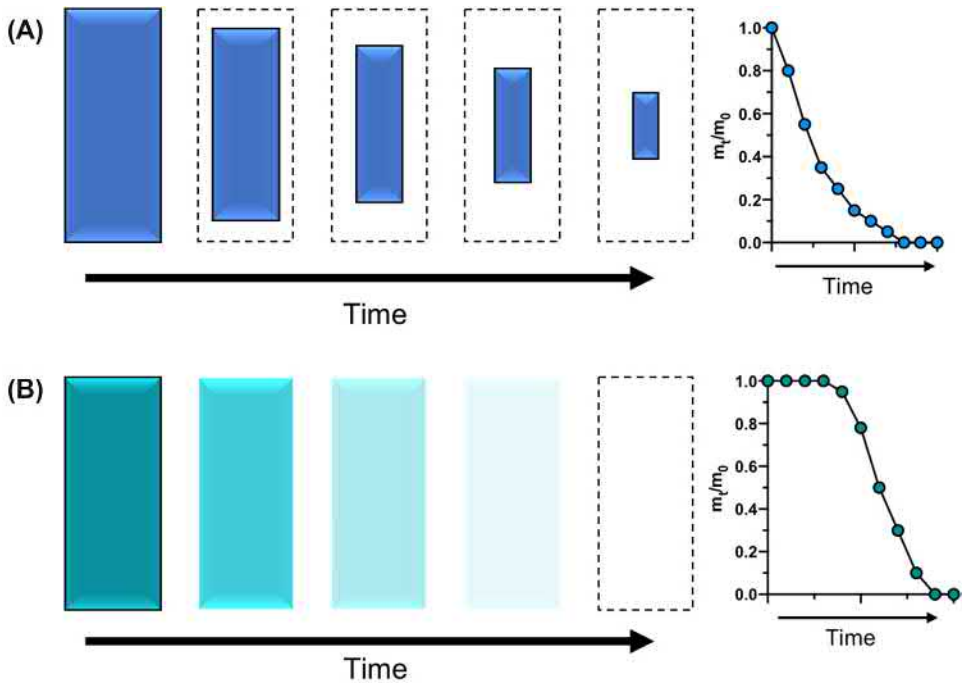
While natural polymers are also able to degrade, given the correct conditions and timescale, synthetic polymers offer specific advantages with respect to controlled synthetic routes, resulting in highly defined polymers with user-designed degradability and tunable material properties. This chapter, in the context of biomaterials applications, focuses on synthetic degradable polymers, including: (1) degradable polymer properties, (2) types of different degradation processes and their kinetics, (3) design and processing considerations, and (4) performance metrics unique to degradable biomaterials. The chapter concludes with case studies of commercially available degradable polymers that are used in medical devices and drug delivery systems, demonstrating the importance of degradable polymers to the field of biomaterials.

Brief History of Degradable Polymers

The application of degradable polymers in medicine can be dated back to the early 1960s when polymers (e.g., poly(glycolic acid) (PGA)), which were initially found unstable due to rapid degradation, were used as suture materials (Dardik et al., 1971; Morgan, 1969; Vert, 1989). Since then, numerous degradable biomaterials have been investigated and continue to play a critical role in clinical applications, as well as laboratory research. In recent decades, there have been major advances in the design and applications of synthetic polymeric degradable materials (Vert et al., 1992; Anderson and Shive, 1997; Langer and Tirrell, 2004). Through theoretical and experimental investigations, degradable polymers have found numerous applications, particularly in the fields of drug delivery (Siepmann and Göpferich, 2001) and tissue engineering (Langer and Tirrell, 2004; Tibbitt et al., 2015; Tibbitt and Anseth, 2009), and have resulted in high levels of commercialization (Deshayes and Kasko, 2013).

Definition of Degradation, Erosion, Bulk, and Surface Processes

Many of the important terms related to biodegradable materials are explained in this section and their definitions are summarized in Table 1.3.2F.1. Degradation is defined as a bond cleavage event leading to a change in structure of a material,



• **Figure 1.3.2F.1** Schematics (left) and representative mass loss as a function of time (right) for (A) surface erosion (B) bulk erosion. (Adapted from Figures 1 and 4 of Burkersroda et al., 2002).

characterized by a loss of properties and/or fragmentation (Göpferich, 1996; Williams and Zhang, 2019a). Bond cleavage can occur through a variety of processes (i.e., hydrolysis, enzymatic activity, or exposure to light). Consequently, the molecular weight of the polymer decreases to form lower molecular weight oligomers and monomers, and ultimately results in the loss of mechanical stability of the material. While polymers can be degraded through a variety of mechanisms, such as thermal, mechanical, and photodegradation, the most common modes of degradation in a therapeutically relevant in vivo environment are either hydrolytic or enzymatic degradation. The term "biodegradation" is typically reserved for situations where the degradation involves biological entities and environments, such as bodily fluids, cellular activity, and/or enzymatic reactions. The conditions of the biological environment therefore determine the rate of polymer degradation to a great extent. For example, the degradation of a polymeric biomaterial may proceed faster when implanted in a highly inflammatory environment, due to excessive biological and biochemical activity. Thus context matters when selecting a degradable polymer for implantation. The pH and temperature of the local biological environment, enzyme concentrations, and cell infiltration/recruitment to the implant sites affect the rate of polymer degradation.

Erosion is defined as a process in which mass is lost that may result in a change in the physical size or shape of a device. How a material erodes is also an important consideration for polymer design (Burkersroda et al., 2002). Bulk erosion entails mass loss throughout a material, whereas surface erosion is restricted to the surface of the material and proceeds via an erosion front (Tamada and Langer, 1993; Woodard and Grunlan, 2018). Surface erosion is useful in drug delivery applications, as the release rate of a drug from surface-eroding polymers is independent of diffusion and is easily altered by changing the device geometry (Tabata et al., 1993; Wei et al., 2015). It is important to note that both degradation and erosion processes can occur without the presence of water (Fig. 1.3.2F.1). Following this, bioerosion is defined as the process of erosion in a biological setting (e.g., enzymatic erosion).

Resorption is the process of eliminating the products produced through degradation. Resorption occurs in a variety of ways. For example, the degradation product of PGA is glycolic acid, which can be used in the Krebs cycle when produced in vivo. This example also highlights bioresorption, where the process of removal is via cellular activity and/or the dissolution of a material is in a biological environment (Williams and Zhang, 2019b).

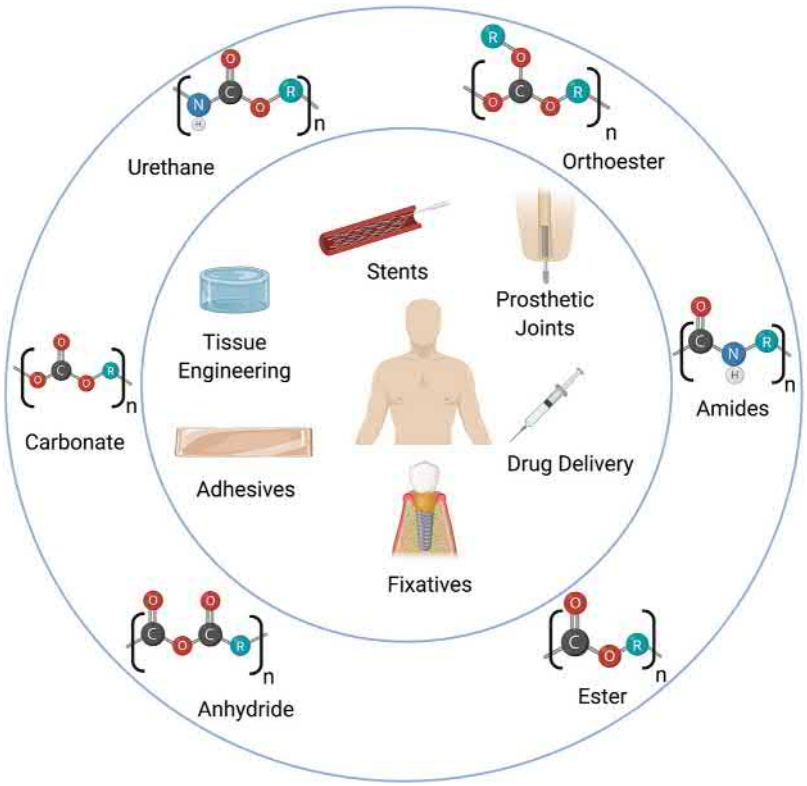
While this chapter primarily discusses degradation that is engineered into the polymer and its structure by design, one should always remember that in vivo implantation of any degradable polymer device can result in unintended degradation. For example, polyesters can be degraded in vivo by cell-secreted esterases in addition to hydrolysis.

Degradable Polymer Properties

Since the concept of polymerization emerged in the 1920s, development of polymers with defined molecular weights and chemical functionality has grown, especially as precursors to synthesize degradable biomaterials (Fig. 1.3.2F.2). To date, a wide range of degradable polymers has been developed to achieve controlled and tailorable degradation behavior (Langer and Tirrell, 2004; Nair and Laurencin, 2007; Piskin, 1995). In this section, important polymer properties that affect biomaterial degradation (e.g., polymer backbone functionality, polymer architecture, hydrophobicity/hydrophilicity, crystallinity) are discussed.

TABLE 1.3.2F.1 Definition and Examples of Key Processes

Term	Definition	Example
Degradation	A chemical process by which bonds are cleaved	Hydrolysis of poly(lactic acid)
Resorbable	The process of eliminating the degradation products	Bone resorption
Erosion	A process that results in the mass loss of a material that may result in a change of size, shape, or mass	Release of a drug through layer-by-layer erosion of a nanoparticle
Biodegradation	Cleavage of bonds as a consequence of a biological agent, such as an enzyme, cell, or microorganism	Enzymatic degradation of amorphous poly(L-lactide) by proteinase K
Bioerosion	Erosion in a biological setting	Microborers graze on the surface of coral slowly breaking down limestone
Surface Erosion	Erosion that is restricted to the surface of a material and proceeds via an erosion front	Surface erosion of polyanhydrides
Bulk Erosion	Erosion that occurs throughout a sample causing the whole material to degrade	Degradation of poly(glycolic acid)



• **Figure 1.3.2F.2** Overview of degradable polymer backbone functionalities and some of their applications as biomaterials. (Image created with biorender.com).

Polymer Backbone Functionality

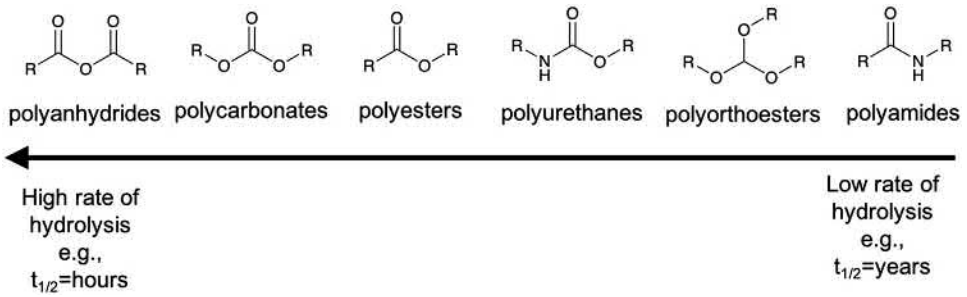
The most common backbone functionalities incorporated into polymer chains are hydrolytically susceptible groups (i.e., covalent bonds that degrade in the presence of water), which enables polymer degradation under biologically relevant conditions (Table 1.3.2F.2). In general, anhydrides and carbonates are among the fastest degrading chemical bonds, followed by ester and urethane bonds. Ortho esters and amides have the lowest rate of hydrolysis (Fig. 1.3.2F.3). The degradation rates of these chemical bonds, however, are affected by several factors, such as the presence of nearby hydrophobic groups, changes in local pH due to degradation products, molecular weights of the polymer, and polymer architecture (Gombotz and Pettit, 1995).

Polyanhydrides

The anhydride linkage is among the least hydrolytically stable, so polyanhydrides are typically synthesized from hydrophobic diacids (Rosen et al., 1983). Hydrophobicity, which limits water penetration into the polymer, combined with the fast

TABLE 1.3.2F.2 Examples of Degradable Polymers and Their Commercial Uses as Biomaterials

Functional Group	Structure	Commercial Example	Commercial Use
Polyanhydrides	 Poly(PCPP-SA anhydride)	Gliadel	The treatment of glioblastoma multiforme
Polyesters	 Poly(lactic acid)	Lactosorb	Meniscal staples
	 Poly(glycolic acid)	Unify	Surgical sutures
Polycarbonates	 Poly(ε-caprolactone)	Monocryl	Drug delivery sutures
	 Poly(trimethylene carbonate)	Maxon	Monofilament resorbable sutures



• **Figure 1.3.2F.3** Relative hydrolytic rates of degradable functional groups. The rate at which the functional group degrades also depends on pH, crystallinity, equilibrium water content and architecture. (Adapted from Gombotz and Pettit (1995)).

hydrolysis rate of the anhydride linkage, leads to surface erosion, producing diacid monomers that can be metabolized by the body. Due to the fast-degrading anhydride bonds (days to weeks) and the nontoxic acid degradation products, polymers made from polyanhydrides have been used for short-term drug release for more than three decades (Leong et al., 1986; Rosen et al., 1983). The unique properties of polyanhydrides result in near zero-order drug release profiles from thin disks, but the geometry of the polymer (e.g., porous scaffolds, microspheres, disks) and composition of the diacids used to synthesize the polymers allow further tailoring of the release profile (Tabata et al., 1993; Tamada and Langer, 1992).

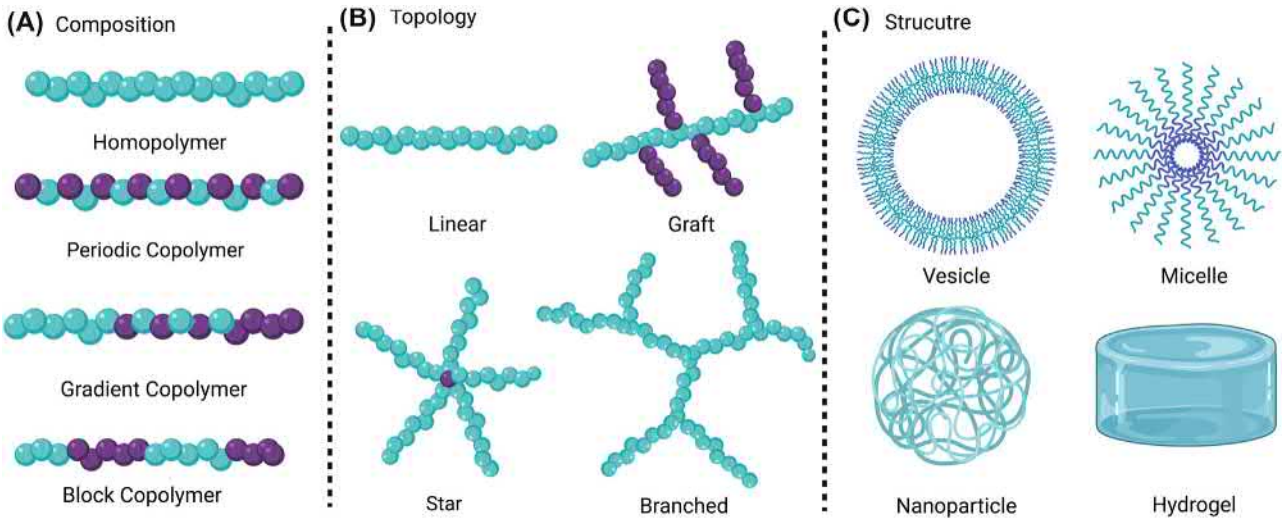
Poly(Ortho Esters)

Compared to polyanhydrides, poly(ortho esters) are more hydrophobic, but still undergo surface erosion when degrading, albeit with slower degradation rates compared to polyanhydrides (Heller et al., 2002). The degradation of poly(ortho esters) produces esters as initial degradation products, followed by further degradation into acids and alcohols. The use of poly(ortho esters) as controlled release devices dates back to the early 1970s (Heller and Barr, 2004). Since the polymers are surface eroding, drug release rates are controlled by the rate of polymer erosion, similar to the polyanhydrides, and can be tuned by the polymer composition and geometry of the device.

Polyesters and Polycarbonates

One of the most popular classes of degradable polymers, poly(α-hydroxy esters), falls into this category and includes poly(lactic acid) (PLA), PGA, and their copolymer, poly(lactic-co-glycolic acid) (PLGA). Poly(α-hydroxy esters) were among the first synthetic polymers with clinical applications (Gilding and Reed, 1979; Reed and Gilding, 1981). For example, PGA has long been used as a suture material due to its rapid erosion rate.

The hydrolysis of poly(α-hydroxy esters) occurs at the ester bonds in the polymer backbone, and is governed by the accessibility of water to those bonds. Upon cleavage, acidic degradation products (e.g., lactic acid and glycolic acid) are released that can lower the local pH and accelerate the hydrolytic degradation rate (Cha and Pitt, 1989). In addition, the monomers of PLA, lactic acid, and lactide have chiral centers (i.e., four different groups attached to a carbon atom, L and D form)



• **Figure 1.3.2F.4** Different polymer (A) compositions, (B) topology and (C) structures. (Images created with biorender.com).

enabling different stereo polymeric isomers to form (e.g., poly(L-lactic acid) and poly(D-lactic acid) (PDLA)). These PLA isomers have different degradation rates as a consequence of the accessibility of the ester groups to water molecules. The effect of crystallinity and hydrophobicity as a function of PLGA composition or stereochemistry of PLA and the influence on the degradation rate are discussed later in this chapter.

This category also includes poly(ε-caprolactone) (PCL), a commercially available polycarbonate, which has high solubility and a low melting temperature (59–64°C). It is a semicrystalline polymer with a low glass transition temperature, T_g. As such, in comparison to PGA, PCL has a lower mechanical strength but has been commercialized as an implantable contraceptive device, Capronor (Brannigan and Dove, 2017).

Many degradable devices are made from polymers with nondegradable backbone functionalities (e.g., poly(ethylene glycol) (PEG), polycyanoacrylates, and polyphosphazenes). Devices made from these polymers can be engineered to degrade through the addition of degradable functional end groups, side chains, or cross-linkers. Nondegradable polymers confer advantageous properties to the polymeric device. For example, PEG is a hydrophilic and nonfouling material that has been used extensively in the formation of degradable hydrogels through functionalization of pendant hydroxyl groups (see Chapter 1.3.2E). These polymer systems have found applications in adhesives, bandages, and photodegradable scaffolds (Doppalapudi et al., 2014).

Polymer Architecture

Polymerization Routes

Varying the architecture of a polymer, rather than its backbone chemistry and pendant functional groups, is equally important for controlling the final degradation pathways and kinetics. By considering polymerization conditions, polymers can be synthesized in a controlled manner with predictable degradation routes and products (Nair and Laurencin, 2007; Shalaby and Burg, 2003). Many degradable polymers are synthesized through condensation and addition polymerization routes (discussed in Chapter 1.3.2 (Odian, 2004)). Polycondensation of difunctional monomers preferentially yield low molecular weight polymers that can reduce the mechanical properties of the material (Vroman and Tighzert, 2009). Ring-opening polymerization reactions are commonly used to prepare polyesters from six- or seven-membered lactones that result in high molecular weight polymers (Albertsson and Varma, 2003).

To increase the predictable nature and to enhance the sophistication of the polymeric biomaterial, degradable polymers are synthesized through controlled radical polymerization routes, which allow for precise molecular weights and lower polymer dispersity to be obtained. The ratio of comonomers is included in a controlled, statistical manner. Two examples of controlled radical polymerization routes are reversible addition–fragmentation chain transfer (RAFT) and atom transfer radical polymerization (ATRP). RAFT is a living radical polymerization technique using a chain transfer agent, typically a thiocarbonylthio, that influences reaction kinetics and, consequently, properties of the resultant polymer (Barner-Kowollik, 2008). Alternatively, ATRP uses a metal complex to control the rate of monomer addition to the propagation polymer chain end, reducing termination of polymer end groups and lowering the dispersity of the polymer (Wang and Matyjaszewski, 1995). Both of these routes form polymers with predictable molecular weights, high functionality, and low dispersity, three important factors with regards to polymer degradation rate (see Chapter 1.3.2 for more details).

In addition, these routes enable controlled synthesis of copolymers with different polymer compositions (e.g., statistical, gradient, and block copolymers, Fig. 1.3.2F.4A) and topologies (e.g., graft, dendritic, and star polymers, Fig. 1.3.2F.4B), each with different degradation profiles. For example, high ratios of hydrophilic monomers in a block copolymer would accelerate the degradation rate. Furthermore, star polymers synthesized with a degradable core (in which water can easily infiltrate) exhibit rapid degradation of pendant arms under the correct environmental conditions (Rosselgong et al., 2013). Copolymers are also able to self-assemble into different

structures (e.g., micelles, vesicles, and worm structures) (Fig. 1.3.2F.4C), facilitating sustained release of a drug or layer-by-layer degradation of a nanoparticle, with and without the use of external stimuli (e.g., light or pH) (Kocak et al., 2017; Rinkenauer et al., 2015; Zhang et al., 2015).

Molecular Weight

Degradation rate is also influenced by polymer molecular weight and is therefore an important consideration when designing a degradable polymeric device. The degradation rate increases as molecular weight increases as a consequence of the accessibility of functional groups for the degrading species. For example, PDLA with a molecular weight higher than 5000 Da is hard and rigid, making it difficult for the degrading species (e.g., water or enzymes) to access the backbone of the polymer. As a result, the time it takes to degrade high molecular weight PDLA is longer than for softer, lower molecular weight PLDA devices (Niaounakis, 2013).

Morphology

Depending on the structure, packing, and chemistry of the polymer chains, the resultant polymeric devices will have different rates of degradation. One of the most important polymer properties in the context of degradation is the T_g. T_g is the temperature at which a polymer transitions from a "glassy" to a "rubbery" state as the polymer chains gain sufficient thermal energy to undergo coordinated movement. Therefore a more rapid diffusion of degrading species occurs within the polymer matrix and, consequently, more rapid degradation is expected at temperatures above the T_g of the polymer. These characteristics are especially important when the T_g is near body temperature (37°C), which could lead to abrupt or unexpected changes in the bioerosion kinetics of the device.

In addition to polymers being classified as glassy or rubbery, polymers are also classified based on how the polymer chains pack together. Specifically, polymers have amorphous regions, where the polymer chains are randomly and loosely packed, and sometimes crystalline regions, where the polymer chains are densely packed in an ordered structure. Polymers that have both amorphous and crystalline regions are characterized as semicrystalline. For further explanation of these polymer characteristics, see Chapter 1.3.2. In the crystalline state, the crystalline domains resist the infiltration of the degrading specie (e.g., water, enzyme) because the polymer chains are densely packed, often leading to surface erosion in these areas (Fig. 1.3.2F.5A). Degradation is faster in the amorphous regions of semicrystalline polymers, where transport of degrading species is more facile, compared to the crystalline regions. A classic example of a strong dependence of degradation and erosion as a function crystallinity is PLGA. Both PLA and PGA have higher degrees of crystallinity, but the copolymers lead to decreased organization and lower degrees of crystallinity. Miller et al. showed that the half-life of the homopolymers to copolymers decreased from 5 months for 100% PGA to 1 week for 50:50 PGA:PLA and rapidly increased to 6.1 months for 100% PLA (Miller et al., 1977; Reed and Gilding, 1981) (Fig. 1.3.2F.5B). This effect has been exploited in the commercialization of these polymers tailoring the degradation rate to specific applications by using different monomer ratios (Middleton and Tipton, 2000).

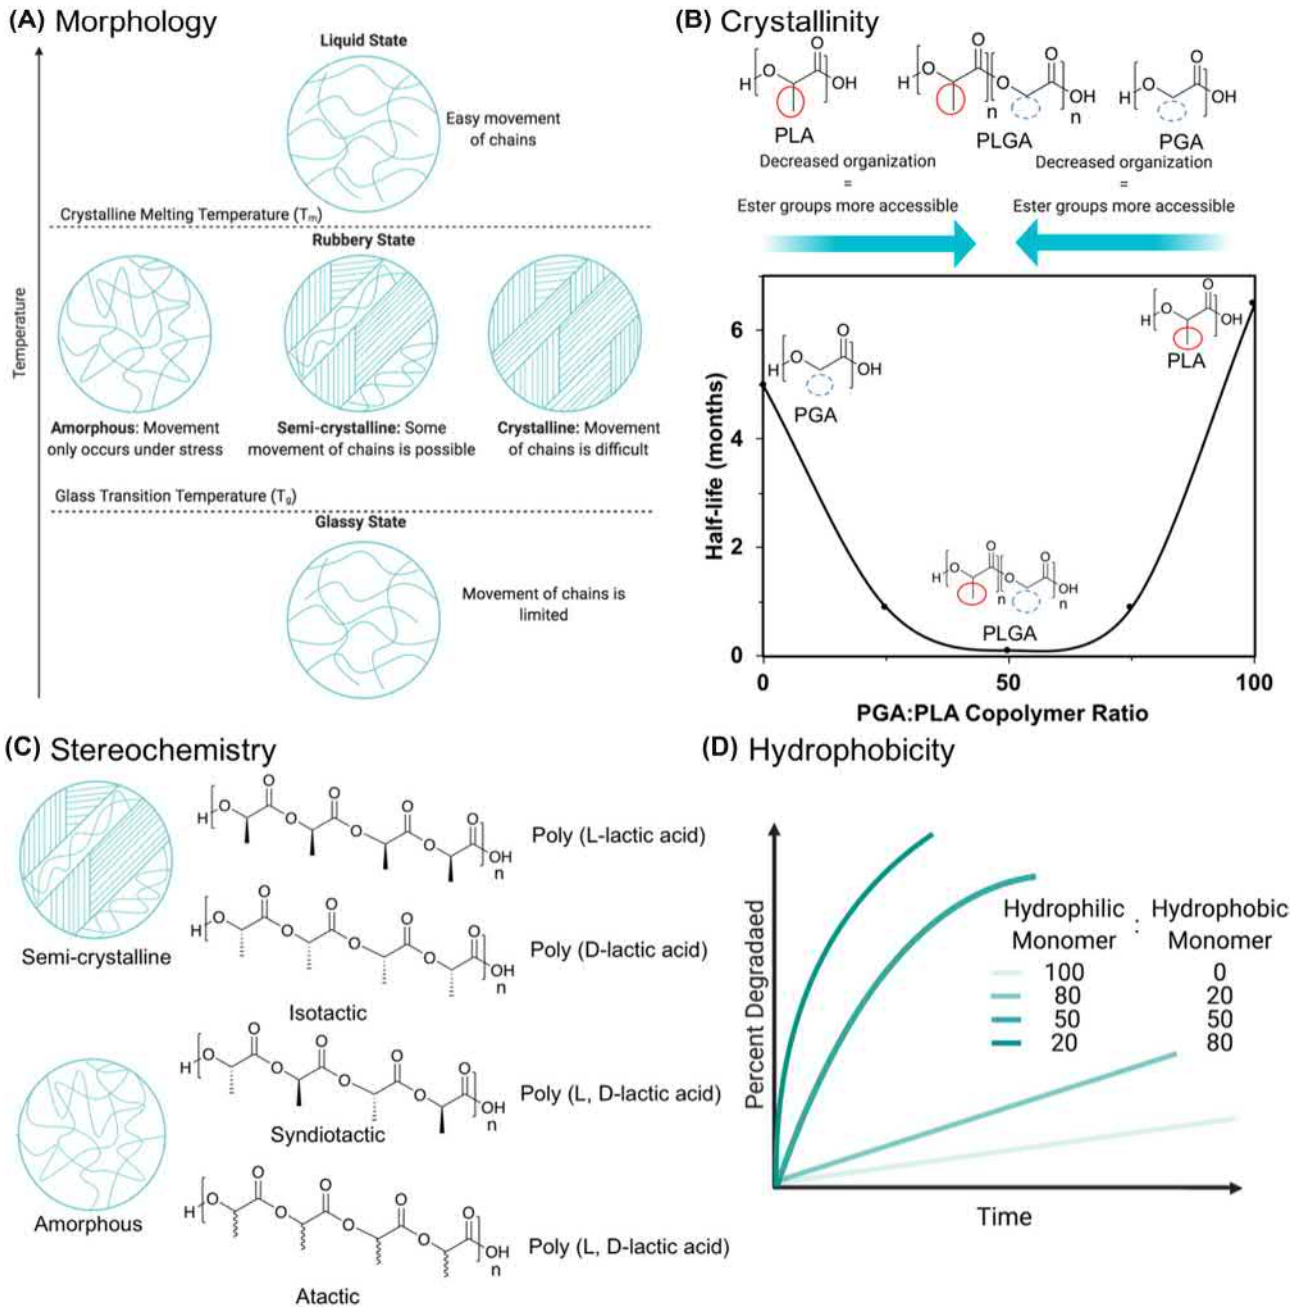
Stereochemistry also affects morphology and crystallinity and thereby the degradation rates of degradable polymers. One predominant example is in the synthesis of PLA from different stereoisomers (D-lactide, L-lactide, DL-lactide). Although both monomers lead to the same chemical backbone structure and degree of hydrophobicity, biomaterials made from the L isomer will degrade slower than identical polymers made from a mixture of the D and L isomers. This is a consequence of the stereoregularity of the pure L isomer making it a semicrystalline polymer, whereas the racemic polymer (made from D and L isomers) is amorphous (Farah et al., 2016) (Fig. 1.3.2F.5C).

Relative Hydrophobicity versus Hydrophilicity

Although polymers can degrade through many different processes, in most biomedical cases water is present and will affect the rate of degradation. For hydrolytic degradation the amount of water surrounding the polymer and its proximity to neighboring functional groups underpins the rate of degradation. For enzymatic degradation, enzyme diffusion into polymeric matrices, and thereby accessibility to the enzyme labile linkages, is also directly influenced by water distribution. Therefore the hydrophilic/hydrophobic nature of the polymer will affect the degradation rate of both hydrolytically and enzymatically degradable biomaterials. For example, the erosion rate of polyanhydrides can be controlled through the addition of a more hydrophobic monomer, bis(carboxy phenoxy)propane (CPP), compared to sebacic acid (SA) as the monomeric starting material (Tamada and Langer, 1993). Pure P(CPP) has a lifetime of over 3 years, whereas after copolymerization with 80% SA the lifetime is reduced to a few days, allowing this material to be used for drug delivery (Leong et al., 1986) (Fig. 1.3.2F.5D). P(CPP:SA) (20:80) is approved by the US Food and Drug administration (FDA) for the treatment of malignant glioma as Gliadel wafers. It is processed into a wafer with the chemotherapy drug carmustine dispersed throughout. The hydrophobic nature of P(CPP:SA) provides the encapsulated drug with some protection from hydrolytic degradation before release from the wafer. This is important as carmustine has a half-life of only 52 min at 37°C (pH 7.4) (Fleming and Saltzman, 2002). For more information on Gliadel wafers, see Case Study III (Askeland et al., 1996).

Degradation Routes and Kinetics

The route of polymer degradation depends not only on the linkers within the polymer backbone and its pendant functionalities, but also external stimuli. As noted previously, degradable polymers are designed to break down under biologically relevant conditions, primarily through hydrolysis or enzymatic activity. However, other unintended degradation routes can occur as a consequence of insertion of a biomaterial into the body, including oxidative and physical degradation. Oxidative degradation typically occurs as a result of



• **Figure 1.3.2F.5** Effect of: (A) Morphology; where increasing temperature allows a polymer to go from a glassy structure where polymer chains are unable to move, reducing degradation rate to above their Tg and are able to degrade depending on the stacking of the polymeric chains. an inflammatory response. Macrophages from the inflamed site produce peroxide radicals that react with covalent bonds within the polymeric structure, leading to polymer degradation. Physical degradation is often attributed to mechanical forces on the implanted material, including mechanical loading of the implant, discussed in detail in Chapter 2.4.2. This section will primarily focus on intended or engineered chemical degradation pathways, including hydrolytic, photo-, and enzymatic degradation, and their kinetics.

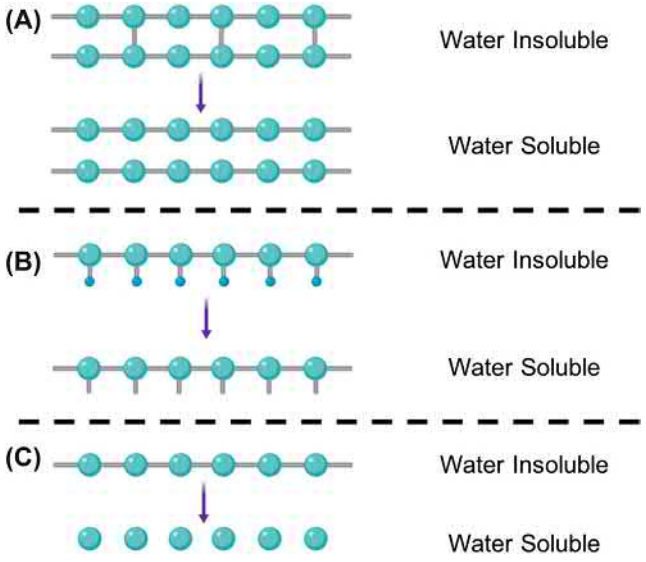
Chemical degradation is the term used when covalent bonds are cleaved through a stimulus (e.g., hydrolysis, enzymes, pH, or light). Three mechanisms of chemical degradation by which

cleavage of bonds leads to the formation of water-soluble polymers or oligomers have been identified: (1) cleavage of crosslinks between polymer chains, (2) cleavage of side chains, or (3) cleavage of the polymer backbone (Rosen et al., 1983) (Fig. 1.3.2F.6). In reality, a combination of these routes is used for the degradation of polymeric biomaterials.



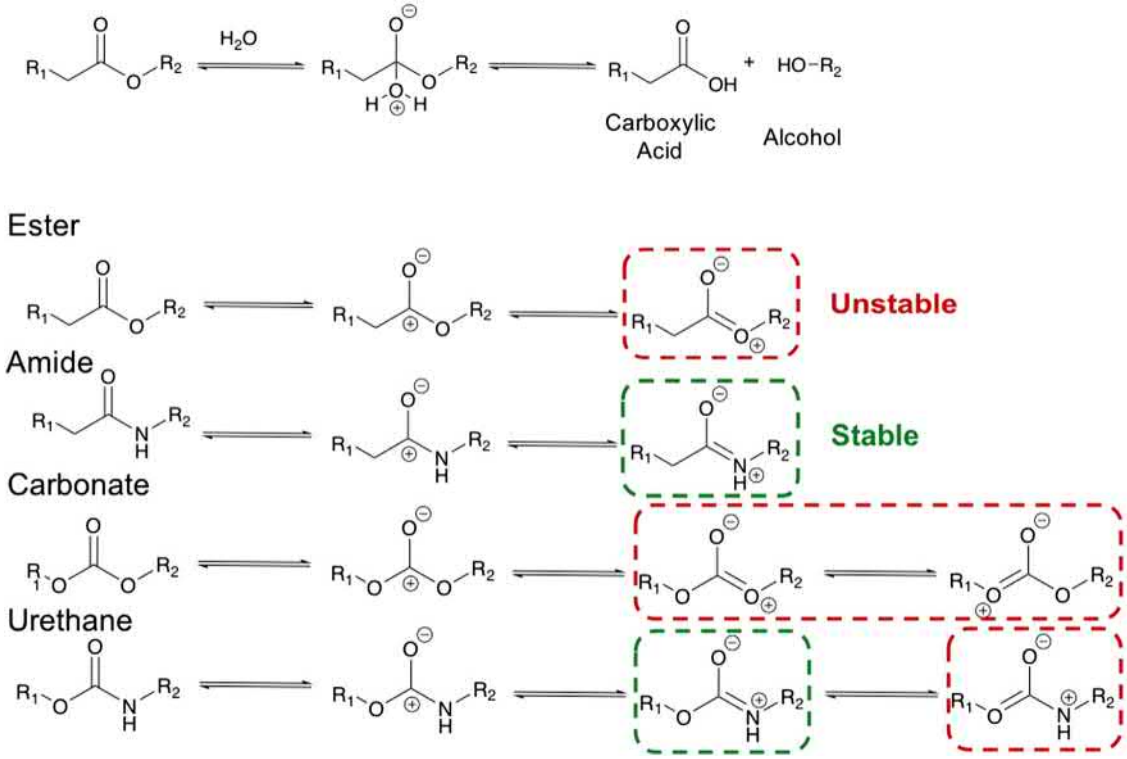
• **Figure 1.3.2F.6** Mechanism of chemical degradation, adapted from Gombotz and Pettit 1995, (A) Mechanism 1: Cleavage of crosslinks between water soluble polymer chains, (B) Mechanism 2: Cleavage of side chains leading to polar groups or charged groups, (C) Mechanism 3: Cleavage of backbone linkages between polymer repeat units. (Images created with biorender.com).

Hydrolytic Degradation

Hydrolysis is defined as the reaction of water with susceptible bonds in a compound to form two or more products (Göpferich, 1996). The susceptibility of a covalent bond to hydrolysis is dependent on the charge of the reacting carbon, steric effects, and the conjugated structures formed (Fig. 1.3.2F.7). The more stable the conjugated structure, the lower the rate of its hydrolysis (e.g., amides, carbonates, urea). For hydrolytic degradation of polymer chains, chemically identical bonds should have equal reactivity irrespective of chain position, unless steric hindrance, hydrophobicity of repeating unit, or pH of the local environment changes (Brannigan and Dove, 2017; Lyu and Untereker, 2009). Depending on the rate of the hydrolysis reaction relative to the rate of water penetration, the degradation either occurs uniformly throughout the polymer device (i.e., bulk degradation) or is confined to an interface (i.e., surface erosion). These processes are discussed in more detail below.

Surface Erosion

The kinetics of surface-eroding polymers has been well studied. The hydrolysis of surface-eroding polymers starts at any exposed interface and gradually proceeds to the interior. If a drug or other molecule is entrapped in the polymer, the release rates are often correlated directly to the mass loss. To facilitate experimental observation, surface-eroding polymers, such as polyanhydrides, are often fabricated as disks with high aspect ratios (e.g., large diameter compared to the thickness of the polymer), such that the surface area of the



• **Figure 1.3.2F.7** Stability of conjugated structures of hydrolyzable bonds. (Adapted from Brannigan and Dove (2017)).

polymer remains roughly constant throughout degradation. Thus the rate of polymer erosion can be expressed as:

$$\frac{dM}{dt} = -k \tag{1.3.2F.1}$$

where M is the polymer mass at any given time (t) and k is the kinetic rate constant of the degradation. Assuming one-dimensional erosion and constant density, Eq. (1.3.2F.1) can be rearranged into:

$$\frac{dl}{dt} = -k' \tag{1.3.2F.2}$$

where l is the dimension of the polymer in the direction of degradation front at any given time (t) and k' is the adjusted rate constant.

Eq. (1.3.2F.2) can be easily solved to obtain:

$$l = l_0 - k't \tag{1.3.2F.3}$$

Eq. (1.3.2F.3) illustrates a linear decrease in polymer thickness as the polymer degrades. This linear relationship is very useful in controlled release applications, as drug release rates can be stringently controlled by the rate of polymer mass loss and approach zero-order release. Eqs. (1.3.2F.1)–(1.3.2F.3) dictate the kinetics of surface erosion when the device is fabricated as thin slabs. For other geometries, such as cylinders and spheres, similar equations can be derived accordingly, and once k' is known, multidimensional degradation profiles can be predicted as well.

Experimental Tools for Characterizing Surface Erosion Kinetics

Qualitatively, surface erosion is often characterized using imaging methods, including scanning electron microscopy and atomic force microscopy, which show changes in the surface of the device (e.g., nonuniform surfaces). Other tools, including ellipsometry, surface plasmon resonance (SPR), and Fourier transform infrared (FTIR) spectroscopy, are being used to experimentally quantify degradation and erosion kinetics as a function of polymer thickness (Deng et al., 2019). Ellipsometry, SPR, and FTIR are all optical techniques, where signal changes correspond to changes in the sample's thickness, refractive index, and/or composition. These are useful tools for characterizing hydrolytic degradation, because as water diffuses into a polymer matrix or erodes the surface of the polymer, the refractive index and/or thickness decreases, leading to a detectable change in signal.

Bulk Degradation

For hydrolytic bulk degradation, a majority of studies focus on the mechanism of polyester degradation, particularly PLA and its copolymers with PGA. More contemporary examples include the bulk degradation of hydrogels with degradable cross-links, in which case the water content is much higher compared to PLA and PGA. For the purpose of this discussion, we focus on polyester degradation, as it is one of the most widely used linkers in polymeric biomaterials. Hydrolysis of a polyester is usually described as a random polymer chain scission throughout the polymer and is auto accelerated by increasing carboxylic acid end groups. The hydrolysis of ester bonds to produce carboxylic acids can be expressed as:

$$-\frac{d[Ester]}{dt} = k[Ester][H_2O] \tag{1.3.2F.4}$$

Here, $[Ester]$ is the concentration of ester bonds in the polymer, t is the degradation time, k is the kinetic rate constant, and $[H_2O]$ is the concentration of water. As a simplifying assumption for bulk degrading polyesters, the water concentration is often considered constant. Then, Eq. (1.3.2F.4) simplifies to:

$$-\frac{d[Ester]}{dt} = k'[Ester] \tag{1.3.2F.5}$$

where k' is a pseudo-first-order rate constant. Integrating Eq. (1.3.2F.5) yields the following equation:

$$\frac{[Ester]}{[Ester]_0} = e^{-k't} \tag{1.3.2F.6}$$

where $[Ester]_0$ is the initial ester bond concentration. Since $[Ester]$ is related to the molecular weight (M_n) of the polymer at any time during degradation, Eq. (1.3.2F.6) can be expressed as:

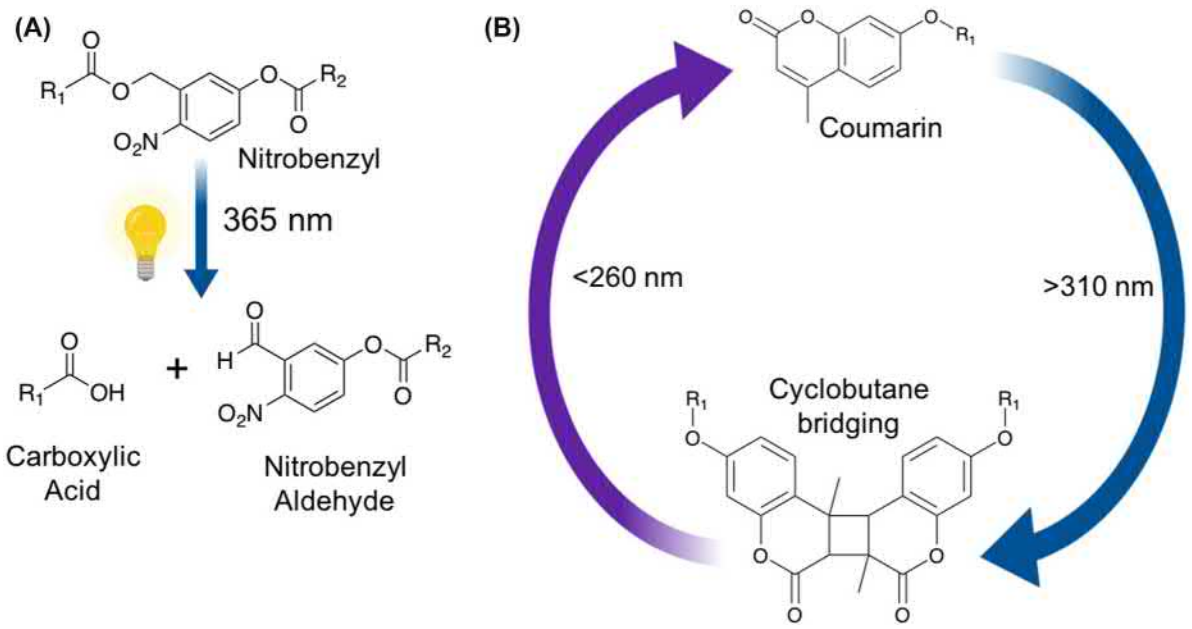
$$\frac{M_n}{M_{n0}} = e^{-k't} \tag{1.3.2F.7}$$

In examining Eq. (1.3.2F.7), one readily notes that the molecular weight of the degrading polymer decreases exponentially. It should be noted that Eq. (1.3.2F.7) only holds until significant degradation causes the loss of oligomers and carboxylic acids. It has been observed that this relationship is approximately true until the molecular weight of the polymer decreases to below 5000 Da (Pitt et al., 1981). Substitution of the Mark–Houwink equation ($[\eta] = KM_n^{\alpha}$) into Eq. (1.3.2F.7) yields:

$$[\eta] = [\eta]_0 \cdot e^{-\alpha k't} \tag{1.3.2F.8}$$

Here, η is the intrinsic viscosity of the polymer, and α is the Mark–Houwink exponent, which depends on the solvent in which the polymer degrades. Eq. (1.3.2F.8) is practical as it allows the experimenter to monitor polymer degradation by measuring the change in its intrinsic viscosity.

Eqs. (1.3.2F.4)–(1.3.2F.8) only illustrate the basic kinetics of ester bond hydrolysis in bulk-degrading polymers. The prediction of mass loss kinetics in the bulk-degrading polymers, however, often requires more sophisticated mathematical models, as simple cleavage of bonds does not accurately reflect loss of mass from the polymer device (e.g., hydrogel networks). For more information on hydrogel degradation and statistical models, see Wong and Bronzino (2007).



• **Figure 1.3.2F.8** Examples of photodegradable groups, (A) nitrobenzyl degrades with 365 nm light, (B) 2+2 cycloaddition of coumarin at 310 nm to form a cyclobutene link. The group degrades back to coumarin at wavelengths below 260 nm. (Images created with biorender.com).

Photodegradation

In recent decades, the advantage of using light as a tool to synthesize and degrade biomaterials has been recognized. Photodegradable polymers have been used in numerous applications for biopatterning, photo(un)caging of biologics, and drug delivery using different polymeric structures, including block copolymers, surfaces, and hydrogels (Bajaj et al., 2014; Li et al., 2014). Light offers specific advantages over more traditional degradation routes, as it allows for precise temporal and spatial control by controlled illumination via photomasks, using focused laser light, or varying the light intensity or shuttering the light source. There are a variety of photodegradable groups that have been incorporated into polymers depending on the application and function of the device (e.g., nitrobenzyl derivatives, coumarins, vinyl ketones, pyrene esters) (Fig. 1.3.2F.8, Pasparakis et al., 2012). Through careful choice of wavelength and intensity, cytocompatible light (e.g., >365 nm) can be used to degrade biomaterials in the presence of cells. Photodegradable biomaterials have predominantly been used in tissue engineering, allowing for precise spatiotemporal control over material properties, capturing extracellular matrix heterogeneity in a synthetic scaffold (Brown and Anseth, 2017). Furthermore, photodegradation has been applied for release of biomolecules from a network, as well as spatially controlled photopatterning (Kloxin et al., 2010; DeForest and Anseth, 2011; Arakawa et al., 2017).

In this field, a common method involves incorporation of photolabile cross-linkers into a network, especially hydrogels. When irradiated with a specific wavelength, the cross-linked molecules absorb light causing bond rearrangement and cleavage of the cross-links. The reactions depend on the intensity and wavelength of light, as well as the photophysical properties of the photodegradable linker. First-order kinetics are often relevant to describe the rate of cleavage through a material with uniform illumination, Eq. (1.3.2F.9):

$$\frac{dC}{dt} = -kC, \quad k = \frac{\Phi \varepsilon I}{N_A h\nu} \tag{1.3.2F.9}$$

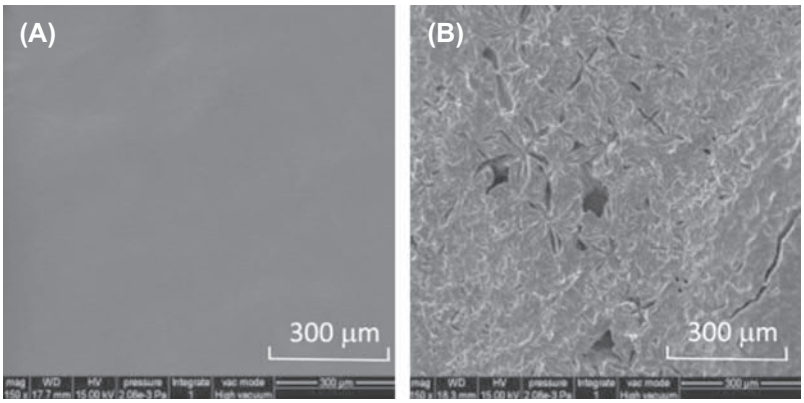
Here, C is the concentration of absorbing species and the kinetic rate constant k is a product of the quantum yield (Φ) and absorptivity (ε) of the photoactive species at the wavelength used along with the light intensity (I), light frequency (ν), Planck's constant (h), and Avogadro's number (N_A). For elastomers, the rate of cleavage of a photolabile cross-linker can be related to a network's storage modulus (G') and cross-link density (ρ_x), which can be used to predict changes in material properties and mass loss with time, Eq. (1.3.2F.10):

$$\frac{G'}{G_0'} = \frac{\rho_x}{\rho_{x,0}} = e^{-kt} \tag{1.3.2F.10}$$

Enzymatic Degradation

Several synthetic polymers are susceptible to enzymatic degradation. For example, amorphous PLA can be degraded by proteinase K, while both amorphous and crystalline PCL can be degraded by lipases of various origins (Liu et al., 2000, 2019) (Fig. 1.3.2F.9).

Enzymatic degradation of synthetic polymers can occur by either surface or bulk mechanisms, depending on the location and stability of the acting enzyme. However, due to the limited water accessibility of most hydrophobic polymers, surface erosion is often the dominant degradation mechanism, described in an earlier section of this chapter. The degradation for a hydrophilic polymer, permitting the diffusion of the



• **Figure 1.3.2F.9** Scanning electron micrographs of esterase degraded PCL films after 48 h; (A) control PCL film (no enzyme present), (B) Lipase degraded film, Magnification 150x. (Adapted from Liu et al. (2019)).

enzyme to the interior of the polymer, can also be mediated by a surface erosion mechanism if the rate of enzymatic polymer bond cleavage is faster than the rate of enzyme diffusion. Bulk degradation of synthetic polymers induced by enzymatic activity may occur under two conditions: (1) the enzyme is able to infiltrate and distribute uniformly throughout the bulk of the polymer, and (2) the rate of enzymatic bond cleavage is slower than the diffusion of the enzyme. Typically, hydrogels containing enzymatically cleavable units in their polymer backbone fall into this category of degradation. Under these assumptions, Michaelis–Menten enzymatic kinetics are commonly used to predict the enzymatic degradation rates of synthetic polymers via a bulk degradation mechanism:

$$v_0 = v_{max}\frac{[S]}{K_M + [S]} \qquad \textbf{(1.3.2F.11)}$$

Here, v_0 and v_{max} are the initial and maximum reaction rate of degradation, respectively. $[S]$ is the degradable polymeric substrate concentration, and K_M is the Michaelis–Menten constant.

In Eq. (1.3.2F.11), v_{max} can also be expressed as:

$$v_{max} = k_{cat}[E] \qquad \textbf{(1.3.2F.12)}$$

where k_{cat} is the catalytic constant describing the rate of enzymatic degradation of polymer bonds and $[E]$ is the concentration of enzyme catalytic sites.

As in other enzymatic reactions, both k_{cat} and K_M are important parameters in characterizing the enzymatic degradation of polymers. While k_{cat} represents the sensitivity of an enzyme for a specific polymeric substrate, K_M is the substrate concentration needed to achieve a half-maximum enzyme velocity. Factors affecting these parameters will also determine the rate of polymer degradation.

While simple Michaelis–Menten kinetics can be used to describe enzymatic polymer bond cleavage, they do not provide information regarding the mass loss behavior of the polymers. Sophisticated mathematical models are often required to correlate microscopic enzymatic bond cleavage to macroscopic polymer mass loss, and it depends on the structure and connectivity of the polymer. For example, to describe the mass loss of cross-linked hydrogels containing enzymatic cleavable substrate (e.g., PCL), a statistical-kinetic model integrating the structural information of the hydrogels with the enzyme degradation kinetics is required (Rice et al., 2006).

Orthogonal Stimuli-Labile Strategies
While most degradable polymer systems rely on single degradation pathways, materials capable of undergoing multiple routes of degradation have emerged in recent years. For example, release of model therapeutics from hydrogels with orthogonal stimuli-labile linkers was demonstrated. The degradation routes were reduction of disulfide bonds, enzymatic cleavage, photodegradation, or combinations thereof, leading to logic-based, controlled release (Ruskowitz et al., 2019). Adopting such a strategy to include light, enzyme, or other stimuli-degradable linkages within a hydrolytically degradable scaffold will enable development of other tailorable scaffolds for precision medicine applications.

Polymer Design and Processing

The chemical structure (e.g., backbone functional groups, crystallinity, and architecture) of a polymer significantly influences its degradation mechanism and rate. Because of this, it is often desirable to use well-studied degradable polymers (e.g., PLA, PLGA) for the synthesis of biomaterial devices, because their breakdown is better understood in vivo and they are used in many FDA-approved applications, giving precedent for use in other applications. As biomaterials are required for a growing number of clinical applications, from synthetic replacements for biological tissue to materials as diagnostics (Langer and Tirrell, 2004), more sophisticated polymers are continually being developed. However, in designing a new degradable biomaterial, one must first understand the unique performance requirements and constraints for the intended application, including lifetime, location, mechanical properties, and delivery method (Table 1.3.2F.3). Then, different polymer-processing strategies can be applied to meet the design requirements, in terms of both degradation rate and overall performance. This section covers the design and processing considerations that are especially important for degradable biomaterials, providing examples of degradable systems that are commercially available or are being explored in academia.

TABLE 1.3.2F.3 Design Criteria of Different Degradable Biomaterial Application With Polymer Examples

Application	Function	Lifetime/ Biodegradation Time	Location in the Body	Mechanical Properties	Mechanism of Delivery	Degradable Polymer Examples
Bone Fixatives	Provide support to the joint, alleviate pain/arthritis	More than 10 years	Bone joint, high mechanical load	High modulus, good fracture toughness	Surgery	Poly(lactic acid), poly(glycolic acid), poly(caprolactone)
Sutures	Allow improved healing process without secondary surgery/reduce inflammation	1 week–1 month	Organ, skin	High tensile strength	Surgery	Poly(trimethylene carbonate), polydioxanone
Drug Delivery	Releases drug to a target site	Dependent on location/delivery short term/ long term	Digestive track, blood stream, tumor	Not critical	Oral/ injection	Poly(ortho-esters), polyphosphazenes
Adhesives	Wound healing, hemorrhage control, drug carriers, closure of pulmonary leaks	1 week–Years	Skin	High adhesion strength	Surgery	Poly(lactic-*co*-glycolic acid), degradable hydrogels

Lifetime—How Long Does the Biomaterial Need to Function?

For any given device, the time that a biomaterial is required to perform a desired function must be known. Some materials are only required for a short period of time, on the order of days to week, serving a temporary function that allows for rapid tissue healing (e.g., sutures). Other biomaterials are required to last longer and degrade slowly over months and years as regrowing tissue infiltrates the scaffold (e.g., some bone fixation devices). In drug delivery, an important aspect is to deliver a drug at a constant rate over a predictable amount of time and at a dose that can be tuned for the patient (Sershen and West, 2002). The lifetime of a biomaterial can be controlled by varying different aspects of the polymer design (e.g., backbone functionality, porosity, shape). For example, diabetic patients require daily intravenous insulin injections, which could lead to "peak-and-valley-shaped" drug-concentration profiles in the body and cause gastrointestinal side effects and patient discomfort (Bratlie et al., 2012). Through the use of biodegradable polymeric nanoparticles (e.g., poly(3-hydroxybutyrate-*co*-3-hydroxyhexanoate) embedded in a thermosensitive, injectable hydrogels), the release rate of insulin can be tightly controlled, a strategy with significant potential to meet the therapeutic needs of diabetic patients (Peng et al., 2013) (Fig. 1.3.2F.10).

Location—Where Will the Biomaterial Perform Its Task?

The body is made up of a range of different environments (e.g., different pH levels, high vs. low moisture environments, varied enzyme concentrations) that need to be considered collectively when designing a functional polymeric biomaterial for any given setting. For example, when designing gastric devices (e.g., weight loss balloons, ingestible diagnostic devices, oral drug delivery formulations) the biomaterial needs to reach its target area intact after traveling through areas with vastly different pH and enzyme profiles (Knipe et al., 2015). For example, Zhang et al. designed a gastric-retentive device from a supramolecular hydrogel (e.g., poly(acryloyl 6-aminocaproic acid) and poly(methacrylic acid-*co*-ethyl acrylate) system) that could respond to changes in pH through protonation and deprotonation of carboxylic acid side chains (Zhang et al., 2015). The elastic nature of the polymer enabled packing of the structure into a gelatin capsule to allow for oral delivery. The material was designed to change shape as it moved through the digestive tract, retaining its extended shape in the gastric environment to perform its function (e.g., release of a drug or delivery of a gastric balloon) before degrading at neutral pH once it moved into the small intestines, preventing intestinal obstructions (Fig. 1.3.2F.11). This application demonstrates how the application of degradable polymers can increase the safety and efficacy of biomaterials.

Mechanical Properties—What Mechanical Properties Are Required for the Task?

The mechanical properties required for the application should be determined based on both the location of the device and the timescale of degradation required (Engelberg and Kohn, 1991). While nondegradable devices have stable and predictable mechanical properties throughout their duration of use, degradable devices will exhibit a decrease in most mechanical properties (e.g., strength, modulus) as the polymer degrades. In some cases, especially those that involve implantation in a load-bearing site, it is critical to match the breakdown of the polymer mechanical properties with the biological repair time. For example, sutures must maintain sufficient tensile strength to keep the wound closed until it heals. The polymer used to make sutures should also allow doctors to easily stitch and tie the sutures without breaking. For orthopedic applications, polymeric devices with initially high mechanical strength and good fracture toughness, comparable to the mechanical properties of the native tissue, are required to support load bearing. Ideally, gradual stress transfer will occur as the biomaterial degrades and the tissue heals (Brauer et al., 2008) (Fig. 1.3.2F.12).

Delivery—How Will the Biomaterial Reach the Required Site?

The delivery mechanism by which the biomaterial will reach its intended site without degrading should also be carefully considered when designing degradable polymeric biomaterials. Popular modes of delivery are injection, surgical implantation, or ingestion. Injections are commonly used to deliver shear thinning hydrogels that serve as drug and cell delivery vehicles (Bakaic et al., 2015). Injections minimize invasive surgery, leading to faster recovery times and reduced infection rates and costs. Furthermore, the material injected can fill voids and pack defects specific to the patient, without needing to preshape the material, which leads to improved comfort and efficacy. A range of different approaches is available to make degradable polymers injectable, including use of covalent adaptable networks (e.g., oxime and hydrazine chemistries) or use of in situ-forming devices that rely on thermoresponsive chemistries (Kretlow et al., 2007), photopolymerization (Rydholm et al., 2005), or solvent-exchange strategies (Parent et al., 2013).

Covalent Adaptable Networks
Covalent adaptable networks are structures that incorporate exchangeable chemical bonds that undergo cleavage and reformation in response to an external stimulus (e.g., mechanical force, heat, base). An active species undergoes a reaction that results in bond exchange and the formation of new active species, which subsequently undergoes an additional exchange reaction (Bowman and Kloxin, 2012). Covalent adaptable chemistries used in polymeric biomaterials include boronate esters (Smithmyer et al., 2018), Diels–Alder (Kalaoglu-Altan et al., 2017), imines (i.e., oxime and hydrazone) (Boehnke et al., 2015), and thioester chemistries (Brown et al., 2018). The presence of these dynamic chemistries can lead to depolymerization or dynamic changes in mechanical properties. In tissue-engineering applications, covalent adaptable hydrogel networks have been synthesized to more closely mimic tissue viscoelasticity and support matrix deposition by encapsulated cells. For example, hydrazones and their network reorganization allow stress relaxation in a hydrogel with encapsulated, proliferating chondrocytes. The relaxation can be tuned to foster the deposition of a collagen and proteoglycan-rich matrix by the encapsulated cells (Richardson et al., 2019).

Injectable, in situ-forming devices or implants that rely on solvent-exchange strategies have been designed such that they set into their shape inside the body by relying on insolubility of the polymer in water. Specifically, degradable polymers (e.g., PLGA) are dissolved in a biocompatible solvent, such as *N*-methyl-2-pyrollidone or dimethylsulfoxide, before injection. Upon injection, solvent exchange occurs, increasing the concentration of water near the polymer as the solvent diffuses away from the injection site. When the surrounding concentration of water is sufficiently high, phase inversion occurs, causing the polymer to precipitate. The shape that the polymer takes depends on the concentration of polymer in the solvent and the miscibility of the solvent with water. The rate of in situ formation and the structure formed by the polymer, which are

dictated by polymer concentration and solvent identity, determine the burst and sustained release kinetics of drugs from the in situ-formed device (Parent et al., 2013).

While noninvasive strategies are preferred for many applications, other applications, such as joint replacements, still require open surgery to get the biomaterial to the correct site in the body. The joint replacement is often a prefabricated, synthetic joint shaped to match the native joint. Alternatively, bone cement, which cures in situ to take the shape of the cavity, can be used. Both delivery techniques are invasive processes and pose a high risk of infection, causing postoperative pain and numerous side effects for the patient (ter Boo et al., 2015). To help prevent infections, prosthetic joints and implants have been designed with degradable polymer coatings that deliver a local dose of antibiotics, thereby reducing the changes of infection and localizing the antibiotics to a specific region of the body. A clinical example is ETN PROtect, where gentamicin-loaded PDLA (Fuchs et al., 2011; Metsemakers et al., 2015) is coated on intramedullary nails to reduce infection. Clinical studies with this degradable polymer coating revealed no deep wound infections, good fracture healing, and increased weight-bearing capacity after 6 months compared to the nail alone (Fig. 1.3.2F.13). These results were found even in patients with complex fractures and multiple traumas.

Composites—When Should a Composite Be Used and How Will Additives Affect Degradation?

If the desired mechanical properties of a temporary support device or erosion kinetics of a controlled release system are not accessible through changing the degradable polymer composition alone, composites with nondegradable materials can be used. For example, low concentrations of natural materials (e.g., ceramic fibers or particles) are often embedded within degradable polymers used to increase the mechanical properties of degradable scaffolds for orthopedic applications (Rezwan et al., 2006). The effect of nondegradable additives on the final mechanical properties, and degradation, of the device/materials is dependent on both the loading density and hydrophobicity of the additive. For example, low loadings (<5%) of hydrophilic nanohydroxyapatite were shown to reinforce PLGA scaffolds, improving the storage modulus, while higher loadings acted as defects and weakened the scaffolds and accelerated erosion (Jose et al., 2009).

The effect of additives on degradation kinetics is especially important to understand when designing controlled release systems, which are inherently composites because of the addition of therapeutic molecules and/or excipients. For example, if there is a well-studied, commercially available PLGA formulation that has been used to deliver a specific compound, the release profile of a different drug from the same polymer may be significantly different depending on the drug loading and properties (i.e., molecular weight, hydrophobicity) of the drug (Jain et al., 2000). During the embedding or encapsulation process, hydrophobic drugs tend to lead to formation of more compact particles, which ultimately impedes water adsorption such that degradation and release are slowed (Rodrigues de Azevedo et al., 2017). Options for tuning the release/degradation include changing the polymer composition or using combinations of additives until the desired release kinetics are achieved (Shikanov et al., 2005; Song et al., 1997).

In another composite-based strategy for controlled release, degradable particles can be embedded in a nondegradable matrix, such as a hydrogel, to slow down

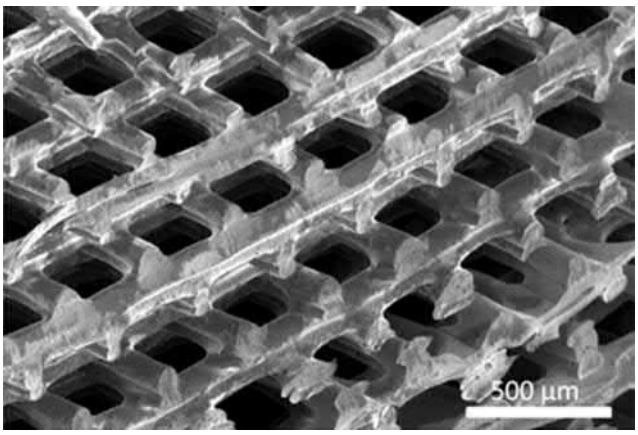
• **Figure 1.3.2F.14** Effect of surface area to volume ratio (S/V) on degradation rates. Biomaterials made from the same surface eroding polymer and that have the same initial volume but different S/V will have different degradation kinetics. The biomaterials with the highest S/V will have the fastest degradation, because there are more hydrolytically labile bonds accessible to water.

degradation and therapeutic release (Liu et al., 2007). Commercially, this strategy has been employed in Urolon, a bioresorbable urethral implant for stress-induced incontinence, which consists of degradable PCL microparticles embedded in a hydrogel matrix.

Shape—How Will the Material Be Shaped and How Does Shape Affect Degradation Kinetics?

The shape of the biomaterial is dictated by the intended application. In particular, the surface area-to-volume ratio is an important determinant of degradation kinetics for surface-eroding polymers, but can be less important for polymers that undergo bulk erosion (Chew et al., 2016). Larger surface areas mean increased exposure to water at the polymer interfaces and, consequently, faster erosion (Fig. 1.3.2F.14). Some examples of shapes that have large surface area-to-volume ratios are fibers, micro/nanoparticles, thin flat slabs, and porous scaffolds. In all of these cases, if a surface-eroding polymer is used, the rate of degradation can be tuned by changing the dimensions of the material. For example, several small, thin, polyanhydride Gliadel wafers (up to eight), rather than one large wafer, are implanted for the treatment of glioblastoma (Kleinberg, 2016). Polyanhydride micro/nanoparticles are being extensively explored in academia for controlled release applications (Basu and Domb, 2018). As with hydrolytic degradation, surface area-to-volume ratios also dictate the rate of enzymatic degradation, where the larger the surface area, the better the accessibility for enzymes to reach and cleave polymer bonds, as explained earlier in this chapter. Thin,



• **Figure 1.3.2F.15** SEM images of 3D[HYPHEN]printed, biodegradable PLA orthogonal displaced structure. (Adapted from Serra et al. (2013)).

photodegradable scaffolds will also degrade more quickly than thick scaffolds, because light absorbance can lead to significant attenuation with depth (Tibbitt et al., 2013).

While a biomaterial of a certain composition and shape may be seemingly perfect for a certain application because of its expected degradation properties, it is also necessary to consider if and how the polymer can be processed into the desired shape. There are many options for making micro/nanoparticles from biodegradable polymers, including emulsion polymerizations, photolithography, and nanoprecipitation (Jain, 2000). In cases where the shape must exactly match the shape of the void or have a shape for a specific purpose (e.g., a bone screw), the shape can be achieved via a wide range of processing methods, depending on the polymer melting temperature and desired architecture. For example, porous PLGA scaffolds have been synthesized from methods including injection molding plus particulate leaching (Wu et al., 2006), extrusion plus solvent casting (Widmer et al., 1998), or additive manufacturing (Serra et al., 2013). Of all the options, additive manufacturing gives the most precise control over scaffold geometry, an important feature for controlling degradation (Fig. 1.3.2F.15).

Custom, Degradable Inks for 3D Printing
Significant progress in both additive manufacturing and polymer chemistry over the past several decades has led to the development of custom-designed 3D printable biomaterials. Through rational design, polymers with specific chemical and mechanical properties that make them 3D printable, biologically functional, and degradable can be achieved. For example, a novel polyester-based copolymer with pendant reactive alkene and alkyne functional groups was synthesized and formed into a scaffold using an extrusion-based printing method. The reactive groups on the polymer allowed functionalization of the scaffolds with bioactive molecules for diverse tissue-engineering applications (Ji et al., 2019).

Sterilization—Will Degradation Properties Be the Same After Sterilization?

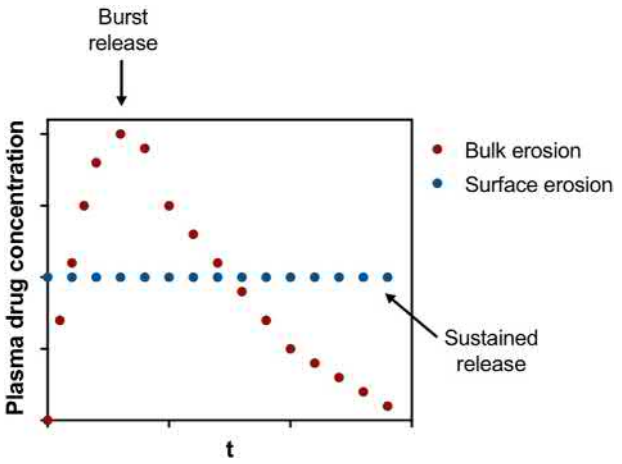
The last step in processing a new device before it can be put in the body is sterilization, a physical or chemical process used to remove or inactivate microorganisms present on the biomaterial. While most nondegradable biomaterials are sterilized via autoclaving (i.e., using high-temperature steam), this sterilization procedure is not a good choice for hydrolytically degradable polymers because of their inherent sensitivity to moisture and heat. However, autoclaving may be an option for sterilizing nonhydrolytically degradable materials (e.g., enzyme or photodegradable polymers). Regardless of the mechanism, materials that are designed to degrade need to be sterilized in facilities with strict control over environmental conditions (i.e., heat, humidity, light) to avoid premature degradation. For scaffolds containing living cells or biological agents, which cannot handle harsh sterilization conditions, sterility must be maintained throughout the course of the manufacturing process (Treiser et al., 2013).

Degradable biomaterials not containing biological agents are most commonly sterilized by gamma irradiation or ethylene oxide gas (EOG) treatment. It is important to test how the degradation properties of these materials change after such treatments. For example, gamma irradiation of PLGA devices lowers the average molecular weight and deteriorates the original mechanical properties of the device (Jo et al., 2012). EOG treatment is a more common choice for PLA-, PGA-, and PLGA-based biomaterials because of their poor tolerance to radiation (Treiser et al., 2013). Polymers treated with EOG, however, pose another serious concern: the toxicity of residual EOG. The International Organization for Standardization defined an EOG exposure limit of 25 ppm to minimize potential health risks associated with EOG exposure (Shintani, 2017). For this reason, devices sterilized by EOG require extensive degassing prior to use to minimize health risks for patients.

Performance Metrics

Every biodegradable material designed for in vivo use must undergo careful evaluation to ensure it performs as expected. As with any material, the polymer must be evaluated for cytotoxicity, efficacy, and storage stability. However, for polymers that degrade over time, it is particularly important to consider and carefully evaluate the cytotoxicity of their degradation products as well. While monomers are typically more cytotoxic than polymers, some degradable polymers degrade into monomers that are natural metabolites. For example, PLGA degrades into lactic acid and glycolic acid, which are natural metabolites. In any case, cytotoxicity studies should always be performed on both the intact polymers and degradation products before advancing to in vivo studies.

In addition to establishing cytocompatibility, degradation properties of new degradable biomaterials should be carefully characterized in vitro, following well-vetted experimental protocols. This is important especially for slowly degrading materials, for which accelerated degradation studies are often used rather than quantifying degradation of the material over the course of months to years. When characterizing a new biodegradable material,



• **Figure 1.3.2F.16** Typical time course profiles of plasma drug concentrations released from bulk eroding and surface eroding polymers. Bulk eroding formulations exhibit burst release, while surface eroding polymers exhibit sustained release.

experimental variables should be kept consistent with those used in previously performed studies on materials designed for similar applications (e.g., nanoparticles for insulin delivery, antibiotic-containing sutures for wound healing). Some examples of experimental variables that will affect degradation properties of controlled release devices include solution-to-specimen mass ratio, pH, temperature, mixing rates, light exposure, and ionic strength. While literature searches provide a good starting point for identifying best practices, standardized methods for evaluating degradable biomaterials still need to be established (Woodard and Grunlan, 2018).

Following in vitro cytocompatibility and degradation studies, degradable polymer devices should be characterized in vivo for a better understanding of the complex interactions that will occur between the material and the body. For example, release of lactic acid and glycolic acid can lower the pH of the environment quite dramatically, depending on the volume of the implant, and this can elicit a foreign body and inflammatory response to PLGA biomaterials, which in turn will alter the degradation kinetics (Ji et al., 2012).

Other in vivo studies for characterizing degradable biomaterials depend on the application. For controlled release studies, pharmacokinetic and bioavailability studies provide important information on the burst and sustained release of the therapeutic payload (Steinijans, 1990). Bulk-eroding polymers exhibit characteristic burst release profiles, while the concentration of drugs released from surface-eroding polymers is more constant (Fig. 1.3.2F.16). Even when theoretical and in vitro studies suggest that the drug release will occur over the desired timescale, biological responses to the materials may lead to dramatically different results. For example, opsonization of nanoparticles, leading to uptake by phagocytes, may lead to clearance on a much shorter timescale than the expected degradation timescale. Modifications to particle surfaces, such as PEGylation, can be performed to improve the distribution and circulation time of the particles (Owens and Peppas, 2006). For temporary support devices, mechanical testing is often performed on devices both preimplantation and on the explanted device to learn about how cell–material interactions, which lead to scaffold remodeling, affect the mechanical properties of the device (Hong et al., 2011). Additionally, histology of explanted temporary support devices provides invaluable information regarding cell–material interactions.

While degradation in the body is the goal, it is critical to avoid premature degradation during storage. As such, materials made from degradable polymers require strict storage conditions because of their inherent sensitivity to moisture and heat. In cases where living cells or sensitive biological agents are included, shelf life is very limited. The properties (e.g., tensile strength, degradation rate) should be characterized over different storage time periods to ensure the device performs as expected.

Worked Examples

Question

Cells have been encapsulated in a polymeric hydrogel composed of polyamides and polyesters. When immersed in cell culture media, the material swells over time. Identify the routes of degradation and explain why the hydrogel has swollen and why the hydrogel will not completely degrade in a week.

Solution

The polymer chains reorganize when placed in water, causing swelling as water infiltrates the network. With time, hydrolytic degradation will break the ester bonds, reducing the cross-linking density and increasing the water influx to the network, leading to additional swelling. In addition, the cell will secrete enzymes accelerating the rate of degradation. As amide bonds are present, the network will not completely degrade as amides form stable conjugates when in the presence of water.

Question

Sculptra is an injectable PLA cosmetic filler that is used to reduce the signs of aging. The formulation, which can last for 2 years, consists of PLA microspheres in water that initiate a twofold mechanism of action. Identify the benefits of using PLA as a degradable polymer for this application. What are the two steps of action and why are the affects sustained for 2 years?

Solution

PLA is a biodegradable, biocompatible, and immunologically inert polymer. It is a polyester and therefore can degrade through hydrolytic and enzymatic degradation

pathways. It is beneficial to use PLA as it is already FDA approved and is one of the most researched and utilized biodegradable polyesters. The mechanism of degradation is well understood and the kinetics of degradation can be controlled. The monomers are produced from a nontoxic renewable feedback and it is also a naturally occurring acid. PLA microspheres cause a gradual tissue response and stimulate collagen production. Initially, the volume of the injected area increases before collagen synthesis. After 1 month, the microparticles have been shown to increase vascularity and the capsule thickness starts to decrease until the area is composed of collagen fibers. After 18 months, the microparticles are still present with the collagen that has formed, with no inflammation (Engelhard et al., 2005; Humble and Mest, 2004).

PLA is more hydrophobic compared to PLGA and the single L isomer makes the polymer stereoregular, increasing the degradation rate and sustaining the effects of the PLA filler for longer as water cannot infiltrate as efficiently. The metabolism of the polymer involves bioadsorption and then hydrolysis of the ester bonds into monomers and oligomers. The degraded products can then be phagocytized by macrophages and ultimately degraded as CO_2 or converted into glucose.

Question

You need to fill a void of certain dimensions with a biomaterial made from a poly(sebacic anhydride) to support tissue regrowth. You are deciding between using a device that has been finely tuned to match the exact shape of that void or using smaller particles that will assemble and pack together with some space between particles. Assuming the total mass of material and chemical composition used are the same in both cases, should you use the large plug or small particles if you want to maximize the lifetime of the implant? Why? What if the biomaterials were made from PLGA?

Solution

Because poly(sebacic anhydride) is a hydrophilic polyanhydride, it is expected to undergo surface rather than bulk degradation. For surface-degrading polymers, the small particles would be expected to degrade much faster than the single large plug, because of larger surface area-to-volume ratio, and degradation is proportional to surface area. Thus the large plug would be the better choice for extending the lifetime of the implant. If PLGA, a bulk-degrading polymer, had been used instead, both the large plug and small particles should degrade at the same rate, because bulk degradation depends on composition and total amount of material (which was constant) but are less dependent on material shape or size.

Case Studies on Degradable Polymers Used in Medicine

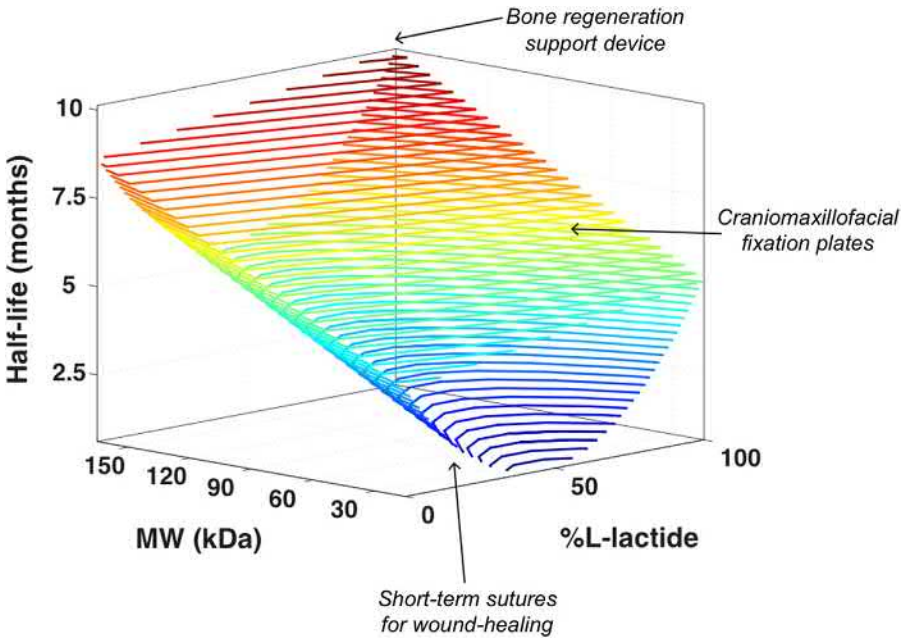
The use of degradable polymers in medicine has grown significantly since their initial use as sutures more than 50 years ago. Scientists have many avenues by which they can tailor the properties of these degradable biomaterials, ranging from simply changing the chemical composition to developing sophisticated composite materials and shapes. The following case studies focus on materials design considerations as they relate to commercially available devices made from degradable polymers.

CASE STUDY I

PLGA in Temporary Support Devices

PLGA is a widely used, FDA-approved copolymer with tunable properties that depends on the ratio of glycolide:lactide (G:L) monomers, molecular weight, and processing of the material (Fig. 1.3.2F.17). PLGA copolymers with low G:L ratios are well suited for orthopedic applications because their high degree of crystallinity improves their mechanical strength and toughness. For example, OSSIOfiber is a support device for bone regeneration that is made from 100% poly(L,D,-lactic acid) that is initially stronger than bone, enabling the device to bear the load of the broken bone until the bone heals. It degrades over the course of 78 weeks, during which time the bone can heal and gradually bear more of its original load. As another example, LactoSorb temporary craniomaxillofacial fixation systems use 18:82 PLGA. With a T_g well above body temperature (58°C), doctors are able to soften plates with gentle heating to mold the plates to a patient's skull, after which the plate hardens in place as it cools.

For soft tissue applications, PLGA copolymers with high G:L ratios are preferred. For example, a suite of Pectryl sutures is available for surgeons to choose from, depending on the application. By changing the composition from 100% PGA to 90:10 glycolide/L-lactide, the tensile strength of the sutures is reduced and the lifetime is decreased. For these reasons, 100% PGA is better suited for orthopedic applications, while 90:10 PLGA is better for soft tissue suturing. Both of these sutures retain 70%–75% of their tensile strength after 2 weeks, so for the shorter term (e.g., wound healing), doctors prefer sutures made from lower molecular weight 90:10 PLGA, which retains only 50% of its tensile strength after 5 days. PLGA copolymers of the same composition (90:10) are also used in VICRYL fiber meshes, which are used as temporary supports for wound and organ healing to foster soft tissue regrowth. Here, meshes with different degradation rates and mechanical properties are achieved by processing (i.e., either weaving or knitting the PLGA fibers into the mesh). When the fibers are knit, the mesh is more porous, causing faster degradation and lower burst strength compared to the woven meshes.



• **Figure 1.3.2F.17** Variations in PLGA molecular weight (MW), percent L-lactide, and processing allow development of a wide-range of biomaterials with distinctive degradation and mechanical properties, making them suitable for a variety of applications.

CASE STUDY II

PLGA in Controlled Release Devices—Formulation Considerations

For controlled release applications, PLGA copolymers with intermediate G:L ratios are often chosen because their shorter half-lives better match the desired pharmacokinetics, where 50:50 copolymers have the shortest half-lives. Ideally, these devices can be delivered through minimally invasive procedures (i.e., injection) to minimize discomfort for patients. FDA-approved, injectable PLGA formulations include in situ-forming systems and suspensions of microparticles. For example, Eligard is an in situ-forming system used for controlled release of leuprolide acetate for the treatment of advanced prostate cancer. Different polymer compositions and dosages are offered to control the duration of treatments, but the most common is a 75:25 PLGA capped with hexanediol in *N*-methyl 2-pyrollidone (NMP) as a biocompatible solvent. Upon injection, quick displacement of the NMP by water causes precipitation and formation of a subcutaneous drug depot. Having the hydroxyl rather than carboxylic acid end groups slows the degradation of the depot, allowing sustained release for 1–6 months (Parent et al., 2013). For even faster release, the composition of the PLGA used in the formulation can be decreased to 50:50 PLGA. For example, Bydureon BCise, a treatment for type 2 diabetes, uses microparticles made from 50:50 PLGA to achieve release of exenatide on the order of weeks. Rather than daily insulin injections, people with type 2 diabetes can inject themselves once per week using this controlled release system (Cai et al., 2013; DeYoung et al., 2011).

CASE STUDY III

Polyanhydrides in Controlled Release Devices

There are fewer examples of FDA-approved biomaterials made from polyanhydrides than there are of polyesters, but the surface-eroding nature of polyanhydrides is crucial for certain controlled release applications. The best example of this is Gliadel wafers, which are implanted in the brains of patients with malignant glioblastoma. The wafers are made from poly(bis(*p*-carboxyphenoxy) propane-*co*-sebacic acid) (poly(CPP-co-SA) at a ratio of 20:80 CPP:SA and are loaded with carmustine, a potent chemotherapeutic. Because the wafer degrades by surface erosion, the release of carmustine is steady and sustained rather than undergoing the initial burst release seen with PLGA-based devices. This is important because the Gliadel wafers are implanted directly into the brain, and carmustine is a potent drug that kills cells by cross-linking DNA and RNA. Slow release mitigates off-target toxicity (overdose) and also prolongs the mechanism of action, which is critical because brain surgery is dangerous and leads to many complications. For this reason, Gliadel wafers are advantageous because they are implanted once, slowly release carmustine from the wafers to continue killing cancer cells as they proliferate over the course of 2–3 weeks, and then are fully resorbed by the body, eliminating the need for a second surgery to remove the wafers (Kleinberg, 2016).

Unlike with PLGA, initial studies on the poly(CPP-co-SA) wafers showed that initial molecular weight of the polymers used did not affect erosion rate (Dang et al., 1996). Beyond the benefit of steady release as a result of surface hydrolysis, polyanhydrides have also been extensively investigated in vaccine development because of the inherent adjuvant properties of these polymers (Kipper et al., 2006; Vela Ramirez et al., 2016).

Chapter Exercises

1. Define the term erosion.
2. What are the major routes of degradation for an orally administered drug? How could the activity of this drug be extended?
3. What factors should be considered when designing a photodegradable polymeric device?
4. How could a nondegradable polymer be useful in a degradable biomaterial?
5. Proteinase K has been added to a PLA device. How quickly will the device degrade? What are the degradation products?
6. How would the rate of degradation change for polymers made with a macrolactone (C_8–C_{17}) over PCL? Why does the degradation rate change?
7. What polymer composition, degradation rate, and delivery route would you use for a dental fixative?
8. What are the important factors to consider when designing biodegradable nanoparticles to deliver therapeutics?
9. Research an FDA-approved commercial PLGA product of your choice that was not covered in this chapter. Identify as much information about the polymer properties as you can (G:L ratio, molecular weight, end group chemistry, processing, etc.) and then use this information to explain why this specific design was well suited for the biomaterial's application.
10. Biochronomer, a poly(ortho ester)-based technology for controlled release applications, is used in two commercially available therapeutics, CINVANTI and SUSTOL, loaded with aprepitant and granisetron, respectively. Aprepitant has a logP value of 4.5 while granisetron has a logP value of 2.6, where a higher logP corresponds to more lipophilic drugs. Assuming the polymer formulation and drug loading are the same in both therapeutics, which treatment would you expect to have faster drug release? Why?

1.3.2G

Applications of "Smart Polymers" as Biomaterials

ALLAN S. HOFFMAN[1], PATRICK S. STAYTON[2]

[1]Bioengineering and Chemical Engineering, University of Washington, Seattle, WA, United States

[2]Bioengineering, University of Washington, Seattle, WA, United States

Introduction

Stimulus-responsive, "intelligent" polymers are polymers that respond to small changes in physical or chemical conditions near a critical condition with sharp and relatively large phase or property changes. They are also known as "smart," stimuli-responsive, or "environmentally sensitive" polymers. These polymers can take many forms; for example, they may be dissolved in aqueous solutions, adsorbed or grafted on aqueous–solid interfaces, or cross-linked in the form of hydrogels. They may also be combined chemically or physically with other molecules, especially a variety of bioactive molecules. A number of reviews over the past 20–25 years have highlighted applications of smart polymers in the biomedical field (Hoffman, 1987, 1995, 1997; Hoffman et al., 2000; Okano et al., 2000; Roy and Gupta, 2003; Roy et al., 2010; Hoffman, 2013; Moad, 2017, MacEwan and Chilkoti, 2017; Reineke, 2016). In this chapter, we have prioritized earlier historical examples with some exciting and representative more recent developments. The reader is referred to classical and more recent reviews of the ever-expanding applications of smart polymers in the biomaterial field (e.g., Hoffman, et al., 2000; Heredia and Maynard, 2007; Hoffman and Stayton, 2010; Grover and Maynard, 2010; Broyer et al., 2011). The reader is also referred to the chapter by Benoit on Drug Delivery Systems (Chapter 2.5.12) for more details.

Many different stimuli-responsive polymers have been investigated, and the various stimuli that researchers have used are listed in Table 1.3.2G.1. Typically, when the polymer's smart response is stimulated, the resultant behavior will depend on the initial state of the polymer (Fig. 1.3.2G.1). Four examples of this are described below:

- When a smart polymer is dissolved in an aqueous solution, it will exhibit a sudden onset of turbidity as it phase separates, and if its concentration is high enough it may convert from a viscous solution to a gel.
- When a smart polymer is designed as a block copolymer it can be stimulated to phase separate as a segment that forms a hydrophobic core of a micelle, that can load drugs, and then stimulated to reversibly release the drugs as the polymer is switched back to unimeric soluble chains.
- When a smart polymer is chemically grafted to an aqueous–solid interface and is stimulated to phase separate, it will collapse, converting that interface from a hydrophilic to a hydrophobic interface. If the smart polymer is dissolved in solution and is stimulated to phase separate in the presence of a solid–aqueous interface, it may physically adsorb at the interface, especially when the surface composition has a balance of hydrophobic and polar groups similar to the phase-separating smart polymer.
- A smart polymer may be chemically cross-linked into a network. When it is swollen in an aqueous solution below its critical condition, it may be called a "smart hydrogel." When the polymer network chains are stimulated to phase separate at their critical condition, the hydrogel will collapse and release much of its swelling solution as a burst.

These phenomena all reverse when the stimulus is reversed. The phase separation of a water-solvated smart polymer chain is driven by the release of the hydrophobically bound water molecules on the polymer backbone, which creates a large gain in entropy in the system. Often the rate of reversion back to the hydrated state is slower than the collapse, because the reverse process of water moving back into the collapsed phase and to the apolar groups of the polymer is slower than the original release of waters to bulk solution. The rehydration of the hydrophobic groups of the polymer as a process is thermodynamically opposed by the resultant decline in entropy of the system (the reswelling process is favored by the exothermic hydration and expansion of the polymer chains). The rate of collapse of smart

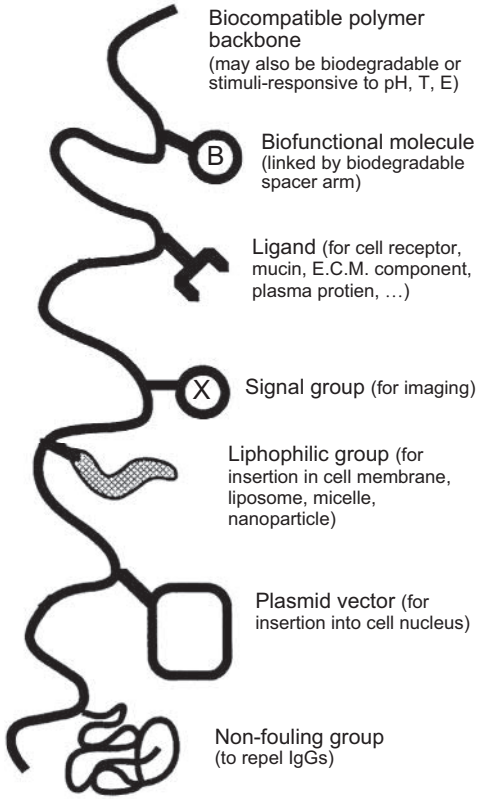
• **Figure 1.3.2G.1** Schematic illustration showing the different types of responses of "intelligent" polymer systems to environmental stimuli. Note that all systems are reversible when the stimulus is reversed. (Hoffman et al., (2000) *Journal of Biomedical Materials Research* (JBMR): Reproduced with permission of *JBMR*, J. Wiley, Publisher.)

polymer systems and its reversal can also depend on the dimensions of the smart polymer system. Rates will be more rapid for systems with smaller dimensions, e.g., nanoscale versus microscale dimensions.



• **Figure 1.3.2G.2** Schematic illustration showing the variety of natural or synthetic biomolecules that may be conjugated to a smart polymer. In some cases, only one molecule may be conjugated,such as a recognition protein, which may be linked to the protein at a reactive terminal group of the polymer, or it may be linked at a reactive pendant group along the polymer backbone. In other cases more than one molecule may be conjugated along the polymer backbone, such as a targeting ligand along with many drugmolecules. (Hoffman et al., (2000) *Journal of Biomedical Materials Research* (JBMR): Reproduced with permission of *JBMR*, J. Wiley, Publisher.)

The rate of collapse of smart polymer systems and its reversal can depend on the dimensions of the smart polymer system. Rates will be more rapid for systems with smaller dimensions, e.g., nanoscale versus microscale dimensions.

Smart polymers may be physically mixed with, complexed with, or chemically conjugated to biomolecules, small-molecule drugs, and/or imaging agents to yield a large and diverse family of biomaterials that can respond to biological, as well as to physical and chemical, stimuli. Biomolecules that may be combined with smart polymer systems include proteins and peptides, sugars and polysaccharides, single- and double-stranded oligonucleotides, RNA and DNA, simple lipids and phospholipids, and a wide spectrum of recognition ligands and synthetic drug and contrast agents. In addition, other polymer compositions such as polyethylene glycol (PEG) may be conjugated to the smart polymer backbone to provide it with "stealth" properties (Fig. 1.3.2G.2 schematically shows many different molecules, one or several together, which may be conjugated to a single smart polymer chain).

Smart polymer–biomolecule conjugates in solution, on surfaces, and within hydrogels represent an important and exciting extension of polymeric biomaterials beyond their well-known uses in implants, medical devices, and drug delivery.

Smart Polymers in Solution

There are many polymers that exhibit thermally induced precipitation out of aqueous solutions (Table 1.3.2G.2), and the polymer that has been most extensively studied is poly(*N*-isopropyl acrylamide), or PNIPAAm. This polymer is soluble in water below 32°C, and precipitates sharply as temperature is raised above 32°C (Heskins and Guillet, 1968; Schild, 1992). The precipitation temperature is called the lower critical solution temperature, or LCST. If the solution contains buffer and salts the LCST may be reduced several degrees. If NIPAAm monomer is copolymerized with more hydrophilic monomers, such as acrylamide, the LCST will increase and may even disappear. If NIPAAm monomer is copolymerized with more hydrophobic monomers, such as *n*-butylacrylamide, the LCST decreases (Fig. 1.3.2G.3) (Priest et al., 1987).

pH-responsive polymers have also been extensively studied due to the many biomaterial settings where physiological or device-related pH gradients can be used to couple phase transitions to useful actions such as drug delivery. The incorporation of carboxylic acid-derived monomers, such as acrylic acid (AA) or methacrylic acid (MAA), has been used to impart pH sensitivity in a variety of copolymers. By copolymerizing these monomers with more hydrophobic monomers, the pH transition can be tuned to higher pH values. Peppas and coworkers have extensively studied pH-sensitive acrylic acid-acrylate copolymer smart gels (e.g., Peppas et al., 1999, 2000; Robinson and Peppas, 2002; Peppas, 1997, 2001). This work is discussed in more detail in Chapter 1.3.2E on Hydrogels. The synthesis of longer alkyl-segment members such as propyl(acrylic acid), butyl(acrylic acid), and longer apolar segments also has provided new opportunities to tune the pH transition point. Tirrell originally characterized a newer member of the alkylacrylic acid family in ethyl(acrylic acid) and more recently, Stayton, Hoffman, and coworkers have studied the behavior of pH-sensitive alpha-alkylacrylic acid polymers in solution (Tirrell, 1987; Lackey et al., 1999; Murthy et al., 1999; Stayton et al., 2000; Murthy et al., 2003a,b; Yin et al., 2006; Stayton and Hoffman, 2008). As pH is lowered, these polymers become increasingly protonated and hydrophobic, and eventually phase separate; this transition can be sharp, resembling the phase transition at the LCST. Bae and coworkers also developed interesting temperature- and pH-sensitive polymers for endosomal release of drug formulations (e.g., Na et al., 2006; Kang and Bae, 2007).

Dual-sensitive smart polymers have also been developed to provide further tunability. NIPAAm may be copolymerized with pH-sensitive monomers, leading to random copolymers with both temperature- and pH-responsive behavior (Murthy, et al., 1999; Zareie et al., 2000; Murthy

• **Figure 1.3.2G.3** Copolymerization of a thermally sensitive polymer, PNIPAAm, with a more hydrophilic comonomer, AAm, raises the LCST of the copolymer, whereas copolymerization with a more hydrophobic comonomer, N-tBAAm, lowers the LCST. (Hoffman et al., (2000) *Journal of Biomedical Materials Research* (JBMR): Reproduced with permission of *JBMR*, J. Wiley, Publisher.)

et al., 2003a,b; Yin, et al., 2006). NIPAAm has been copolymerized with pH-responsive macromonomers of acrylic acid (AAc), which yielded graft copolymers that independently exhibit two distinct stimuli responses, one for the backbone PNIPAAm and one for the side chain PAAc (Chen and Hoffman, 1995). Block copolymers of two such smart polymers also exhibit two distinct stimuli responses if the two individual blocks are each long enough. Such smart polymers can form physical hydrogels in response to changes in temperature and/or pH and have been broadly investigated for use as injectable drug-delivery systems (their high water content provides good biocompatibility, and the lack of chemical cross-links facilitates eventual elimination from the body (see also Chapter 2.5.12 on Drug Delivery Systems for more details). A family of thermally gelling and biodegradable triblock copolymers has been developed by Sung Wan Kim and coworkers for injectable formulations that form degradable, drug depot masses at body conditions (Vernon et al., 2000; Lee et al., 2001; Jeong et al., 2002). The formulation is a medium viscosity, injectable solution at room temperature, and a phase-separated hydrogel mass at 37°C. Doo Sung Lee, You Han Bae, and coworkers have developed similar biocompatible and degradable A–B–A triblock copolymers having both pH and temperature sensitivity; they are based on two blocks of poly(caprolactone-co-lactic acid) copolymers (PCLA), combined with a central PEG block. The pH sensitivity is derived from short blocks containing the sulfonamide group (OSM) that are attached at each end of the triblock (Shim et al., 2005, 2006).

In addition to vinyl-based polymers, there have been exciting advances in developing stimuli-responsive biopolymers for biomaterial applications. Urry and colleagues first developed elastin polypeptides that showed temperature- and pH-responsive behavior, i.e., LCST properties. Subsequently, elastin-like polypeptides (ELPs) have been developed extensively by Chilkoti and coworkers. Because the ELPs are genetically encoded and produced biologically, the sequence and size of ELPs can be exactly designed and controlled. This precision in engineering their sequences and molecular weights is thus unattainable by synthetic chemistry and as a result they have been rapidly developed into biomaterial applications. By controlling the incorporation of hydrophobic or charged amino acids, different trigger points for temperature and pH transitions can be engineered. Block architectures have also been developed with similar architectural transitions as smart synthetic block copolymers. Finally, they can be engineered as genetic fusions to therapeutic or targeting peptides and proteins and thus do not always require bioconjugation. Due to these versatile attributes, ELPs have been used extensively as scaffolds for tissue engineering, in drug-delivery systems as soluble biopolymer therapeutics, micelles, nano- and microparticles, and as thermally triggered drug depots (Urry et al., 1991; Meyer and Chilkoti, 2002; MacEwan and Chilkoti, 2017; Panitch et al., 1999).

Smart Polymer–Protein Bioconjugates

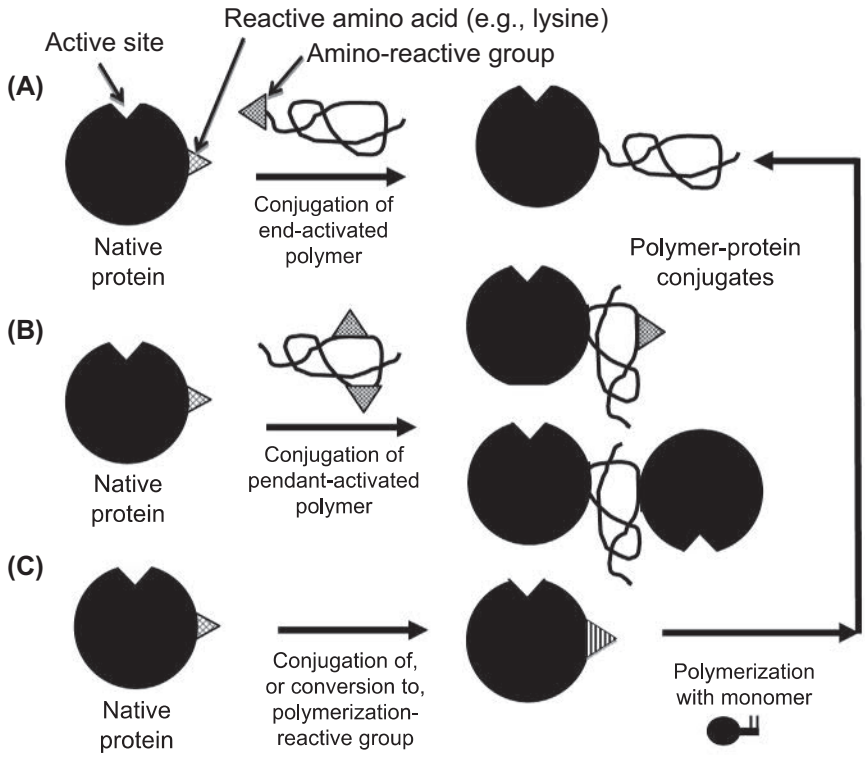
Smart polymers may be conjugated randomly to proteins by binding the reactive end of the polymer or reactive pendant groups along the polymer backbone to reactive sites on the protein. One may utilize functionalized free radical initiator or chain transfer agents to synthesize oligomers with one functional end group, which can then be derivatized to form a reactive group that can be conjugated to the protein. For example, NIPAAm has been copolymerized with reactive monomers such as *N*-hydroxysuccinimide acrylate (NHS acrylate) to yield a random copolymer with pendant NHS groups, which have then been conjugated to the protein. (These synthesis methods are described in Cole et al., 1987; Monji and Hoffman, 1987; Chen et al., 1990; Chen and Hoffman, 1990; Yang et al., 1990; Takei et al., 1993a; Chen and Hoffman, 1994; Ding et al., 1996, 1998.) Vinyl monomer groups may also be conjugated to proteins to provide "comonomer" vinyl groups for copolymerization with free monomers such as NIPAAm (Shoemaker et al., 1987).

Normally the lysine amino groups are the most reactive protein sites for random polymer conjugation to proteins, and *N*-hydroxysuccinimide (NHS) attachment chemistry is often utilized. Other possible sites include –COOH groups of aspartic or glutamic acid residues, –OH groups of serine or tyrosine residues, –SH groups of cysteine residues, and terminal amino groups. Fig. 1.3.2G.4 shows various ways that polymers may be directly conjugated to proteins or formed by growth from the protein (Hoffman and Stayton, 2010).

Random conjugation of temperature-sensitive (mainly) and pH-sensitive (occasionally) polymers to proteins has been extensively investigated, and applications of these conjugates have been focused on immunoassays, affinity separations, enzyme recovery, and drug delivery. One of the earliest applications of a smart polymer–biomolecule conjugate was an immunoassay developed by Hoffman, along with coworkers at a Seattle company called Genetic Systems Corp. They conjugated PNIPAAm to an antibody and used it to capture an antigen, then added a second, labeled antibody to the antigen, and warmed to phase separate the labeled immune complex sandwich. The assay was similar to an ELISA assay, but was much faster and was as accurate as ELISA. (Other interesting early work on soluble–insoluble polymer–biomolecule conjugates can be found in the following references: Schneider et al., 1981; Okamura et al., 1984; Nguyen and Luong, 1989; Taniguchi et al., 1989; Chen and Hoffman, 1990; Monji et al., 1990; Pecs et al., 1991; Taniguchi et al., 1992; Takei et al., 1993b,1994a; Galaev and Mattiasson, 1993; Fong et al., 1999; Anastase-Ravion et al., 2001, Pelegri-O'Day, 2014; Broyer et al., 2011; De et al., 2008).

Site-Specific Smart Polymer Bioconjugates

Conjugation of a responsive polymer to specific and designed sites of proteins opened new opportunities for

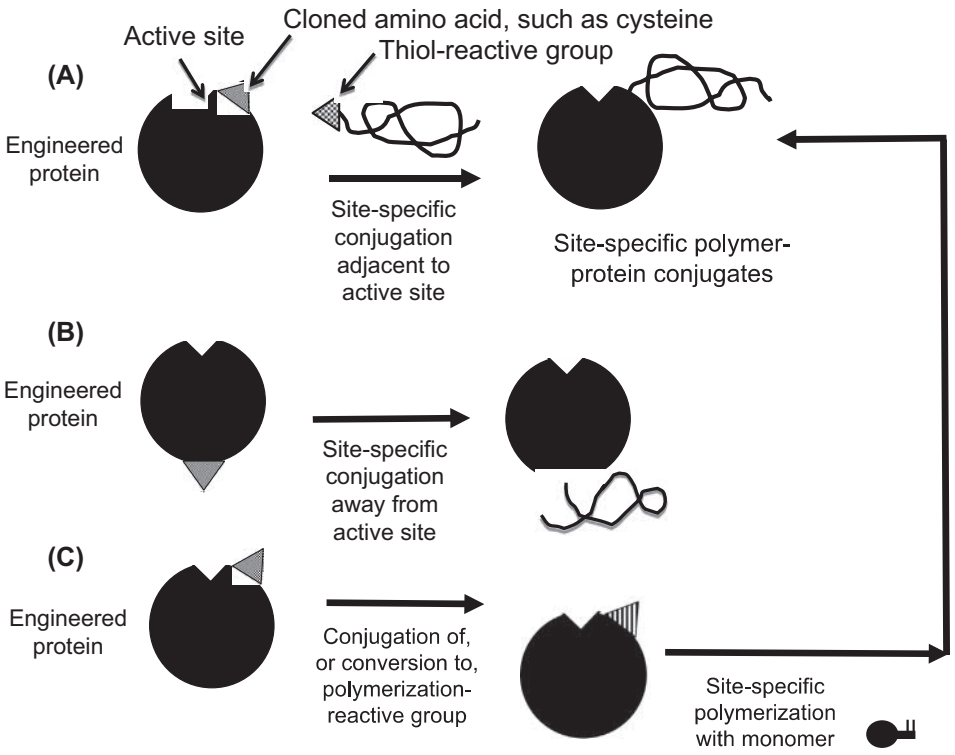


• **Figure 1.3.2G.4** Various methods for synthesizing polymer–protein bioconjugates.

the bioconjugate field (Chilkoti et al., 1994; Stayton and Hoffman et al., 1995, 2000). The possibilities of exploiting the polymer chain transitions to control the desired protein/enzyme activities were opened by this site-selective design of the conjugation site (Stayton and Hoffman et al., 1995). The first application was an "affinity switch" where protein activity was shown to be switchable by the smart polymer switches triggered by external stimuli such as temperature, pH, or light. The molecular switching capabilities were shown to depend on polymeric parameters, such as the composition, MW, attachment site, and magnitude of its conformational and physical change. The switching efficiency was also engineered based on the size of the ligands or substrates, and their affinity for the active site. Smart polymers were conjugated to a reactive –SH thiol group from a cysteine that had been inserted by site-specific mutagenesis at a site nearby the active site of the protein (Fig. 1.3.2G.5). Typical SH-reactive polymer end groups include maleimide and vinyl sulfone groups. The specific site for polymer conjugation can also be located far away from the active site (Chilkoti et al., 1994), in order to avoid interference with the biological functioning of the protein, or nearby or even within the active site, in order to control the ligand–protein recognition process, and the resulting biological activity of the protein (Fig. 1.3.2G.5) (see also Stayton et al., 1995). Temperature-, pH-, and light-sensitive smart polymers have been used to form such novel, "really smart" bioconjugates (Ding et al., 1999, 2001; Bulmus et al., 1999; Stayton et al., 2000; Shimoboji et al., 2001, 2002a,b, 2003).

Similar strategies were shown to create reversible smart polymer shields to reversibly control protein–protein associations (Stayton et al., 1995), and have enabled separation of biotinylated proteins according to the size of the protein (Ding et al., 2001). The smart polymers could serve as dual-sensitive enzyme activity switches. For the site-specific enzyme conjugates, a combined temperature- and light-sensitive polymer was conjugated to specific sites on endocellulase, which provided "on–off" control of the enzyme activity with either light or temperature (Shimoboji et al., 2001, 2002a,b, 2003). Bulmus et al. (1999) conjugated a pH- and temperature-responsive PNIPAAm copolymer to a specific site on streptavidin. Triggered release of bound drugs by the smart polymer-engineered protein bioconjugates could be used to release therapeutics, such as for topical drug delivery to the skin or mucosal surfaces of the body, and also for localized delivery of drugs within the body by stimulated release at pretargeted sites using noninvasive, focused stimuli such as ultrasound or delivery of light stimuli from catheters. Triggered release could also be used to release and recover affinity-bound ligands from chromatographic and other supports in eluate-free conditions, including capture and release of specific cell populations to be used in stem cell and bone marrow transplantation.

A method for thermally induced switching of enzyme activity has been developed, based on the site-directed conjugation of end-reactive temperature-responsive polymers to a unique cysteine (Cys) residue positioned near the enzyme active site. The reversible temperature-induced collapse of



• **Figure 1.3.2G.5** Schematic illustration of various processes for preparing a site-specific conjugate of a polymer with a genetically-engineered, mutant protein.

N,N-dimethylacrylamide (DMA)/N-4-phenylazo-phenylacrylamide (AZAAm) copolymers (DMAAm) has been used as a molecular switch to control the catalytic activity of endoglucanase 12A (EG 12A). The polymer was conjugated to the EG 12A site-directed mutant N55C, directly adjacent to the cellulose binding cleft, and to the S25C mutant, where the conjugation site is more distant. The N55C conjugate displayed a larger activity shut-off efficiency in the collapsed polymer state than the S25C conjugate. Increasing the polymer molecular weight was also shown to increase the shut-off efficiency of the switch.

Block copolymers containing stimuli-responsive segments provide important new opportunities for controlling the activity and aggregation properties of protein–polymer conjugates. Kulkarni et al. prepared an RAFT block copolymer of a biotin-terminated poly(*N*-isopropylacrylamide) (PNIPAAm)–b–poly(acrylic acid) (PAA). The number-average molecular weight (M_n) of the (PNIPAAm)–b–(PAA) copolymer was determined to be 17.4 kDa ($M_w/M_n = 1.09$). The PNIPAAm block had an M_n of 9.5 kDa and the PAA block had an M_n of 7.9 kDa. This block copolymer was conjugated to streptavidin (SA) via the terminal biotin on the PNIPAAm block. This controls the molecular orientation of the PNIPAAm block to be near the streptavidin surface with the PAA block oriented further away toward bulk solution. It was found that the PNIPAAm still went through its chain collapse via thermal stimulation, while the PAA chain in its ionized state prevented the usual PNIPAAm-induced aggregation. Thus the activity switching could be separated from protein aggregation and the molecular switch could operate on isolated polymer–protein conjugates. If aggregation was also desired, reducing the pH to protonate the PAA could remove the charge repulsive properties of the outer segment and protein aggregation could be triggered by dual temperature and pH stimulation.

Smart Polymers on Surfaces

Smart polymers, especially PNIPAAm, have been coated on various surfaces by physical adsorption, chemical conjugation, affinity complexation, radiation-induced polymerization, direct or chain-transfer initiated polymerization from the surface, and plasma discharge deposition. These methods and various applications of them are discussed in this section.

Smart polymers, especially PNIPAAm, have been coated on various surfaces by physical adsorption, chemical conjugation, affinity complexation, radiation-induced polymerization, direct or chain-transfer initiated polymerization from the surface, and plasma discharge deposition.

One may covalently graft PNIPAAm to a surface by exposing the surface to ionizing radiation in the presence of the monomer (and in the absence of air) or by preirradiating the polymer surface in air, and later contacting the surface with the monomer solution and heating in the absence of air to expose trapped radicals. These surfaces exhibit stimulus-responsive changes in wettability (e.g., Uenoyama and Hoffman, 1988; Takei et al., 1994b; Kidoaki et al., 2001). Okano, Yamato, and coworkers have been pioneers in the

area of smart polymer cell culture surfaces. They applied the radiation grafting technique to form surfaces having a surface layer of grafted PNIPAAm (Yamato and Okano, 2001; Shimizu et al., 2003). They cultured cells to confluent sheets on these surfaces at 37°C, which is above the LCST of the polymer. When the PNIPAAm collapses, the interface becomes hydrophobic and leads to physical adsorption of cell adhesion proteins from the culture medium, enhancing the cell culture process. Then, when the temperature is lowered, the interface becomes hydrophilic as the PNIPAAm chains rehydrate, and the cell sheets are released from the surface along with the cell adhesion proteins, which remain bound to the cell surfaces. The cell sheet can be recovered and used in tissue engineering, e.g., for artificial corneas and heart patches, and in periodontal applications. These exciting new applications of smart surface cell sheets are being pursued in the clinic. Patterned PNIPAAm surfaces have also been prepared for cell culture (Yamato et al., 2001).

Ratner and coworkers used a gas plasma discharge technique to deposit temperature-responsive coatings from a NIPAAm monomer vapor phase plasma discharge. When cells are cultured on these surfaces, they also form reversible cell sheets in a manner similar to Okano and Yamato's PNIPAAm-grafted surfaces (Pan et al., 2001).

Smart polymers may also be grafted to surfaces by polymerizing the monomer directly from the surface. This may be done by first attaching to the surface either a radical initiator, such as an azo or peroxide initiator, or a chain transfer agent (CTA) for controlled radical polymerizations such as reversible addition-fragmentation chain transfer polymerization (RAFT) (e.g.,Chiefari et al., 1998; McCormick and Lowe, 2004; Moad et al., 2008) or atom transfer radical polymerization (ATRP) (e.g., Wang and Matyjaszewski, 1995; Matyjaszewski and Xia, 2001; Matyjaszewski and Tsarevsky, 2009). (The ATRP of the smart polymer from a biomolecule such as a protein to form the bioconjugate directly was discussed earlier in this chapter.) Then the polymerization is initiated at the surface or in the surrounding solution, and the result is a smart polymer grafted to the surface. In the case of RAFT or ATRP controlled radical polymerizations, the molecular weights of the grafted polymer can be controlled to a narrow range. In a recent example, Golden and coworkers conjugated an RAFT CTA to the surface of a microporous, hydroxylated nylon membrane, and graft-polymerized NIPAAm directly from the surface, forming a graft polymer of around 9000 MW (Golden et al., 2010). Then this surface was heated, and the collapsed PNIPAAm-coated porous membrane was used in a microfluidic channel to sequester dilute PNIPAAm-antibody conjugates that had earlier captured a biomarker antigen in a blood test sample. In this way, the captured biomarker was concentrated on the membrane surface and later released by cooling to provide a concentrated pulse flowing downstream in the channel for this smart polymer microfluidic immunoassay.

The research team of Stayton, Hoffman, and coworkers developed a variety of nanoparticles coated with PNIPAAm for various applications in diagnostic immunoassays. They include polystyrene latex nanoparticles, magnetic nanoparticles, and gold nanoparticles. For example, PNIPAAm- and antibody-functionalized beads were then used to capture labeled, biotinylated antigens in a diagnostic test sample, to produce a smart polymer competition immunoassay carried out in a microfluidic device (Malmstadt et al., 2003a,b, 2004). Such PNIPAAm-antibody coatings were also developed on magnetic and gold nanoparticles, which were used to capture dilute antigen biomarkers in a test sample, then later were captured on the PNIPAAm-grafted porous membrane surface described above (Golden et al., 2010). After that they were released by cooling, forming a concentrated pulse of labeled nanoparticles for a global health infectious disease assay downstream in a microfluidic device. PNIPAAm-coated magnetic and gold NPs were also applied in lateral flow, "dipstick" assay for diagnostics in global health infectious disease applications by the Stayton–Hoffman group.

In a process for coating magnetic nanoparticles with PNIPAAm, the Stayton–Hoffman group developed responsive magnetic nanoparticles in the presence of a dodecyl-terminated PNIPAAm. The dodecyl-terminated PNIPAAm polymer formed micelles that concentrated the pentacarbonyl iron precursor of magnetic iron oxides in the dodecyl core of the micelle before it was converted at high temperature to magnetic iron oxide (Lai et al., 2007, 2009). To coat the gold nanoparticles, Nash bound RAFT-polymerized PNIPAAm chains to the gold surface via sulfur's affinity to gold, utilizing the sulfur-containing groups in the dithioester or trithiocarbonate terminal groups from the original CTA of the RAFT polymer chain (Nash et al., 2010a,b,c). The coated magnetic particles were mainly used for separating and concentrating the captured antigen, and the coated gold particles were mainly used as color (red) labels to indicate the approximate concentration of the captured antigen.

Smart polymers may also be grafted in gradients to surfaces to provide surfaces of gradually varying hydrophilicity and hydrophobicity as a function of the polymer composition and conditions. This phenomenon has been applied by Okano, Kikuchi, and coworkers to prepare chromatographic column packing for use in eluate-free ("green") chromatographic separations (Kobayashi et al., 2001; Kikuchi and Okano, 2002). Ishihara et al. (1982, 1984) developed photo-responsive coatings and membranes that reversibly change surface wettability or swelling due to the photo-induced isomerization of an azobenzene-containing polymer.

Smart Polymer Hydrogels

When a smart polymer is cross-linked to form a gel, it will collapse and reswell in water as a stimulus raises or lowers it through its critical condition. PNIPAAm hydrogels have been extensively studied, starting with the pioneering work of Toyoichi Tanaka in 1981 (Tanaka, 1981). In the mid-to late-1980s, Hoffman and coworkers were among the first to recognize the potential of PNIPAAm hydrogels

as biomaterials; they showed that smart gels could be used to entrap enzymes and cells, and then by inducing cyclic collapse and swelling of the gel, the enzymes (or enzymes within the cells) could be turned "on" and "off." Park and Hoffman also showed enhanced enzyme efficiency for an entrapped enzyme in a packed bed, hydrogel bead reactor, since the collapse delivered product faster than it could diffuse out, and the reswelling imbibed substrate faster than it could diffuse in. They also could deliver drugs or remove toxic biomolecules, by stimulus-induced collapse or swelling. Dong and Hoffman developed an interesting pH- and temperature-responsive gel that swelled linearly at 37°C and pH 7.4, at rates depending on the AAc monomer content in the gel (Dong and Hoffman, 1986, 1987, 1990, 1991; Park and Hoffman, 1988, 1990a,b,c, 1994) (Fig. 1.3.2G.6).

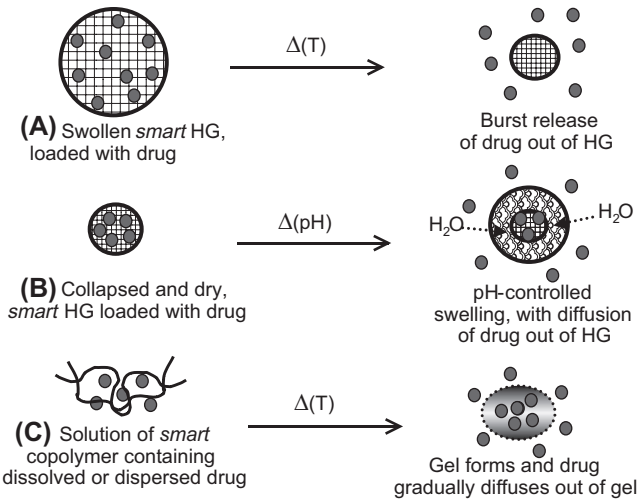
The research team of Kim, Okano, Bae, and coworkers was also actively studying smart hydrogels in the late 1980s and 1990s. For example, they investigated smart gels containing entrapped cells that could be used as artificial organs (Vernon et al., 2000). Since then, the properties of PNIPAAm hydrogels have been widely investigated in the form of beads, slabs or discs, and multilamellar laminates (Park and Hoffman, 1992a,b; Hu et al., 1995, 1998; Mitsumata et al., 2001; Gao and Hu, 2002; Kaneko et al., 2002).

Okano and coworkers designed and synthesized PNIPAAm gels that collapse much more rapidly than PNIPAAm gels that are simply cross-linked with a divinyl comonomer. Yoshida, Okano, and coworkers copolymerized NIPAAm monomer with a PNIPAAm macromer and a cross-linker, which yielded a gel with PNIPAAm chains grafted to the PNIPAAm network. The grafted chains collapsed first at the LCST, enhancing the rate of collapse of the network, along with the related rate of expulsion of water from the gel (Yoshida et al., 1995; Masahiko et al., 2003).

Peppas and coworkers (e.g., Peppas et al., 2000; Robinson and Peppas, 2002) have extensively studied pH-sensitive acrylic acid-acrylate copolymer smart gels. This work is discussed in more detail in Chapter 1.3.2E on Hydrogels (see also Peppas, 1997, 2001; Peppas et al., 1999, 2000).

Matsuda and coworkers incorporated PNIPAAm into physical mixtures with natural polymers such as hyaluronic acid and gelatin, for use as tissue-engineering scaffolds (Ohya et al., 2001a,b). Park and Hoffman developed a unique process for synthesizing mm-size spherical microgels of PNIPAAm (Park and Hoffman, 1992b). Nakamae, Hoffman, and coworkers developed novel compositions of smart gels containing phosphate groups that were used to bind cationic proteins as model drugs, and then to release them by a combination of thermal stimuli and ion exchange (Nakamae et al., 1992, 1997; Miyata et al., 1994).

A number of smart hydrogel drug-delivery systems have been designed to respond to biologic signals in a feedback manner. Many of these gels contain an immobilized enzyme. They are discussed in the Chapter 2.5.12 on Drug Delivery Systems.



• **Figure 1.3.2G.6** Schematic illustration showing three ways that smart gel formulations may be stimulated to release bioactiveagents: (A) thermally-induced collapse, which is relevant to skin ormucosal drug delivery; (B) pH-induced swelling, which is relevant to oral drug delivery, where the swelling is induced by the increase in pH in going from the gastric to enteric regions; and (C) sol-to-gel formation, which is relevant to injectable or topical formulations of a triblock copolymer solution that are thermally gelled at body temperature. For in vivo uses, the block copolymer is designed to bedegradable. The first two apply to cross-linked gels applied topically or orally, and the third is relevant to thermally-induced formation of gels from polymer solutions that are delivered topically or by injection. (See also Chapter 2.5.12 Drug Delivery Systems.)

Stimuli-Responsive Polymer Micelles and Carriers

One of the most rapidly developing biomaterial applications of smart polymers involves their development as drug-delivery systems. This includes pioneering work of Kataoka with pH-responsive and light-responsive photodynamic polymers for both small-molecule and nucleic acid drugs. Their group has carried such small-molecule carriers into advanced clinical trials. Bae and coworkers have done seminal work on sharply pH-responsive micelles that introduced elements of biodegradable, targeting, and triggered drug release (connected to work by Kim on polyhistidine polymers for nucleic acid delivery, see below). For example, they developed drug-delivery systems composed of PLA-*b*-PEG-*b*-P(His)-TAT and P(His) block of P(His)-*b*-PEG, where the surface of the particles was covered by hydrophilic PEG. They showed the targeting and intracellular carrier TAT peptide could be concealed during circulation but be exposed after the hydrophobic transition coupled to histidine protonation in the lower pH environment of tumors. This system showed higher anticancer activity and triggered release compared to free drug in animal models.

There have been many more developments using temperature, pH, redox and other signals to trigger better delivery and also imaging (for recent reviews see). One creative example of couple "theranostic" imaging and therapy was reported by Koo et al., 2011. They described the

development of pH-responsive MPEG poly(β-amino ester) polymeric micelles, which are designed to undergo a sharp pH-dependent transition to unimers in the lower pH environment of tumors. The tertiary amine groups are copolymerized into the hydrophobic amino ester block and these become protonated and highly destabilizing to the micelle core when they localize into the tumor when pH falls below 6.5. By coupling the imaging agent and drug release to this micelle destabilization they showed this theranostic system enabled in vivo tumor diagnosis and therapy simultaneously.

The area of nucleic acid delivery and the advent of gene medicine and other biologic drugs has driven considerable development of stimuli-responsive carriers over the past two decades. Stimuli-responsive polymers have played a continuing part of the nucleic acid carrier field as it has developed from and across plasmid, siRNA, mRNA, and most recently gene-editing technologies. Considerable effort has in particular been aimed at overcoming one of the most significant barriers for the delivery of biomolecular therapeutics that function inside the cell—endosomal release and cytosolic delivery (e.g., Stayton and Hoffman, 2008; also see Chapter 2.5.12 on Drug Delivery Systems). Many exciting developments continue today—and are still badly needed for ever-evolving biologic drugs that could benefit from DDS—to produce carriers that better target, enhance intracellular delivery, and maintain necessary ADME and manufacturing requirements.

Many cationic polymers were initially developed and some were designed as proton sponges to aid in endosomal escape. Early work with smart polymers from the group of Sung Wan Kim developed pH-responsive carriers that exploited biomimetic polyhistidine, such as in *N*-Ac-poly(L-histidine)-graft-poly(L-lysine) to trigger better endosomal release. These carriers demonstrated the potential of sharply triggered polymers to become endosome-releasing for plasmid DNA as the endosome acidified. Another approach was developed by Stayton and Hoffman with polymers that were engineered to undergo a pH-responsive transition in the endosome to directly destabilize the endosomal membrane. These polymers and the original monomer developed were inspired by the mechanism exploited by pathogens that must deliver nucleic acids and proteins to the cytosol for activity. The polymers also contain similar constituent pH-sensing chemical functionalities such as hydrophobized carboxylate groups—originally with a new member of the alkyl(acrylic acid) family in propyl(acrylic acid) (PAA). These polymers were initially built into DDS as an endosomal-releasing polymer for plasmid delivery, and were subsequently built out to be stand-alone carriers that retained the built-in segments for pH-responsive endosomal release. These new carriers incorporated a targeting component, a versatile conjugation or complexation element that allows biomolecules to be incorporated and released through pH- or redox-triggered release, the endosomal releasing segment, and a stealth component as necessary to optimize circulation stability. These carriers have been applied to siRNA and mRNA therapeutics in academia and are still being further developed in the biotechnology industry. They have been further developed in vaccine applications, for intracellular delivery of adjuvants where access to cytosolic danger receptors is critical, and for peptide and protein therapeutics, including de novo designer proteins that act against intracellular disease target. With the advent of modern biologic and vaccine drug space, including cell therapies, the field continues to expand and the reader is referred to many recent reviews (Lu et al., 2014; Zhao et al., 2018; Reineke, 2016; Shae et al., 2019).

Conclusions

Smart polymers in solution, on surfaces and as hydrogels, have been utilized in many interesting ways, especially in combination with biomolecules such as proteins and drugs. Important applications include affinity separations, enzyme processes, immunoassays, drug delivery, and toxin removal. These smart polymer–biomolecule systems represent an important extension of polymeric biomaterials beyond their well-known uses in implants and medical devices.

Metals: Basic Principles

JEREMY L. GILBERT

Department of Bioengineering, Clemson University, Charleston, SC, United States

Introduction

Medical Devices and Metals in the Body

The use of metals in the body has in many ways paralleled and enabled the advancement of medicine in the 20th and 21st centuries. A majority of medical devices (joint replacements, spinal devices, cardiovascular stents, mechanical heart valves, fracture fixation devices, dental implants) require the presence of a metal alloy to provide the strength and fatigue resistance to perform over the life of the patient. Indeed, the adaptation of metals and alloys for use in skeletal repairs and dentistry has foundations that go back millennia. Bechtol, Fergusson, and Laing (Bechtol et al., 1959) in 1959 provided an excellent review of the development and use of metals in the body from the first half of the 20th century. Many of the concepts and directions of study of metallic biomaterials are outlined in this monograph and many of these are the subject of ongoing research around metals in the body. Here, as early as 1775, iron wires were explored for use in internal fracture fixation and in 1829 tests in dogs of platinum, gold, silver, and lead showed promise. As early as 1908 there was research around the cellular reaction to metal fragments. In addition, coimplantation of copper and zinc induced periodic muscular contractions.

Early studies identified scientific topics that included magnesium (Mg) alloy corrosion and its ability to induce bone formation or inhibit cancerous tumors, and that infections may be limited by copper (Cu), silver (Ag), and other elements. Significant advances in metallurgy up to the 1920s began to introduce stainless steels (AISI-302, AISI-304, AISI-316, and AISI-317 versions), and Stellite and/or Vitallium (cobalt–chromium–molybdenum [CoCrMo] alloys) for use in internal fracture fixation devices (screws, plates). In the late 1950s up to the 1970s, titanium and its alloys were also found to exhibit excellent properties in strength, corrosion resistance, and biocompatibility for use in a wide range of medical device applications and were subsequently introduced into use in medical devices. Other alloys related to platinum (e.g., Pt-10% Ir for electrodes), gold (Au–Cu alloys for dentistry), silver–mercury (Ag–Hg amalgams), and others have been in use for decades or longer in various applications and have resulted in significant enhancements in the health and quality of life for millions of patients.

Metals, in general, are required for medical devices because they have the requisite mechanical properties necessary for many applications that no other class of biomaterials can replicate. The human body is, essentially, a fatigue machine where millions to tens of millions of loading cycles are generated in specific locations every year. For example, at 70 beats per min, the human heart contracts about 37 million times per year, and a typical human who walks 10,000 steps per day (5000 per leg) loads their joints about 1.8 million times per year. These loads can be significant and result in stresses that can reach hundreds of megapascals. Cyclic loading results in fatigue failure modes, sustained wear mechanisms, the potential for mechanically assisted corrosion mechanisms, and other effects. No other biomaterial class can perform at the stress and degradation-inducing levels that metals can. Metallic biomaterials have provided the medical device community with a large and successful toolbox of alloys with which to perform many of the required functions, and new alloys are being investigated even today. These facts are likely to continue to be the case for decades to come and metal and alloys will remain an essential part of the biomaterials armamentarium for the foreseeable future.

The Major Alloy Systems (Ti, NiTi, CoCrMo, SS, Pt, Au, Mg, Ag)

While greater detail of each group of metals currently in use or under development will be described in later sections of this text, this introduction is intended to give the reader basic insights into the metallic biomaterial alloys available today and the underlying basic metallurgical science associated with them.

In part due to the enactment of the Medical Device Amendments of 1976 (Wizemann, 2010), as well as the limited number of alloys with the right combination of mechanical, corrosion, and biocompatibility properties, there are a limited set of alloys currently used in the human body. Most of these alloys had been in widespread use prior to the enactment of the Medical Device Amendments and were therefore grandfathered in to be used in medical devices after passage. However, it is also the case that the alloys in use today represent some of the most corrosion resistant, highest strength alloys available and have shown themselves to be successful in their application to medical devices by their decades of use. Since 1976, the experience within the body of the major alloys used has elucidated the safety and effectiveness of these alloys for most applications. It has also raised new concerns related to degradation and biological–biomaterial interactions, including immune responses, hypersensitivity, and allergic responses that are often multifactorial and interacting degradation processes.

The major alloys in use today consist of metals intended for indefinite use within the body (permanently implantable) and those that are designed to be temporary, ultimately degrading or biocorroding over time (biodegradable alloys). The permanently implantable alloys are the principal ones applied to a wide range of medical devices currently in use today, while the biodegradable alloys are in development or used in a small set of approved applications.

The three major permanently implantable alloy systems used in the body across the spectrum of medical devices are: (1) stainless steels (primarily 316L stainless steel [ASTM F-138]), (2) cobalt–chromium–molybdenum (CoCrMo [ASTM F-75; ASTM F-799; ASTM F1537]) alloys, and (3) titanium (ASTM-F76) and its alloys (ASTM F136). Other permanently implantable alloys include Pt, Au (ASTM-F72), and Ag alloys. The degradable alloys under consideration include Mg, tin (Sn), iron (Fe), and zinc (Zn) alloys. One needs only look at the periodic table to realize that there are a wide range of metallic elements present that may be able to serve as potential biomedical alloys. Some of the more promising ones include zirconium (Zr) (ASTM-F2384), niobium (Nb), palladium (Pd), and tantalum (Ta). There are others as well such as rhenium (Re), molybdenum (Mo), and alloys of these two elements that are beginning to be considered for medical device use. Recent research is evaluating these alloys, and while some advantages in strength or other properties may be present, the three major alloy systems described earlier (stainless steel, CoCrMo, and Ti-alloys) remain the workhorse alloys in biomaterials.

For degradable alloys, the primary interest is to find alloys that will remain capable of carrying the applied loads and wear processes until the body has healed sufficiently that they are no longer required, and will then corrode away and be resorbed and eliminated by the body. Magnesium alloys (Witte, 2010) have been investigated the most. This alloy is known to corrode rapidly in physiological solutions and that the oxidation products are mostly Mg oxide (MgO or $Mg(OH)_2$), which is relatively innocuous, and hydrogen gas, which can be problematic. Other alloy systems, including Sn, Fe, and Zn, are under consideration as degradable alloys for biomaterials applications as well.

The alloys comprised of Au, Ag, and Pt, which are noble alloys, typically utilize their electrical properties to serve as electrodes, their noble electrochemical properties to resist corrosion or degradation, and/or other properties to serve in certain dental applications. Silver is also being adopted for its antibacterial properties, typically as a coating, nanoparticles, or other approaches to place the silver on the surface of a medical device. It is also used in silver–mercury amalgams in dentistry. Other alloys are also being considered for their antibacterial effects. These include alloys that rapidly corrode, and in so doing generate significant reduction reaction products (reactive oxygen intermediates) that can induce killing effects as well.

The big three—stainless steel, CoCrMo, and Ti–have a number of alloy systems that have seen widespread adoption for applications within the body. Stainless steels (primarily 316LVM stainless steel [ASTM F-138]) are used in surgical instrumentation, but also, importantly, in many medical devices, including screws, rods, and plates for bone fixation and in spinal fusion devices. Cobalt–chromium–molybdenum alloys (ASTM F-75; F-799; F-1537) are typically used in applications where high strength, fatigue resistance, and wear resistance are needed. CoCrMo is one of the most wear resistant alloys known and has been used for decades in total joint applications. Titanium and its principal alloy (Ti-6Al-4V) are used in dental implants as well as total joint replacements among other applications (ASTM F-67; ASTM F-136). This alloy has high strength, low modulus, and is particularly good at interfacing with the biological system. Bone ingrowth into porous titanium surfaces, known as biological fixation, is a primary means by which orthopedic implants affix to bone directly.

Metal Processing

Metals can be processed in many different ways to result in the end-products used in medical devices. Typically, to start, metals must be obtained from ore, which is mostly metal oxides found in nature. The metal cations in these metal oxides need to be reduced to elemental metals and this is often done in high-temperature furnaces under low (to no) oxygen-reducing conditions. In some cases, chemical reactions are used to pull the ions from the ore and then to subsequently reduce the ions to an elemental state.

Once elemental metals are formed, they can be melted together to form alloys of specific weight or atomic concentrations. Heating to melting and then casting the mixture is typically the first step. Once this billet of metal is cast, it is usually immediately hot worked (i.e., wrought or otherwise thermomechanically processed) into rod, sheet, plate, or bar stock. Continuous casting systems with follow-on thermomechanical treatment systems are often used. In some cases, like CoCrMo orthopedic devices, the alloy is cast directly into the near net final shape.

Forging, drawing, extruding, and other deformation processes are typically applied to metals under high-temperature conditions (i.e., thermomechanically processed) to allow the metal to recover and refine its grain size and allow far larger deformations to occur without damaging the alloy. These processing steps can affect the structure and properties of the materials (see later). Typically, metals are received in rod, bar, sheet, tube, or plate form for further processing by machining or thermomechanical processes.

Thermomechanical processing is the combination of high temperature and plastic deformation so that the effects of each can work together to obtain the final form of the metal. Plastic deformation at low temperature, known as cold working or work hardening, imparts plastic deformation into the alloy. This is manifested structurally as the generation, movement, and entanglement of dislocations (see the Section "Line Defects"). These defect structures act to increase the yield stress and lower the ductility of the metal. Often, alloys can be prepared with some amount of cold working in them to raise their strength. However, the loss of ductility associated with plastic deformation can raise the risk of fracture of the alloy and care must be taken to assure that the proper conditions for the metal are obtained (e.g., annealed vs. cold worked).

Thermal treatments, known as annealing, are often performed on previously cold-worked alloys to provide thermal energy to the microstructure so that dislocations can be eliminated (recovery) or new deformation-free grains can be nucleated and grown (recrystallization) from the prior deformed (or cold-worked) grains. Annealed alloys are those metals that have been cold worked and then heated to remove the effects of deformation. Thus annealed alloys tend to have lower yield strengths than their cold-worked counterparts, and higher ductility. Thus ASTM standards (e.g., ASTM F-138) have specifications that link to the cold-worked state of the alloy.

In some cases, powders of these alloys are generated by high-temperature spraying of molten alloy into a fine mist that solidifies into spherical powders. These powders can then be used in subsequent processes where either hot isostatic pressing (HIPing) (Pilliar, 2009) or selective laser sintering (or selective laser melting (Hedberg et al., 2014) can be used in 3D printers. HIPing is a process where powders are placed in a near net shape of the part and then put into a high-temperature and -pressure container and the powder alloy particles are diffusion bonded (or sintered) together to make a fully condensed and consolidated part. This occurs by raising the temperature of the alloy to a high temperature while still in the solid state. With this increased temperature, surface diffusional processes allow atoms of the surface to move and result in a metallurgical bond (diffusion bond or sintering) to form between adjacent surfaces in contact. The advantage of this approach is that the grain size is governed by the starting particles and can be very small, which results in very high-strength alloys (see later on grain size strengthening). For 3D printing, powdered alloy particles can be sintered or melted together by a short laser pulse, or electron beam methods that are used in a fixed pattern to print the part. Such selective laser (or e-beam) sintering methods are gaining in use and application in the medical device industry.

For many of the alloys in biomaterials the presence of oxygen during fabrication is detrimental and often inert gas environments are required to limit oxidation of the surface or the alloy, or uptake of oxygen into the alloy. This is particularly true for titanium and its alloys. It has a high affinity for oxygen uptake into the hexagonal close-packed (HCP) phase of the alloy. A small amount of oxygen may increase the strength of the titanium (through interstitial solid solution strengthening), but too much can make the alloy brittle and easily fractured. Indeed, surface diffusion of oxygen can result in a so-called alpha case on titanium that can reduce the fracture resistance of the alloy.

Ultimately, for many parts, manufacturing requires machining of the metal into a final shape. Such milling machines, lathes, and CNC machines are highly precise and require very hard and sharp cutting tools to make the precision cuts necessary. Tool-driven localized plastic deformation of the surface can induce effects like the formation of residual stresses that may impact the surface strength (hardness) of the alloy.

Finally, the surfaces of metals will require several different potential treatments to impart specific surface properties. These include shot peening (or glass beading) where high-velocity particles are blasted at a surface to induce compressive deformation of the surface. This has the effect of generating large compressive residual stresses on the surface and these can be beneficial in improving the fatigue strength of the part. Other processes may include grinding, polishing, electropolishing, anodizing, thermally oxidizing, nitriding, and/or plasma coating (physical vapor deposition or chemical vapor deposition coatings).

Surfaces of metals are typically treated to a passivation step where the part is immersed in an acid (typically nitric or citric acid) to remove unwanted surface contaminants and to induce the passive oxide film to become more chemically uniform and provide increased corrosion resistance. Such passivation treatments (ASTM F-86) typically consist of 30% nitric acid at 130°F for 30 min. In some cases, citric acid has been considered for passivation treatments. These treatments, while they are applied to the three main alloy systems, have not been shown to have the same effects on different alloy surfaces. This passivation method was initially developed for stainless-steel passive films to remove iron and other elements from the oxide and to drive the oxide to be mostly a Cr-based oxide (Cr_2O_3). Use of this treatment may not have similar effects on CoCr alloys or Ti alloys; however, it is considered standard practice for the preparation of metals for use in the body and is generally applied across all alloy systems. At the end of fabrication, sterilization steps are needed and these may include gamma irradiation, ethylene oxide treatment, or even steam sterilization (as in the case of reused surgical instruments).

Passive oxide films are not static and are affected by immersion in electrolyte and time. They can also be modified by changes to the oxidizing power of the body solution

or the electrode potential across the metal electrolyte interface. Passive oxides are known to grow with time and to change chemistry. In some cases the oxides can incorporate other ions (phosphates, calcium, etc.).

Processing–Structure–Properties–Performance Paradigm

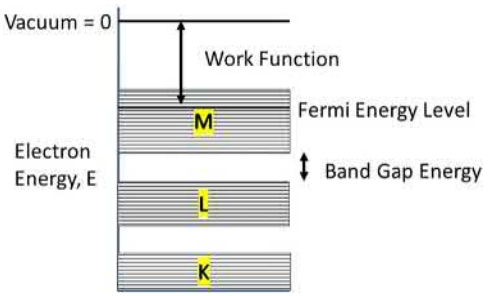
To understand these alloys, it is important to understand the processing–structure–properties–performance paradigm for alloys. That is, the processes used to make the alloy, in its final form, result in structures, from atomic scale (defects), to grain size (grain boundaries, texture), to a whole device, which determine the specific bulk and surface properties for the alloy. These properties, including strength, ductility, fracture toughness, fatigue strength, and wear resistance, in turn, determine the ultimate performance of the alloy. Since the surfaces of alloys are where the biological interactions occur and where many of the initiating events for failure begin (fatigue crack initiation mechanisms are typically surface driven), the surface processing of the alloy is an important element of the overall performance.

Thus processing affects structure, structure affects properties, and properties affect performance, and this approach to metallurgical control of medical devices has been a foundational element of the success of metal-based implants for decades. Below is a short discussion of the structure of metals.

Structure of Metals and Alloys

Electronic and Atomic Structure: Crystal Structures

To understand metal alloy performance, it is important to discuss the structural elements of metals from the atomic through the bulk size scales. Metal atoms consist of a nucleus made of protons and neutrons with electrons orbiting the nucleus in specific and quantized energy levels out to the outer valence electrons. The electrons occupy quantized energy levels starting with the inner-most bound electrons (K or 1s) and moving out from there (L, M, N, or 2s-2p, 3s-3p-3d, etc.). In a metal, no two electrons can occupy the same energy level and have the same spin, thus alloys are considered to have electron energy bands (Reed-Hill, 1973) made up of discrete (or quantized) electron energy levels that are occupied by electrons from the lowest K-level bands up to the outermost valence band for the alloy (Fig. 1.3.3.1). Since transition metals have unfilled valence bands (typically in the M or N, or "3" or "4" orbital), these bands are only partially filled with electrons up to the highest energy level called the Fermi energy level. The empty levels above the Fermi level represent energies available to electrons to jump into and conduct. This is why metals are high electron conductors (availability of energy levels immediately above the Fermi level provide easy conduction of electrons). In addition, there are energy gaps between the main quantum



• **Figure 1.3.3.1** Electron energy levels associated with the band energy theory of electrons in metals.

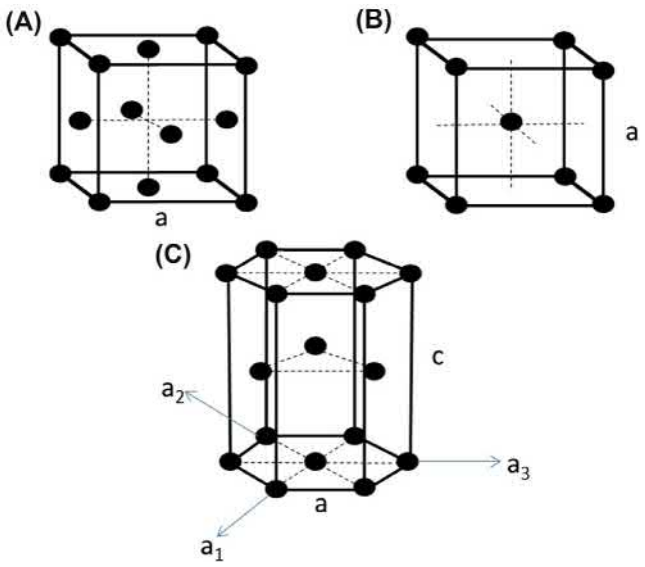
levels called band gaps, and there is a work function of the material, which is the energy required to raise an electron from the Fermi level to the vacuum (or to pull an electron out of the metal). The work function plays a significant role in photoelectric methods of materials analysis (e.g., X-ray photoelectron spectroscopy, Auger spectroscopy, etc.).

Because of the distinct and unique energy levels for inner bound electrons for each element, measurement of the energy of these electrons using various high-vacuum photoelectric methods (e.g., energy dispersive spectroscopy of characteristic X-rays, etc.) allows for the detection and quantification of these elements using an electron microprobe, scanning electron microscopy with energy dispersive spectroscopy, etc.

For the most part, atoms can be considered roughly spherical in their outer orbital and thus will act like hard spheres where each atom is attracted to every other atom. These attractive forces form the metallic bond and result in the hard sphere atoms coming together into crystalline forms or lattices. The short-range repulsive forces from atomic overlap (a result of the Pauli exclusion principle) keep the atoms as separate and distinct hard spheres.

Thus attractive electrostatic forces pull the atoms together and will drive them to form specific ordered crystalline structures (known as crystal lattices). There are 14 different lattice structures (Bravais lattices (Calister and Rethwisch, 2010)) that can form crystals (long-range repeating symmetry of atomic placement). For the most part, metallic biomaterials form either cubic or HCP structures (Fig. 1.3.3.2). In the cubic system there are face-centered cubic (FCC) and body-centered cubic (BCC) structures. For example, HPC elements (at room temperature) include Ti and Mg. Austenitic stainless steel (Fe–Cr–Ni–Mo alloy) is FCC, while iron alone at body temperature is BCC.

The crystal-forming electrostatic attractive forces (i.e., metallic bonds) are counteracted by thermal (kinetic) energy associated with increasing temperatures above 0 K. That is, thermal energy, given by kT (Boltzmann's constant, 1.38×10^{-23} J/K, times temperature, in K), is the average kinetic (or vibrational) energy present in a system and drives increasing entropy. This thermal energy acts on metal crystals to generate phonons (quantized atomic mechanical vibrations) and plasmons (quantized plasma [or electron] vibrations). The higher the temperature, the greater are these oscillations. Ultimately, at sufficient temperatures,



• **Figure 1.3.3.2** Crystal structures of typical alloys. (A) Face-centered cubic, (B) body-centered cubic, (C) hexagonal close packed.

the thermal (vibrational) energy of the system overwhelms the attractive electrostatic forces and changes in the atomic structure can occur. This is known as a phase transition (from one solid phase to another, or from a solid to a liquid, in which case it is called melting). Some metals (e.g., Fe) may have multiple solid crystal structure phases (allotropes) that arise at different temperatures (pure iron is BCC at room temperature, FCC, and then a different BCC, with different lattice parameters, as the temperature is raised, until it ultimately melts). Thus the temperature of the system relative to the transition temperature for different allotropes determines the possibility of forming different crystal structures. Similarly, the stronger the electrostatic interatomic bonding forces, the higher will be the melt temperature of the metal.

Alloying, Microstructure, and Phase Diagrams

Alloys, typically used in metallic biomaterials, are metals that consist of more than one element combined together. The addition of carbon into iron results in steel, for example. When relatively small atoms (C, O, N, H) are mixed with larger atoms (Fe, Ti, Cr, etc.) they can fit in the open or interstitial spaces between the larger atom crystal structure and become **interstitial** atoms. When two elements of about equal size are mixed, the lower concentration atoms (the solute) will replace the higher concentration atoms (solvent) on the crystal lattice of the solvent atoms. This is called a **substitutional solid solution**. Thus adding nickel (Ni) to Fe would result in a substitutional solid solution.

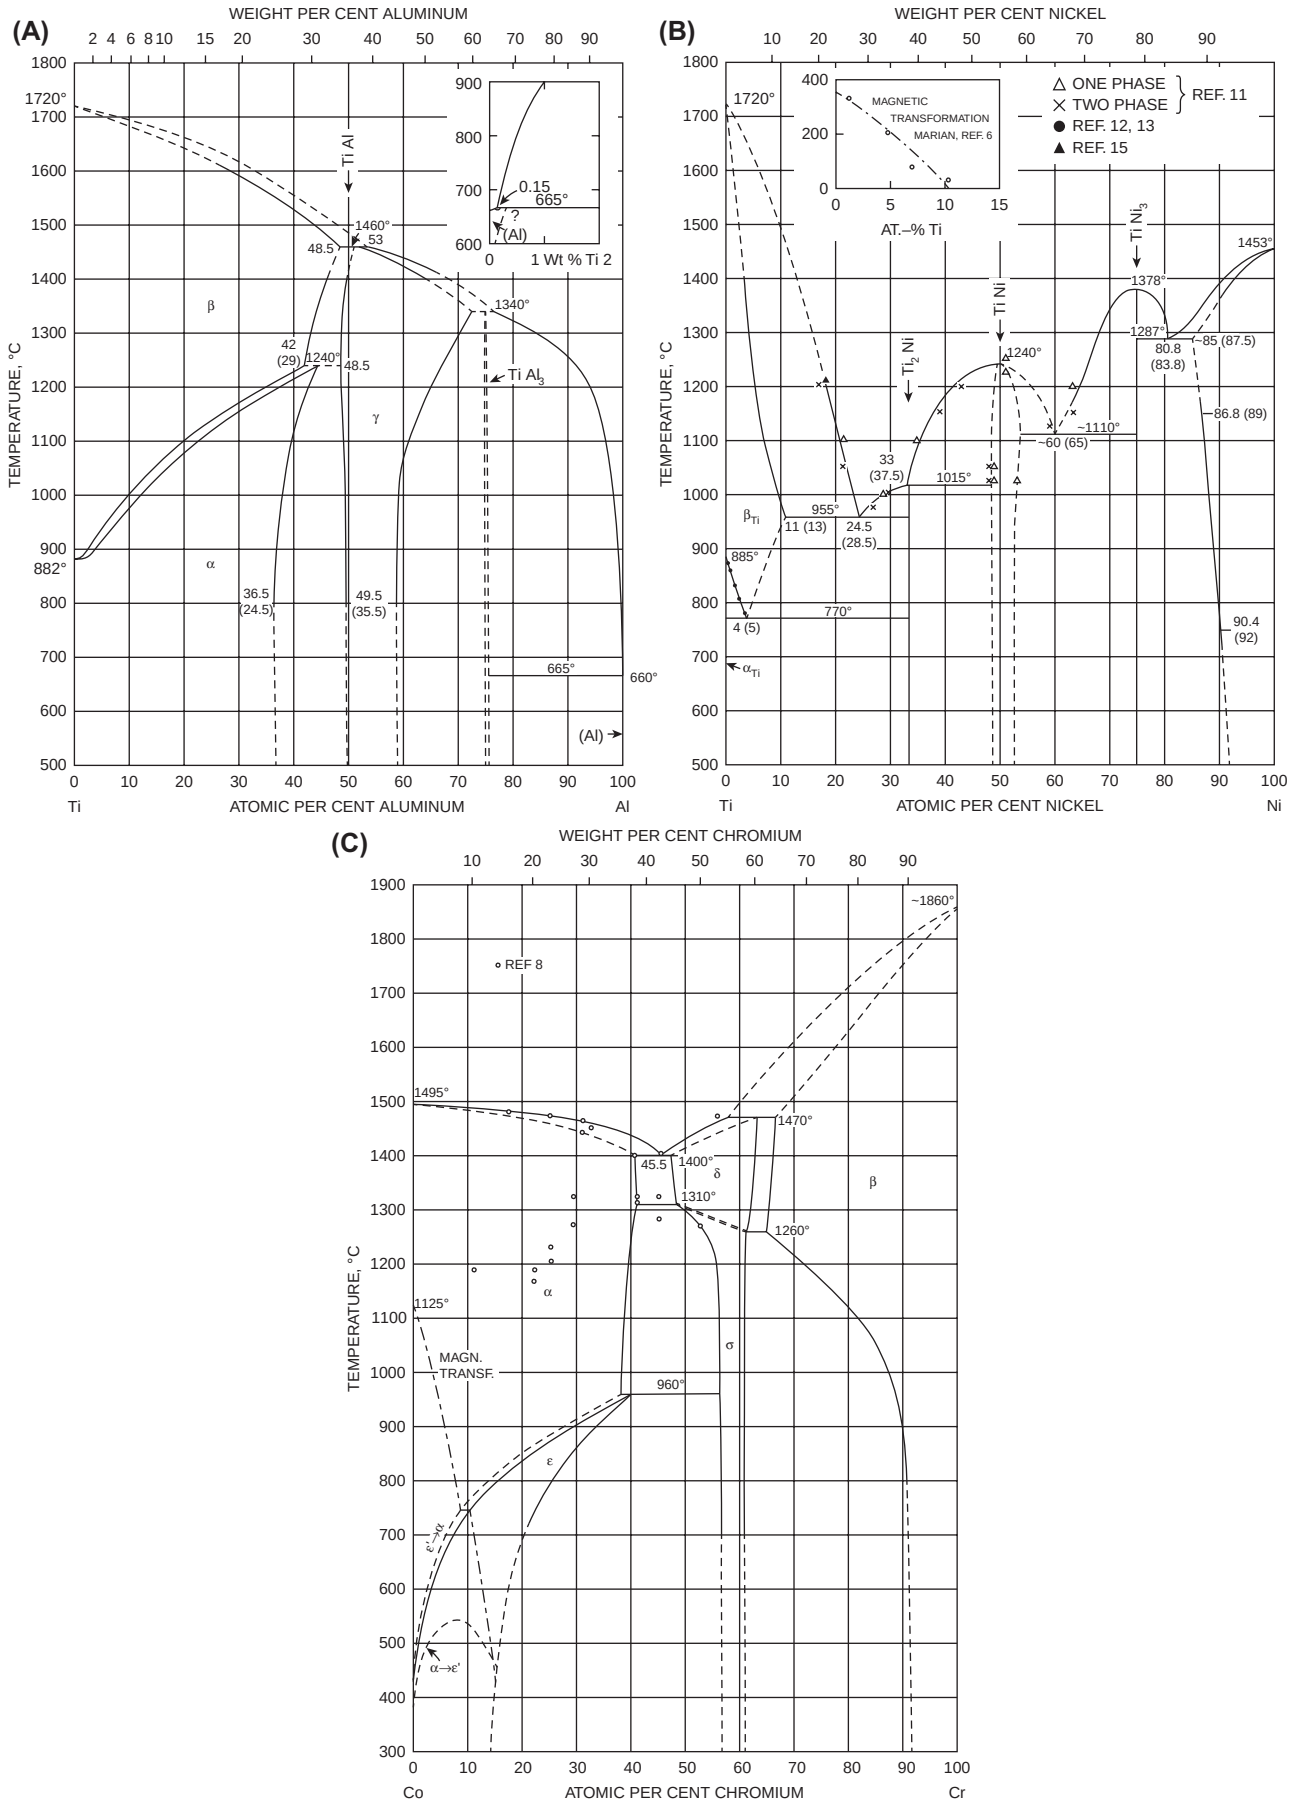
When multiple elements are mixed together, several factors come into play to dictate the types of atomic structures that form. These have to do with the various attractive (or ordering) forces and the disordering forces (entropy) and their relative magnitudes. These combined effects lead to a wide variety of changes in crystal structures, distribution of different solid phases that may arise within an alloy, and the shape, size, and distribution of multiple phases. That is, the microstructure of the alloy can be affected by the processing methods used. For example, Ti-6Al-4V is a two-phase alloy. The alpha phase (HCP) is comprised primarily of titanium and has most of the aluminum in it since Al is a so-called alpha stabilizer (i.e., it stabilizes the HCP crystal structure). The beta phase (BCC) is comprised of Ti and most of the V present. Vanadium is a beta stabilizer and drives the Ti to form the BCC structure instead of the HCP structure. Thus this alloy has two phases due to the Al and V present.

In terms of steel, the Fe atoms form a BCC crystal structure (at room temperature) and the addition of carbon (C) into the Fe crystal (i.e., steel) results in an interstitial solid solution. If enough carbon is present and it is possible that second-phase metal carbides can form within the alloy, to minimize carbide formation, low levels of carbon are typically present in steels used in biomaterials. If Ni is added to Fe, the Ni atoms will begin to replace the Fe atoms on the BCC Fe lattice. However, because Ni is naturally an FCC structure, as more is added to the Fe, the BCC structure becomes less stable as Ni drives the crystal structure to want to transform into the FCC structure (i.e., Ni is an FCC stabilizer or austenitic stabilizer). With sufficient Ni, the Fe crystal structure will become an FCC structure, which is what occurs with austenitic stainless steel (where about 8% Ni is added to stabilize the FCC structure). Thus the alloy 316L stainless steel is an austenitic stainless steel with an FCC crystal structure.

Not all elements can mix together in any proportion and there are rules for mixing of elements to get high solubility of one element in a crystal structure of another. These are called the Hume–Rothery rules for substitutional alloying. The rules include the relative size of solute and solvent (within about 15% for full solubility), the native crystal structure for each (it should be the same for full solubility), and the electronegativity of the element (should be close). When these rules are not met, more complex microstructures may arise and even nonequilibrium crystal structures (i.e., those not present in phase diagrams) can arise.

Phase diagrams are a graphical means for showing what equilibrium phases (i.e., crystal structures, liquids, etc.) are present at which temperatures, concentrations of elements, and pressure. They provide insight into the microstructures that may arise with certain specific thermal processes (heating and cooling). They can show, for example, the solubility of one solute metal in another solvent metal, or if two distinct phases can exist in the alloy at the same temperature. Phase diagrams are a representation of the equilibrium conditions associated with specific compositions and do not provide for the formation of metastable or nonequilibrium phases that may arise from nonequilibrium treatment, for example, rapid cooling (quenching) of the alloy. Thus while very useful, phase diagrams are not a complete representation of the possible conditions of the alloy, only that which may form if equilibrium (long times) is achieved.

Examples of two-component phase diagrams for Ti–Al, Ni–Ti and CoCr metallic biomaterials are shown in Fig. 1.3.3.3 (Massalski et al., 1990). The plot of temperature



• **Figure 1.3.3.3** Phase diagrams for: (A) Ti–Al, (B) Ni–Ti, and (C) Co-Cr binary alloys.

versus composition is shown and it is assumed that the pressure is held constant (typically atmospheric). The lines on the diagram represent solubility limits of one metal in another and define the boundaries between different regions of phase stability. On the far left (Fig. 1.3.3.3A), for example, a single solid α phase in the Ti–Al alloy system with limited solubility of the solute (Al) atom is present. At some critical composition, the single solid phase cannot take any more of the solute atoms (i.e., saturation is reached). At this point (temperature and composition), if additional solute atoms are added, they start to make a second phase that is more solute rich and based on the crystal structure of the solute–solvent combination. The topic of phase diagrams and their specific scientific underpinnings are beyond the scope of this chapter and the reader is referred to a basic physical metallurgy text.

The diagrams in Fig. 1.3.3.3 show what phases are stable at specific temperature–composition points on the graph. For example, for the Ti–Al phase diagram (Fig. 1.3.3.3A), the HCP alpha phase is stable at low temperatures up to about 6 wt% Al and the Al increases the temperature where alpha is stable (i.e., where alpha-to-beta transformation may occur). Higher amounts of Al begin to generate Ti_3Al intermetallics. At higher temperatures (above about 880°C), Ti transforms from the alpha (HCP) to the beta (BCC) phase. The NiTi phase diagram (Fig. 1.3.3.3B) shows that the near-50 atomic % NiTi compositions used as metallic biomaterials are single phase. However, this alloy's shape memory and superelastic behavior are highly sensitive to the specific composition and deformation state of the alloy around this 50% compositional range. Nonequilibrium phases (e.g., martensite) may arise and the transition from deformation-induced martensitic to austenitic phases with temperature increases is the major mechanism for the shape memory behavior of this alloy.

For the CoCr phase diagram (Fig. 1.3.3.3C) the alloy is an FCC crystal structure at body temperature, but transforms to HCP at higher temperatures. However, it is possible for both FCC and HCP structures to be present due to more metastable behavior of the alloy and its low stacking fault energy (i.e., the energy associated with the area between partial dislocations). A stacking fault in a metal occurs when the normal plane stacking of the FCC phase is shifted, which results in an HCP stacking sequence. This can arise when dislocations break into two partial dislocations and the region between these two partial dislocations has an HCP stacking fault. When an alloy has a low stacking fault energy, the distance between partials can be large, resulting in a large faulted region. Thus both FCC and HCP structures can arise in heavily deformed CoCr alloys.

Defects in Crystals

Many metal crystals come together to make an alloy (i.e., polycrystalline) and these crystals can be randomly oriented to one another or partially aligned such that the axes of the multiple crystals are close to one another. This is called texture and can arise from deformation processes and affect local mechanical properties of the alloy. The size and shape of the crystals also can be affected by the prior thermomechanical history of the metal and this can affect the properties of the material in significant ways. For example, rolling of plate or sheet alloy can flatten crystals and make them elongated. Such changes can affect the mechanical and other properties of the alloy. To understand the processing–structure–property relationships in metals, one needs to understand the nature of the defects that arise in these polycrystalline materials, and how such defects affect properties.

Briefly, there are point, line, area, and volume defects that can arise in metals. Each has a significant effect on the properties of the metal and affects the metal in different ways. A brief summary of the role of each type of defect on the properties of metals is described next.

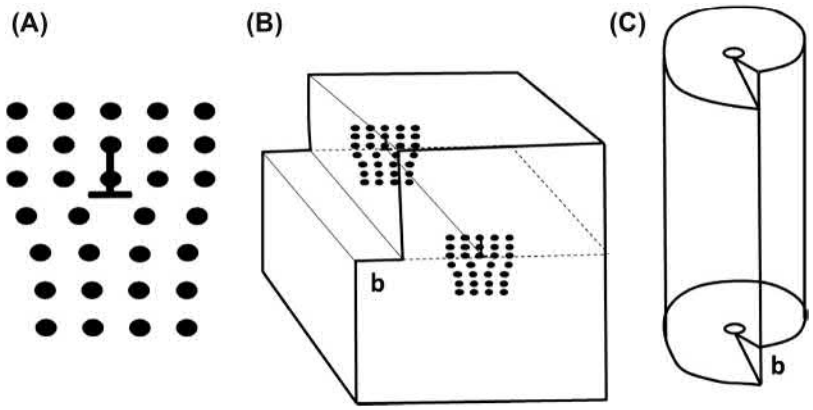
Point Defects

Point defects include vacancies and interstitial atoms. A vacancy is a position within the crystal lattice where an atom should be present but it is missing. An interstitial atom is one of the small atoms that occupies the available interstitial space of the crystal lattice (e.g., O in Ti, C in Fe). Vacancies can have an effect on the diffusion behavior of substitutional atoms in the metal and for most biomaterials applications these have a limited effect on properties. Interstitial atoms, however, can have profound effects on the strength properties of a metal. Whether it is oxygen in titanium alloys or carbon in iron alloys (i.e., steel), these small interstitial atoms increase the yield strength and ultimate strength, and affect the work hardening of metals by creating dislocation atmospheres that can pin dislocations requiring higher stresses to induce plastic deformation (i.e., raising the yield strength). Both substitutional and interstitial atoms affect the mechanical properties of the alloy.

Line Defects

Line defects in crystals include a particular type of defect called a dislocation. These crystal defects are associated with plastic deformation of crystalline materials and are the principal means by which metals deform permanently (i.e., plastically). That is, plastic deformation of metals is associated with the sliding of atom planes over one another and dislocations are a localized elastic distortion of the crystal associated with this plane sliding. There are both edge and screw dislocations that are present, and edge dislocations can be thought of as the distortion around the termination of an extra half-plane of atoms in the crystal lattice (Fig. 1.3.3.4).

Since this distortion is only present at the end of the half-plane, it appears as a line defect. When shear stresses of a sufficient magnitude (critical shear stresses) arise on specific planes (known as slip planes, typically the close-packed planes), in specific directions (slip directions, close-packed directions), dislocations can be generated and moved through the crystal affecting a sliding of the upper plane of atoms relative to the lower plane and inducing plastic



• **Figure 1.3.3.4** Schematic representation of dislocations. (A) Edge dislocation showing the region around the termination of an extra half-plane of atoms in the crystal. (B) Another representation of an edge dislocation where the edge of the crystal is pushed in one plane and the extra half-plane terminates within the crystal at the dislocation line. (C) Representation of a screw dislocation. The variable **b** is known as the Burgers vector. ((A) Olivera, VMCA., et al., 2017. L., & Pérez-Herranz, V., 2009. Pourbaix diagrams for chromium in concentrated aqueous lithium bromide solutions at 25 °C. Corrosion Sci. 51 (4), 807–819.)

deformation. Dislocations are well documented and critical to the understanding of the strength of metals and alloys. Most mechanisms of strengthen of metals rely on affecting and controlling the density (generation and elimination of dislocations) and movement of dislocations. For example, plastic deformation (i.e., cold working) can dramatically increase the density of dislocations in a metal, create entanglements of dislocations (known as dislocation substructure), raise the alloy's strength, and lower its ductility. A heat treatment known as annealing provides thermal energy to allow elimination of dislocations, which then lowers the strength and raises the ductility. Thus annealing treatments are often applied to a metal at the end of processing to reduce the deformation state in the alloy, lowering the yield strength and increasing the ductility.

Area Defects

Area defects can be thought of as grain boundaries (boundaries between adjacent grains or crystals of metal) or free surfaces. Both are locations of higher disorder (randomness or entropy) and both have interfacial energies associated with them that affect the behavior of the crystals. For example, dislocations cannot easily pass highly disordered grain boundaries, and therefore they are piled up at the grain boundary. Thus, increasing the grain boundary area present in a volume of metal (by making smaller grains) creates more barriers to dislocation motion and thereby raises the strength of the alloy.

Free surfaces are another place where defects are present. In the case of most metallic biomaterials, the surfaces of the alloy are covered with a chemically reacted layer of metal oxide, where oxygen from air or water reacts with the metal to form an oxide film on the surface. These are known as passive oxide films in many cases and are critically important for the corrosion resistance and biological interaction of the metal with the body. In other alloys (e.g., Mg alloys) oxides form, but they are not passive and do not substantially slow corrosion at the surface. Thus Mg alloys corrode rapidly and are known as biocorrodible or biodegradable alloys.

Volume Defects

Finally, volume defects can be present as well. These are typically voids (from, say, casting) or cracks, both of which can significantly reduce the fracture toughness or fatigue resistance of the alloy.

Each of these forms of defects are important for the properties of alloys and ultimately their performance as a biomaterial. Of course, metallic biomaterials go to make medical devices and it is the combination of the mechanical properties of these alloys and their corrosion resistance that are critical for success.

Bulk Mechanical Properties of Metallic Biomaterials

As discussed earlier, metals are required for a wide range of medical devices because, simply, they have the strength and fatigue resistance to survive in the hostile mechanical environment of the body.

The mechanical properties of metals are highly dependent on the structure (atomic, crystalline, defect) of the alloys. The following is a short description of the basic strengthening mechanisms in metals and the structural elements that give rise to these properties. The properties of interest include: modulus, strength (yield strength and ultimate strength), fracture toughness, and fatigue resistance, among others. Of these, modulus and fatigue resistance play important roles in medical device design, where the modulus is linked to effects like stress shielding bone resorption, and fatigue strength dictates the ability of the metal to withstand cyclic stresses.

To understand mechanical properties of metallic biomaterials, a tensile test of the material is often performed. These tests provide a significant amount of insight into the mechanical properties of the alloy.

Elastic and Plastic Deformation of Metals

When subjected to tensile or compressive loading, metals will engage, first, in elastic deformation if the stresses are below the proportional limit, and then plastic deformation if the stress reaches a critical level. The yield stress of metals is defined as the engineering stress required to induce 0.2% of plastic strain in the metal and is a common term used to describe the strength of the alloy. Very different processes occur in elastic and plastic deformation. During elastic deformation, atoms of the metal remain fixed within their lattices, but they become stretched (or compressed) from their equilibrium position. In plastic deformation, the deformation results in the permanent movement of atoms within the crystal. These movements occur mostly by dislocation motion, resulting in the sliding of specific planes of atoms over one another, or twinning (a deformation mechanism that kinks the crystal lattice). The sliding of planes of atoms is caused by the creation and movement of dislocations. Interestingly, elastic deformation is not a constant volume process, but plastic deformation is a constant volume process. That is, dislocation movement slides atoms around changing the shape, but does not increase or decrease the volume of metal present. In addition, the modulus of the alloy (i.e., the slope of the elastic portion of the stress–strain curve) reflects pulling atoms slightly away from their equilibrium positions, and not other processes. Thus the modulus of alloys is dependent on the chemistry of the alloy, but not other factors like cold-worked state.

One important point about the modulus of alloys is that they can range from a low of about 50 GPa (some Mg alloys) to as high as 400 GPa (molybdenum alloys) or more depending on the alloy. The workhorse alloys (Ti, CoCr, 316L SS) have moduli of 110, 230, and 210 GPa, respectively.

Strength of Metals and Strengthening Mechanisms

The strength of metals is determined from a number of different tests that basically assess the stresses required to induce some amount of permanent (or plastic) deformation in the metal. There are a variety of strengths that can be reported for metals that include: tensile yield strength (σ_{ys}), flexural strength, compressive strength, ultimate strength, etc. Hardness is another description of the yield strength of an alloy that relates to the stress applied to a surface to induce permanent deformation of the surface. There are a number of different hardness tests that range from Rockwell hardness measurements (more macroscopic indentation tests), to microhardness tests (Brinell and Vickers hardness). Hardness values are meant to describe the stress required to induce plastic surface deformation and are an easy way to assess the strength of an alloy.

In addition to strength, the ductility of metals, defined in terms of the percent elongation, plays an important role in performance as well where higher ductility alloys tend to have high fracture toughness. Ductility measures the amount of plastic deformation a metal can undertake prior to failure and is an important property that allows for the potential of some amount of yielding without fracture.

The strength and ductility of metals can be affected by processing methods that change the structure. Typically, those processes that result in structural changes that increase strength tend also to decrease ductility, and vice versa, for an alloy of a fixed composition. In addition, the fracture toughness (the ability to resist the propagation of a crack in the material) is also a property that combines both strength and ductility.

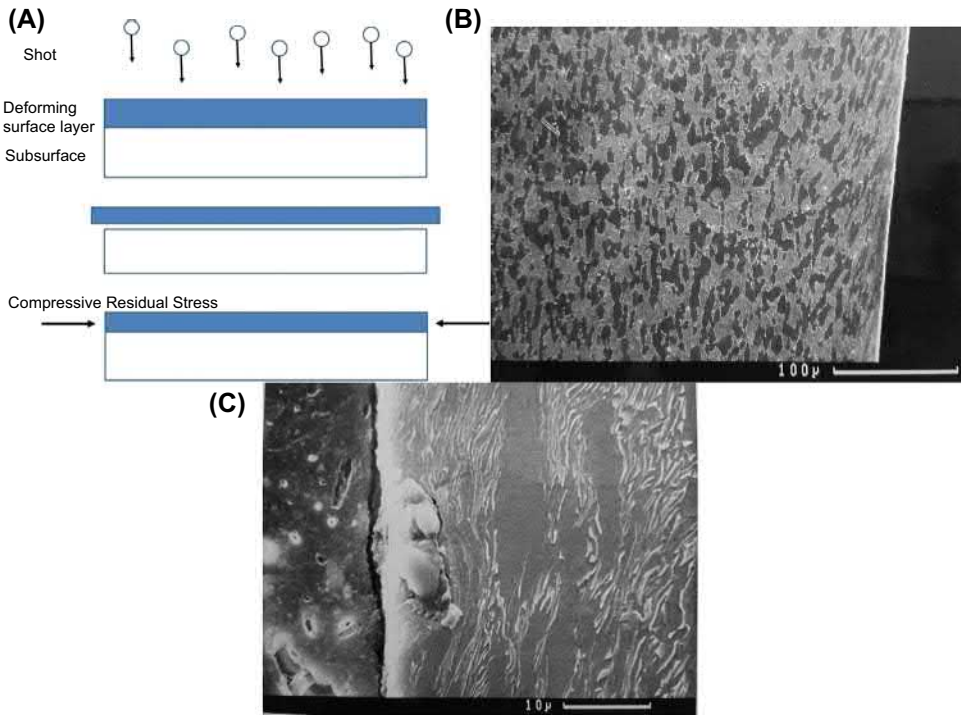
Strengthening Mechanisms: Alloying

Alloying to increase strength has already been described and relates to the increase in yield and ultimate strength that results from the addition of alloying elements to a metal. Pure, single element metals (e.g., iron) have very low strength. That is, their resistance to plastic deformation (i.e., dislocation generation and motion) is low. Such pure metals like iron in an annealed condition (i.e., with low amounts of cold working) can have yield stresses as low as 50 MPa, typical of some plastics. However, with small additions of carbon (e.g., 0.03%), the strength of iron–carbon alloys (steel) rises rapidly to 250–690 MPa depending on other factors. Thus small additions of alloying elements, particularly the interstitial atoms, can have a large effect on the strength of the metal. Carbon additions to iron to make steel is just one example of such interstitial solid solution strengthening. These small interstitial atoms are mobile and tend to accumulate around dislocations, creating dislocation atmospheres (or Cottrell atmospheres) and act to pin them in place requiring higher applied stresses to move such pinned dislocations. These dislocation atmospheres have a pronounced effect on the yield strength of the alloy.

Substitutional elements can also increase the yield strength. These do so by creating elastic strain distortions in the crystal lattice that make movement of dislocations more difficult. In addition, the local modulus is altered by the presence of the substitutional element and this too affects the local strain energy impeding dislocation motion.

Strengthening Mechanisms: Cold Working

A second factor that impacts the strength of alloys is the extent of plastic deformation that is imparted to the alloy during processing. This is called cold working or work hardening. Plastic deformation induces dislocation generation, movement, and entanglement. These changes make it more difficult to induce additional dislocation generation and motion and therefore higher amounts of applied stress are needed to generate additional plastic deformation. Alloys can be purposefully deformed during rolling, forging, extrusion, or other processes to induce high



• **Figure 1.3.3.5** (A) Schematic of shot peening and the development of surface compressive residual stresses. Shot impacts the surface layer of the metal inducing plastic deformation of the outer region (stretching it). (B and C) Scanning electron microscopy micrographs of a Ti-6Al-4V alloy microstructure after shot-peening processes. The surface layer has a heavily deformed surface region and the subsurface region is not deformed. The subsurface constrains the surface layer from stretching, thus creating compressive surface residual stresses. The substrate layer will develop tensile residual stresses to balance the compression of the surface.

amounts of dislocation density and entanglement, which will raise the yield and ultimate strength of the alloy. For example, ASTM F138 describes annealed (undeformed) and cold-worked ultimate strengths for 316L stainless steel. Minimum annealed yield strength is 200 MPa, while the minimum cold-worked yield strength is upward of 690 MPa. One effect of cold working is that the residual ductility of the alloy decreases with increasing cold working. This will make the alloy more brittle and more susceptible to fracture.

One form of cold working used to increase the strength of a surface is **shot peening**. This is a deformation process where high-velocity particles (alumina, glass beads, steel shot) are impacted onto the surface of a metal inducing plastic deformation of the outer layer of the alloy (Fig. 1.3.3.5). This deformation cold works the surface and imparts compressive residual stresses into the metal. Such residual stresses have important technological effects on the alloy's surface strength and can significantly increase the fatigue strength of the alloy.

In this case (Fig. 1.3.3.5) Ti-6Al-4V has been shot peened, sectioned to reveal the microstructure, and imaged in scanning electron microscopy to show the surface deformation that can occur during shot peening. Note the heavily deformed surface layer with the grains flattened and distorted compared to the internal microstructure.

Strengthening Mechanisms: Grain Size

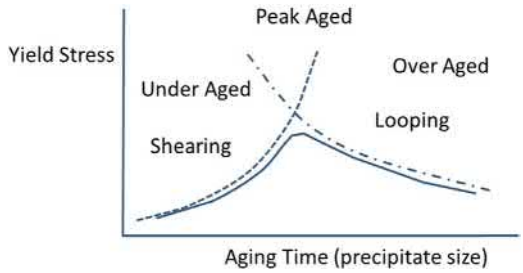
As already described, the size of crystals in a polycrystalline alloy affects the yield strength. In fact, this relationship is known as the **Hall–Petch relationship** where the yield strength increases with decreasing gain diameter to the ½ power:

$$\sigma = \sigma_0 + kd^{-1/2}$$

where s_0 is the stress that causes yielding in large grain alloy and k is a material-dependent factor. Thus smaller grain sizes for a particular alloy will raise the strength of the alloy. This is one reason why titanium alloys and CoCrMo alloys are currently being fabricated with grains in the 5 μm range. Thus fine-grained alloys will have significantly higher yield and ultimate strengths compared to higher grain size equivalent alloys.

Strengthening Mechanisms: Precipitation Strengthening

A final strengthening mechanism is the generation of multiple phases in a single alloy. These second-phase particles may be intermetallics, carbides, oxides, or other crystal structures (phases) and are sometimes referred to as precipitates. Such second-phase precipitates embedded within the primary alloy matrix act to limit dislocation motion in the parent matrix. Two basic mechanisms can be present



• **Figure 1.3.3.6** Effect of particle size (aging time) on the yield strength of precipitation-strengthened alloys.

depending on the size and density of the second-phase precipitates: (1) particle shearing (at small particle sizes) and (2) dislocation looping (Orowan looping, at larger particle sizes). Depending on the particle size, the way in which dislocations interact with the particles changes from shearing of the particle at small particle sizes to generating dislocation loops around particles at larger sizes. It turns out that the stress to shear small particles increases with particle size and the stress to drive dislocations to loop around particles decreases with particle size. Fig. 1.3.3.6 schematically shows the effect of particle size on the yield strength of a precipitation-strengthened alloy. This figure shows that there is an optimal particle size to achieve the highest yield stress.

The particle size of precipitates can be manipulated by a heat treatment process known as aging. As the precipitation-strengthened alloy is heated (or subjected to an aging process) the particles will grow in size and decrease in density (a process known as coarsening). Thus aging first increases the strength, up to the optimal precipitate size, and then decreases with continued aging. Precipitation-strengthened alloys can be under-aged (many small precipitates where shearing occurs), optimally (or peak) aged (where the precipitates are at the ideal size), or overaged (where the precipitates become large and dislocation looping occurs).

Fracture of Metals

The process of fracture has many distinctly different elements compared to the processes of yielding. In the case of fracture, a crack must be initiated and once this geometry is present, the tip of the crack serves as a high-stress concentrator that focuses deformation to the crack tip and once the local plasticity of the alloy is exhausted at the crack tip, propagation of the crack occurs. The concepts of stress concentrations are critically important in understanding crack propagation. The geometry of a surface, for example, can induce local increases of the applied stress. A circular hole in a plate that is subjected to a uniaxial tensile stress, for example, will induce a stress concentration of about 3× immediately adjacent to the hole in the tensile direction. If such a geometry is converted into an ellipse (a = major axis, b = minor axis), then the stress concentration factor becomes

$$\sigma = \sigma_{far}\left(1+2\frac{a}{b}\right) = \sigma_{far}\left(1+2\frac{\sqrt{a}}{\sqrt{\rho}}\right)$$

where $\rho = b^2/a$ is the radius of curvature for the ellipse and σ_{far} is the far-field applied stress.

This shows that the stress at the tip of the crack is increased due to the sharpness of the crack, ρ, and the length of the crack, a. In addition, fracture propagation depends on the energy associated with growth of the crack, the so-called strain energy release rate, and the energy required to grow a crack of some length. When the strain energy released per crack length is larger than the energy needed to grow the crack, catastrophic crack propagation results.

This, basically, is how fracture occurs. However, these analyses presume the existence of a crack of some length being already present in the material. In most cases such cracks would need to develop or initiate and in medical devices, most applications involve cyclic loading and hence fatigue crack initiation behavior becomes important.

The fracture toughness (or mode I critical stress intensity factor, K_{Ic}) of a material is found by loading a precracked test geometry (compact tension sample or three- or four-point bending sample) and measuring the load needed to advance the crack. From this, one can calculate the stress intensity factor needed to fracture. There are ASTM standards for testing the fracture toughness of metal samples (ASTM E-399) where the sample geometry, testing methods, and analysis are described. Such tests provide a measure of a metal's ability to resist fracture once a crack is already present.

The typical fracture toughness analysis is that for mode I opening (where the two fracture surfaces are pulled perpendicularly to the fracture surface), and the fracture toughness is given by the general formula

$$K_{Ic} = \sigma\sqrt{a}Y\left(\frac{a}{w}\right)$$

where a is the crack length, w is the width, $Y(a/w)$ is a geometric factor to account for the sample shape, and σ is the far-field stress applied to the sample. Typical sample geometries include the compact tension sample and the three-point bend sample. In these tests, the crack length should be within the $0.45–0.55w$ range (ASTM E-399).

Fatigue of Metals

When metals are subjected to cyclic stresses, for example, due to walking, a beating heart, chewing, etc., there is a process of fracture that may result from the initiation and propagation of a crack in a subcritical fashion. This process of initiation and propagation to fracture of a crack in response to cyclic applied stresses is called fatigue. The stresses needed to induce a failure by fatigue are typically well below the yield stress or ultimate stress of the material and ultimate fracture of the alloy may require millions of cycles of loading before complete failure occurs. During these cyclic stresses the alloy is being subjected to small-scale, localized damage accumulation processes where local plastic deformation

in some grains, typically at or near the surface, takes place. This damage accumulation ultimately leads to the initiation of a small crack at the surface. Once this fatigue crack is initiated, the sharpness of the crack localizes additional plastic deformation to the crack tip and the crack begins to propagate cyclically. That is, the crack grows intermittently with cyclic loading, advancing little by little. This fatigue crack propagation will ultimately grow the crack to a critical size where the next single cycle of loading will result in catastrophic fracture of the metal.

Fatigue strength is assessed by subjecting a part or sample to a cyclic stress, counting the number of cycles applied until failure, and plotting the stress versus the log of the number of cycles to failure (N_f). These *S–N* curves (or Wohler diagrams, Fig. 1.3.3.7) then demonstrate the fatigue strength of the material by finding the cyclic stress required to induce fracture in some preset number of cycles (e.g., 10^6 or 10^7 cycles) (Fig. 1.3.3.7). An alternative description is the fatigue life, which represents the number of cycles to failure at some preset applied cyclic stress.

An alternative method to assess fatigue crack propagation behavior is to start with a precracked sample of some known geometry, for example, a compact tension sample (see schematic in Fig. 1.3.3.8). Then, the crack length, *a*, is measured as a function of the number of cycles applied. From these plots, the crack growth rate, *da*/*dN*, is determined over a range of crack lengths. The applied cyclic stress intensity factor, ΔK, can be determined from the instantaneous crack length and the applied cyclic stress:

$$\Delta K = \Delta \sigma \sqrt{a} Y \left(\frac{a}{w} \right)$$

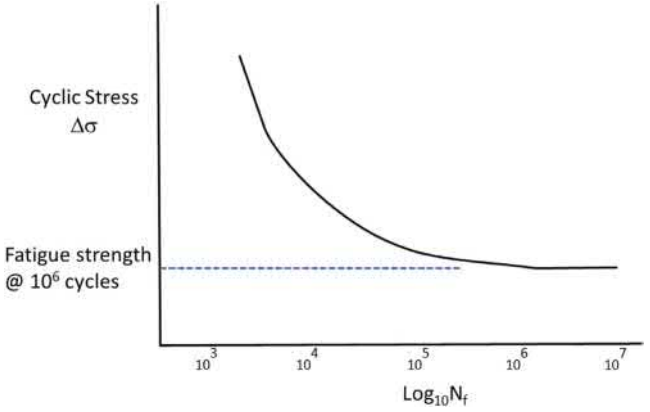
The Paris law crack growth behavior can be determined from

$$\frac{da}{dN} = C \Delta K^m$$

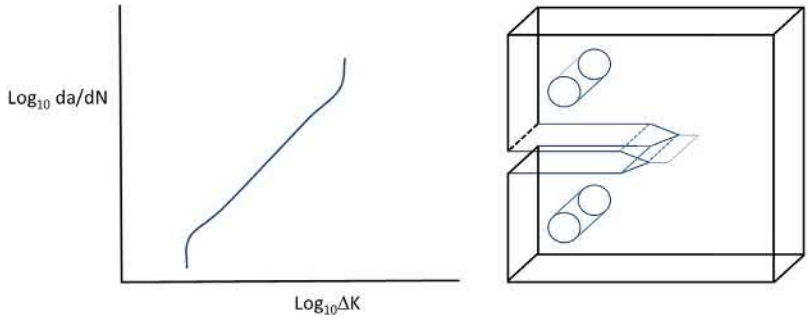
where *m* is the exponent (typically in the range of 4 for metals) and *C* is a material-dependent constant (i.e., the crack growth rate when the cyclic stress intensity factor is equal to 1).

Fatigue of metals is often delineated by high-cycle and low-cycle fatigue behavior. In biomaterials, since the intent is for medical devices subjected to cyclic loading to last for the life of the patient (or at least several years), these metals are subjected to the high-cycle fatigue regime. This distinction is important to understand in that the structures and properties that govern high-cycle fatigue response are different to those of low-cycle fatigue. High-cycle fatigue occurs when the cyclic stresses are smaller and fatigue failure occurs generally at 10^5 cycles or higher, while low-cycle fatigue is typically thought of when the cyclic stresses are larger (closer to the yield stress) and require 10^4 or lower cycles to induce failure.

In most high-cycle fatigue cases the overwhelming preponderance of cycles is spent in accumulating damage within the surface or near the surface of the material up to the point that a crack is initiated. This can require 95%–98% of the total number of cycles applied in a high-cycle fatigue test. The remaining few percent of cycles of load result in the propagation of the initiated crack to failure. Thus structural factors that impede nucleation of a crack are most important. For metals, the initiation process is directly linked to the yield and ultimate strength of the alloy at or near the surface. The higher the yield stress (or hardness) of the material, the better it can resist initiation of the fatigue crack. In addition, factors like surface topography, surface residual stresses (e.g., from shot peening), etc. can raise the fatigue crack initiation resistance of the alloy. Since almost all fatigue cracks initiate at or near the free



• **Figure 1.3.3.7** Wohler diagram (cyclic stress vs. log of number of cycles to failure) plots obtained from fatigue experiments.



• **Figure 1.3.3.8** Fatigue crack propagation test schematic. Crack growth rate versus log of the cyclic stress intensity.

surface, control of the surface topography and residual stress can be an effective method to enhance the fatigue strength of the alloy. In addition, microstructures that are designed to raise the yield strength (e.g., grain size reduction) will also increase the fatigue strength. For example, Ti-6Al-4V alloys are expected to have small (3–5 μm) grains that are equiaxed with blocky beta phases. The alloy cannot have a transformed beta (acicular alpha-beta) structure, which may arise from heating to above the alpha-beta transformation temperature (about 880°C). This is primarily to assure that the highest fatigue strength possible for this alloy is obtained by the proper control of its microstructure.

Fatigue initiation processes typically occur at or near free surfaces (as mentioned) and can sometimes be the result of metallurgical flaws in the device. As an example, Fig. 1.3.3.9 shows scanning electron micrographs of an example of a cast CoCrMo alloy femoral component that failed by fatigue. The fatigue crack initiation site (Fig. 1.3.3.9A, white circle) is very close to the lateral side of the femoral stem component where the tensile stresses are highest. The arrow in Fig. 1.3.3.9A identifies a region where the characteristic fatigue "clam shell markings" are present. These markings are a direct result of the cyclic propagation of the fatigue crack and point back to the site of initiation. At higher magnifications there are features called "fatigue striations" that are characteristic of this fracture process. This failure, however, was contributed to by the presence of significant casting porosity found within the stem as can be seen in Fig. 1.3.3.9B–D. Casting porosity may arise when solidification of the metal alloy, which is accompanied by a contraction in volume from liquid to solid, leaves behind regions of the alloy that have voids present. Such casting voids can act as stress concentration sites and will locally raise the stresses leading to fatigue failure. Fig. 1.3.3.9B–D are increasing magnification images of the initiation region showing the casting porosity structure and the fracture surface emanating from the casting voids. Fig. 1.3.3.9D shows the characteristic fatigue striations seen in CoCrMo alloy fatigue failures. These exhibit the cyclic planar crack propagation and deformation processes leading to fatigue fracture in the alloy.

Ti-6Al-4V fatigue fracture processes generate characteristic features of failure as well (Fig. 1.3.3.10). These data came from a corrosion fatigue test set up for hip stems (Gilbert, 1987; ASTM F1612). The fatigue fracture initiation, propagation, and fast fracture regions typical for such failures can be seen. Fatigue striations, characteristic of fatigue fractures, are also shown for this alloy.

Surfaces of Metals: Oxide Films and Passivity

The three major alloys used in biomaterials (Ti, CoCr, and stainless steel) each owe their corrosion resistance to the presence of a thin (nanometer scale) metal oxide film that forms by the reaction of the surface metal atoms with the surrounding oxygen in contact with the surface. For titanium, the oxide that forms is typically TiO_2, while for CoCrMo and stainless steel, the oxide's principal chemical form is Cr_2O_3 but other oxide-forming reactions can also be present (e.g., NiO, Fe_2O_3, CoO, MoO_3, etc.). When in air, the oxygen to make the oxide can come from molecular oxygen and from water vapor present, while in aqueous solution, oxygen comes from water molecules or dissolved molecular oxygen. These oxide thin film surfaces, known as passive oxide films, are the ultimate smart, self-healing nanobiomaterials. That is, passive oxide films can be manipulated electrochemically (smart), they spontaneously form and reform if any oxygen is present (self-healing), and they are only a few nanometers thick (nanomaterial).

To be a passive film, the oxide that forms on these alloy surfaces must be fully covering, compact, and highly resistive to both electronic and ionic transport of charge across the interface. That is, passive films act as kinetic barriers to the transport and reaction associated with corrosion processes and the films dramatically slow the rate of corrosion that occurs. The alloys with passive films typically have high thermodynamic driving forces (free energy of oxidation) for corrosion, but these passive films limit the rate of transport and reaction by orders of magnitude. Passive films impart compressive residual stresses to the oxide since the volume per cation of oxide is typically larger (1.5–2.0 times) than the volume of the metal atom from which it came. This is known as the Pilling–Bedworth ratio and it is given by

$$PBR = \frac{V_{oxide}}{V_{metal}} = \frac{M_{oxide}\rho_{metal}}{n\rho_{oxide}M_{metal}}$$

where n is the number of metal cations per oxide molecule, the M's are the molecular or atomic mass of oxide or metal, respectively, and the ρ's are the densities of metal and oxide. The Pilling–Bedworth ratio for TiO_2 is 1.7, for Cr_2O_3 it is 2.0, and for Mg it is 0.8. As can be seen by these values, Pilling–Bedworth ratios outside of the 1.5–2 range typically do not result in good passive films (e.g., Mg is not a passive alloy).

Passive oxide films also have a nanostructure that can be affected by processing, immersion in solution, and potential (Bearinger et al., 2003; Liu and Gilbert, 2018). An example of the evolution of oxide morphology of TiO_2 on Ti-6Al-4V with immersion in phosphate-buffered saline and application of potential from –1 V to +1 V is shown in Fig. 1.3.3.11.

High-Field, Low-Temperature Oxide Film Growth

The passive film formation process involves a complex set of reactions at the surface where electrons in the metal tunnel out to the near surface region outside of the metal (see the schematic in Fig. 1.3.3.12). Oxygen atoms in this vicinity can trap these electrons and set up a charge separation (with positive ions inside the metal and negative oxygen ions just outside). This results in the development of a very high-strength electric field (voltage/distance, on the order of 10^5 V/cm) across the interface. This field then drives ion transport by electromigration with positive ions driven out of the surface and negative ions driven inward.

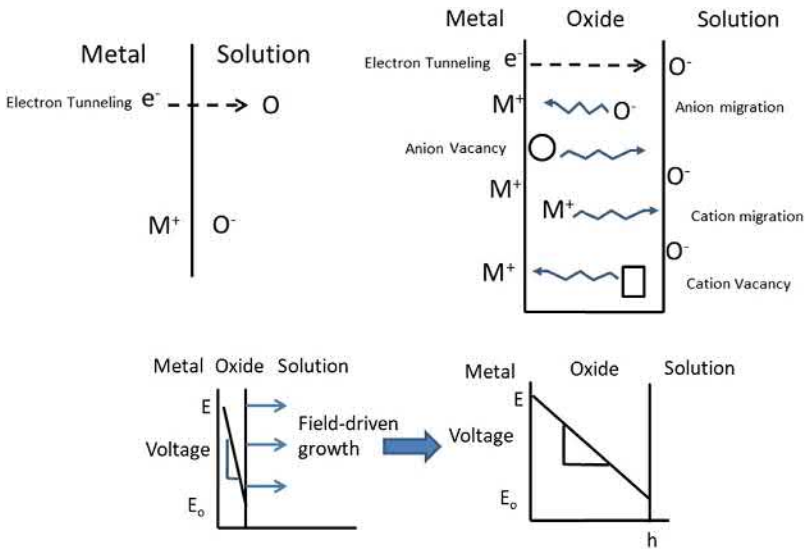
(From Bearinger, J.P., Orme, C.A., Gilbert, J.L., 2003. In-situ imaging and impedance measurements of titanium surfaces using AFM and SPIS. Biomaterials 24 (11), 1837–1852, with permission.)



• **Figure 1.3.3.12** High-field oxide film growth model. Electron tunneling out of the metal is captured by oxygen traps that create high electric fields across the metal oxide–solution interface. These high fields drive cation and anion migration and film growth.

There are corresponding cationic and anionic vacancies also present (i.e., holes in the oxide lattice where cations and anions should be present) that also migrate to enable cations and anions to move in response to the electric field. Reactions between cation and anion form the metal oxide and this process continues to thicken the oxide film, which, in turn, decreases the field strength. Ultimately, the passive film thickness is limited by the decreasing field strength and the oxides cease growing after just a few nanometers. This is known as the high-field, low-temperature film growth law first articulated by Cabrera and Mott (1949), Gunterschultz and Betz (1931).

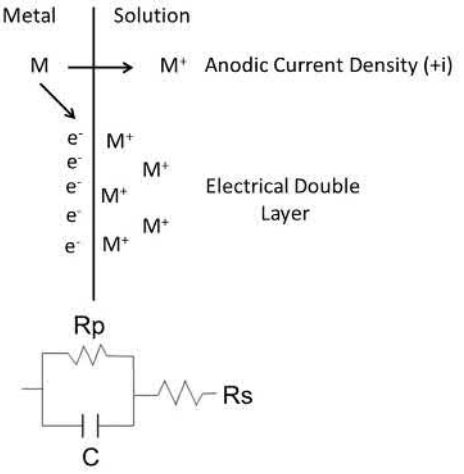
Once the film is established, transport processes through the film are dictated by the field strength and the mobility of charged species through the film. The mobility is linked to atomistic aspects of the film that include the presence of anionic and cationic vacancies, and the semiconducting nature of the film (for electron and hole transport processes). The so-called point-defect model of oxide films has been generally accepted as the atomistic description of how passive films behave (Chao et al., 1981).

Electrically, passive oxides behave like semiconductors with both capacitive and resistive character where charge transport across the film has a resistive character and charge accumulation across in the film leads to capacitive charging effects. These electronic, semiconducting characteristics of passive oxide films can be measured using electrochemical impedance spectroscopy (EIS) methods and other electrochemical techniques.

Passive films are affected by applied voltages across the metal film–solution interface. For example, with titanium, application of high positive potentials across the interface will induce growth of the oxide films by a process known as anodization. It is generally known that titanium oxide films grow about 2 nm/V with application of an external potential. This technique is used in medical devices, particularly spinal and fracture fixation devices, to create surfaces that have different films that result in different colors. That is, when anodized, titanium takes on a range of colors that are affected by the film thickness and the presence of specific anions. Titanium surfaces can become blue, green, purple, or gold, depending on the anodization thickness obtained. Implants are often color coded to assure the proper screw is used with the proper rod, for example.

Introduction to Metallic Corrosion

Corrosion is comprised of a set of electrochemical reactions in which one chemical species oxidizes (i.e., liberates electrons and increases is valence state) and another chemical species reduces (i.e., consumes electrons in the reaction and decreases its valence state). Each of these reactions is called a half-cell reaction in that it is one of the two required reactions needed for corrosion to progress. Reduction–oxidation (redox) reactions are not limited to metallic biomaterials; in fact, there are a wide number of redox reactions that may arise in the body. Often, these are called anabolic (reduction) or catabolic (oxidation) reactions. Cells often require maintenance of redox homeostasis to remain viable and active. Oxidative stress may arise in cells that experience an excess amount of oxidizing species in the biological system. These can include reactive oxygen species, among other chemistries.



• **Figure 1.3.3.13** Schematic representation of the metal oxidation half-cell where metal ions are generated and electrons remain in the surface.

Electrochemical Reactions (Oxidation and Reduction) and the Nernst Equation

All metallic biomaterials are susceptible to corrosion processes in the body (Fig. 1.3.3.13). Metal atoms are present at the surface of the anode and they oxidize by liberating electrons. The electrons remain behind in the surface of the metal (i.e., charge in a conductor moves to its surface), while the metal cations can be released into the adjacent solution (as depicted) or can go to form other compounds, including metal oxides. This process generates a current as the metal ion moves from the electrode to the solution, and there is an inherent resistance to this movement of charge (R_p known as the polarization resistance). In addition, the separation of charge means the electrode surface establishes an electrical double layer with the electrons in the metal and the metal ions in the solution, as if the interface is a charged capacitor (C). In addition, the solution also has an intrinsic resistance to the movement of charged ions (R_s) and the electrical circuit shown is the typical one used to represent an electrode surface. This is known as the Randles circuit and is discussed later.

The oxidation half-cell reaction (Fig. 1.3.3.13) would result in the accumulation of metal ions in solution and electrons accumulated in the metal. This separation of charge results in a capacitive-based electrical energy developing that resists the chemical oxidation free energy (ΔG_{ox}) and the continuation of the half-cell reaction. Ultimately, an equilibrium is reached where the chemical free energy driving oxidation equals the electrical energy resulting from the charge separation inhibiting the reaction. At this

equilibrium condition, there are equal forward and reverse reactions (i.e., metal ions leave the metal and return to the metal in equal rates) and there is an electrode potential established as a result of this process. If the potential is altered, then the reaction will shift to reestablish the equilibrium condition. For example, a more positive potential will increase the amount of metal ion dissolution, raising the concentration in the solution until equilibrium is reestablished.

At equilibrium, the chemical and electrical energies are equal:

$$\Delta G_{ox} = nFE^{eq}$$

where ΔG_{ox} is the chemical free energy driving oxidation, n is the charge per cation, F is Faraday's constant (96,485 coulombs of charge/mole of electrons), and E^{eq} is the electrode potential (i.e., the voltage drops across the metal–electrolyte interface resulting from the accumulation of the charge at the interface).

This equation, known as the Nernst equation, is a measure of the driving force for oxidation and the more negative the potential, the greater is the chemical energy driving the oxidation of the metal (i.e., the more negative is ΔG_{ox}). Some metals have very negative electrode potentials (e.g., Mg, Ti) and are called active, while others have more positive potentials (e.g., Au, Pt) and are called noble. Thus the scale of electrode potential from negative potentials to positive is referred to as the electromotive series, or sometimes the galvanic series depending on the solution in which the electrode is placed.

The Nernst equation can also be related to the chemical activity of species involved in the half-cell reaction. That is, one can relate the free energy of oxidation to the chemical activity (or concentration) of the species involved.

For example, a commonly used electrode in biomedical applications is that of the silver chloride electrode. The half-cell reaction for the Ag/AgCl electrode is

$$Ag + Cl^{-} = AgCl + e^{-}$$

where AgCl is a solid oxidation product of the oxidation of Ag in a chloride-containing solution. The Nernst equation for this reaction, using the chemical potential of species to relate to the free energy of the reaction is

$$E^{eq} = E_0 + \frac{RT}{nF}\ln\left[\frac{[AgCl]}{[Ag]\,[Cl^-]}\right]$$

where E_0 is the electrode potential when all chemical species are at unit activity (i.e., saturated or pure), and is called the standard half-cell potential. Here, the bracketed values are concentrations, or activities, of each chemical species. Since AgCl is a pure substance (activity of 1) and Ag is a pure metal (activity of 1), the equation results in

$$E^{eq} = E_0 - \frac{RT}{F}\ln[Cl^-] = E_0 - \frac{2.303RT}{F}\log_{10}[Cl^-]$$

This equation shows that a chlorided silver wire's electrode potential will depend on the concentration of chloride in the solution. The factor $2.303RT/F$ is known as the thermal potential and has a value of 0.059 V per decade of $[Cl^-]$ concentration (i.e., factor of 10 change in concentration) at room temperature. If the chloride concentration remains below the saturation point (4 M, activity of 1), then for every factor of 10 change in the chloride concentration, the wire electrode potential will change by 59 mV at 300 K (or 61.5 mV at 37°C). This is known as an ion-specific electrode and is a means of determining Cl ion concentrations in solutions. In addition, when the solution is maintained saturated in Cl ions, then the Ag/AgCl electrode is highly stable and fixed in its potential and is often used in corrosion experiments as a reference electrode to fix all potentials relative to a stable fixed value (222 mV vs. the normal hydrogen electrode [NHE]). Another reference electrode often used in biomaterials experiments is the saturated calomel electrode (SCE, Hg/Hg_2Cl_2, 242 mV vs. NHE). In each of these cases the reference voltage is for the case where the solution bathing the electrode is saturated in the ions of the electrode (e.g., 4 M KCl).

In general, the Nernst equation relates to any redox reaction, $r \Leftrightarrow O + ne^-$:

$$E^{eq} = E_0 + \frac{RT}{nF}\ln\left[\frac{[O]}{[r]}\right]$$

where R is the ideal gas constant (8.314 J/mol K) and O is the oxidized form of the half-cell, while r is the reduced form. Thus all electrode half-cell reactions have an associated Nernst equation that describes how the electrode potential is affected by the concentration of the reactants and products of the reaction.

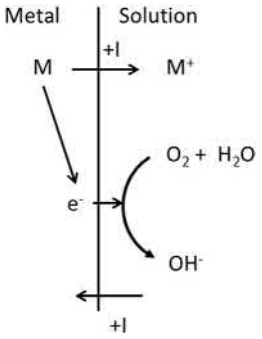
The Principal Reduction Reaction in Biomaterials (Oxygen Reduction)

In most biomaterials applications, it is thought that the primary reduction half-cell reaction is the reduction of oxygen and water according to

$$\frac{1}{2}O_2 + H_2O + 2e^- \rightarrow 2OH^-$$

This reaction, however, is overly simplified and has a number of reactive oxygen intermediates, including hydrogen peroxide and hydroxide radicals, that may arise depending on the potential and solution conditions. It is important to note, however, that there are myriad other chemical species present in the body that are redox active and may participate in reactions related to corrosion.

Together, the oxidation of metal (to form ions or oxides) and the reduction of oxygen combine to form the corrosion reaction (Fig. 1.3.3.14). Importantly, when both reactions are present, electrons do not accumulate at the surface since the reduction reaction consumes them, and there is charge transport (ionic and electronic) across the interface with positive



• **Figure 1.3.3.14** Simplified two half-cell redox reactions to generate corrosion.

current going from the metal to the solution where metal ions are released (i.e., the oxidation reaction), and positive current is returned to the electrode at the site of the reduction reaction. Thus both reactions together complete an electrical circuit and may continue to generate currents at multiple sites on the metal surface as both oxidation and reduction reactions occur. Essentially, the electrical circuit is closed with currents leaving the electrode into the solution at the anode (site of oxidation), while the current returns to the electrode at the cathode (site of reduction). Because the metal electrode is a conductor, these two half-cell reactions may be in close proximity to one another, or they may be spatially separated depending on the conditions, and the local currents associated with these reactions may also be close or separate.

Polarizable and Nonpolarizable Electrodes

Another feature of electrodes used for stimulation or recording of potentials is the concept of polarizability and nonpolarizability. A nonpolarizable electrode is one where even if a current is being passed across the electrode interface, there is little to no change in its electrode potential. A polarizable electrode is one where its electrode potential can be shifted by the injection of charge into the electrode. Ag/AgCl electrodes are excellent reference electrodes because of their nonpolarizability, where even if a small amount of current is passing the interface, the potential of the electrode is not significantly affected. On the other hand, Pt as well as Hg are excellent polarizable electrodes where the potential can reach a wide range simply by injecting charge into the metal. This property results from the high charge transfer resistance (or low exchange current density) typically seen in these metal surfaces. Thus the electrode potential is a measure of the thermodynamics of corrosion reactions. What reactions are possible depends on the reactants present and the electrode potential.

The kinetics of electrode reactions requires additional considerations. As can be seen from the foregoing, the metal oxidation half-cell results in the transport of positive charge across the metal–solution interface. This gives rise to a current that is distributed over the area of the electrode. Current per unit area of the electrode is known as the current density and is in units of amps per cm^2. Thus current density is a direct measure of the rate of an electrode reaction.

Pourbaix Diagrams (Electrode Potentials vs. pH)

Electrode potential is directly linked to the chemical free energy driving the half-cell reaction by the Nernst equation. This relationship can be used to assess when specific electrochemical reactions are thermodynamically favored (i.e., in which direction a half-cell reaction will occur). For example, the metal dissolution half-cell reaction can either be driven toward more dissolution (i.e., oxidation) by increasing the electrode potential (making it more positive) or toward reduction of the metal ions to metal atoms, by applying a potential more negative than the equilibrium potential. The equilibrium potential itself is also dependent on the concentration of the metal ions in the solution.

In many half-cell reactions, the pH of the electrolyte solution is related to the electrode potential because hydrogen ions are involved in the reaction. In these cases it is useful to make plots of the electrode potential versus the pH of the solution. These plots are known as Pourbaix diagrams and they depict the combined conditions of potential and pH where specific products of electrode reactions are thermodynamically stable. For example, when a metal reacts with water to form a metal oxide, the half-cell reaction may appear as

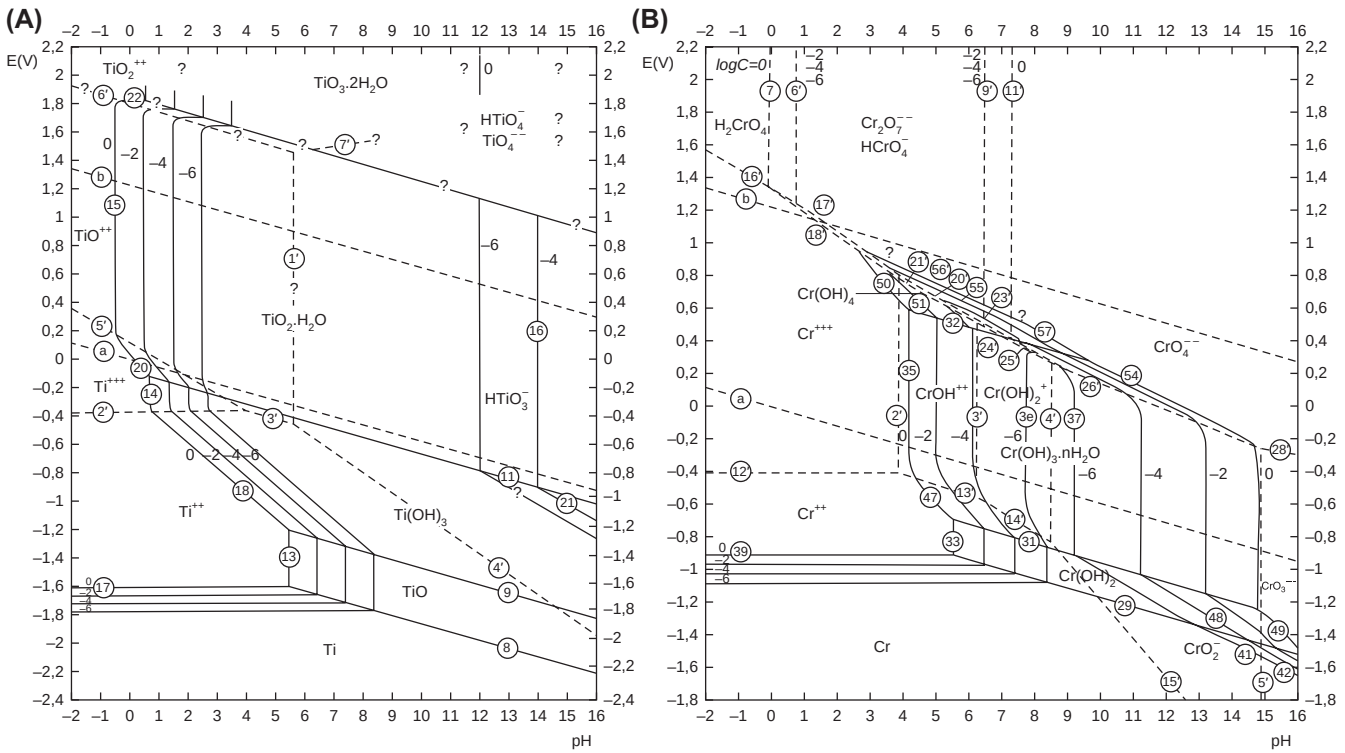
$$mM + nH_2O \rightarrow M_mO_n + 2nH^+ + 2ne^-$$

The Nernst equation depends on the hydrogen ion concentration. Using pH as the measure of hydrogen ion concentration (i.e., $pH = -\log_{10}[H^+]$), the Nernst equation can be written as

$$E^{eq} = E_0 - kpH$$

where $k = 2.303RT/F$. This equation shows that the potential of an electrode in which hydrogen ions participate shifts negatively by about 59 mV (at room temperature) for every unit of pH increase in the solution. An example in which pH plays a role in a half-cell reaction is in the reduction of water $H_2O + e^- \rightarrow 1/2H^+ + OH^-$, which can also be written as $H^+ + e^- \rightarrow 1/2H_2$ (the normal hydrogen electrode reaction). Here, the Nernst equation is $E = E_0 - kpH$ where E_0 is the potential when the electrode is in a solution with a unit activity of H^+ (i.e., pH = 0). In the normal hydrogen electrode (pH = 0, $[H_2] = 1$), $E_0 = 0.0$ and for every pH unit shift from 0, the electrode potential drops 59 mV. At pH 7.4, E for reduction of water is –436 mV versus NHE or –658 mV versus Ag/AgCl. Thus water starts to be reduced at a potential of about –658 mV versus Ag/AgCl at metal electrode surfaces. The water reduction curve is always represented on the Pourbaix diagram as a dashed line with negative slope starting at pH = 0 at 0 V. When the electrode potential sits above this line, then water is thermodynamically stable. When the electrode potential sits below this line, then the thermodynamics of the system drive it to reduce water to hydrogen gas and hydroxide ions.

Pourbaix diagrams were developed (Pourbaix, 1964) to demonstrate the potential and pH where specific chemical species would be thermodynamically stable and where transitions in reactions would occur. These diagrams represent equilibrium conditions and do not



• **Figure 1.3.3.15** Pourbaix diagrams for (A) Ti and (B) Cr in chloride-containing solutions.

speak to the kinetics of any of the reactions. Pourbaix diagrams for Cr and Ti in chloride-containing solutions (Fig. 1.3.3.15) have been determined and are reproduced here. These diagrams show, for example, the potential and pH range where oxides, ions, or metal states of the element are stable.

Electrochemical Currents (Evans Diagrams)

Several factors affect the rate at which corrosion reactions occur. In the case of an active metal undergoing corrosion, where there are no passive films or other limiting structures, the rate of oxidation (i.e., the current density or current per unit area of electrode) is controlled by the chemical reaction rate theory, known as the activated complex theory (Bard and Faulkner, 1980). This theory, under the assumption that there are no other mass transfer limiting processes, results in the Butler–Volmer equation for a single half-cell reaction. This is shown as

$$i = i_0 \left[e^{\frac{\eta}{\beta_a}} - e^{-\frac{\eta}{\beta_c}} \right]$$

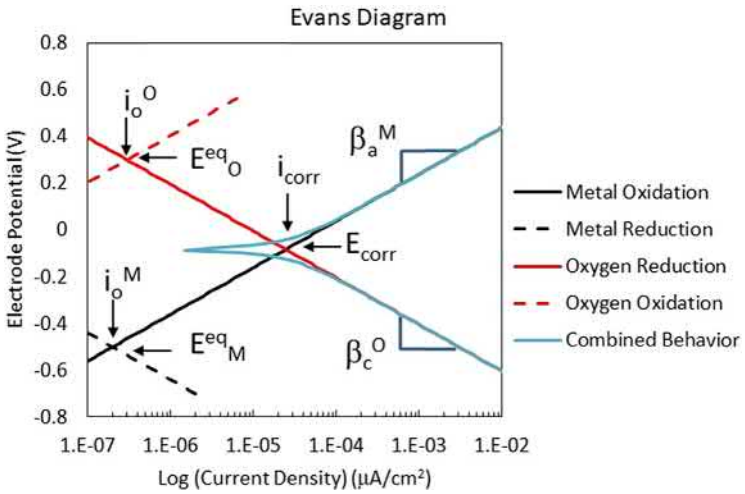
where i_0 is known as the exchange current density (i.e., the current density of the electrode reaction when it is at equilibrium [equal forward and reverse reaction]), β_a and β_c are the anodic and cathodic Tafel slopes, and η is the overpotential (i.e., $\eta = E - E^{eq}$). This equation shows that the current density rises exponentially with potential when the electrode potential is either anodically or cathodically shifted from the equilibrium potential. The Tafel slopes for active electrode reactions governed by reaction rate kinetics are typically given approximately by $2.303RT/0.5F$, which is roughly a 120 mV/decade change in current density. That is, the currents change by a factor of 10 with every 120 mV away from the equilibrium potential for the half-cell reaction.

Importantly, the Butler–Volmer equation is limited to those electrodes where so-called activation-limited reactions dominate. This is not the case typically when passive oxide films are present and thus the Butler–Volmer equation and analyses based on it are not accurate when dealing with passivating electrodes.

Each half-cell reaction has a Butler–Volmer equation and when oxidation from one reaction interacts with the reduction of another reaction, then two Butler–Volmer equations can be combined.

This equation, which is based on the fact that there is an activation energy barrier to electrode reactions that can be modified by the application of an electrical potential across the interface, results in an exponential dependence of the current density on the application of a potential away from the equilibrium (Nernst) potential of the electrode.

Graphical representations of the Butler–Volmer equation are often very useful in understanding electrode reactions when multiple half-cells are present and help to explain how an electrode's current varies with variation in applied potential. Such plots are known as Evans diagrams, which plot the electrode potential versus the $\log_{10}$ of the absolute value of the current density (Fig. 1.3.3.16). The experiments performed to obtain the next response are called potentiodynamic polarization plots. Shown in Fig. 1.3.3.16 are two half-cell reactions, one for metal oxidation and the other for

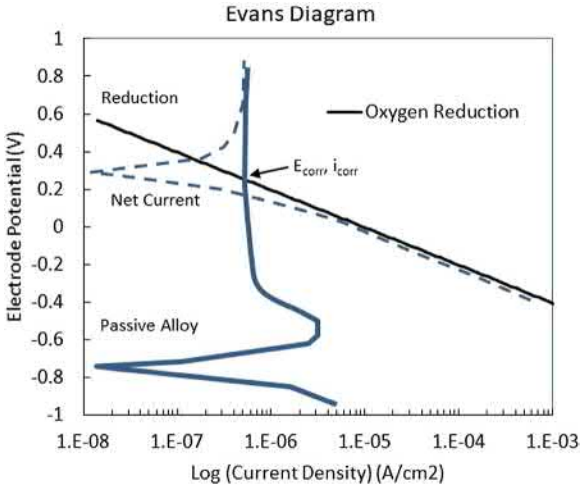


• **Figure 1.3.3.16** Evans diagram (polarization plots—*E* vs. log *i*).

oxygen reduction. Each has its own equilibrium (Nernst) potential and exchange current density (identified in Fig. 1.3.3.16). For the combined reactions (Fig. 1.3.3.13), because the metal equilibrium potential is more negative (active) than the oxygen reduction potential, the metal will be driven to corrode and the oxygen will be reduced. The rate of increase in the redox reactions is given by the slope of these lines, which are the Tafel slopes in the Butler–Volmer equation for each half-cell. During corrosion processes, the sum of the oxidation currents must equal the sum of all reduction reactions on average over time when there is no external source or sink of electrons. This is known as the mixed potential theory (Jones, 1996) of electrode processes. The point on the Evans diagram where the oxidation currents equal the reduction currents (or current densities in this case, assuming the same electrode area) is given by E_{corr} and i_{corr}. The total current density (i.e., the difference between the anodic and cathodic current densities [*blue line*—combined behavior]) can be measured with polarization tests and the total external current versus potential will be measured. Note, polarization tests do not identify the underlying equilibrium potentials or exchange current densities for the individual half-cell reactions, but rather capture the combined behavior of the two electrode processes.

The Evans diagram helps to elucidate the interplay between half-cell reactions to predict corrosion potentials, corrosion currents in the role of different oxidizing species, and the effects of galvanic interactions. However, there are some limitations to the ability of Evans diagrams since they derive from the analysis of activation-limited electrode reactions and are not predictive of passive alloy behavior. Changes in E_{corr} and i_{corr} are easily explained based on shifts either of equilibrium potentials (up or down) or exchange current densities (left or right) and help to visualize the overall electrode behavior with such changes.

Evans diagrams become more complicated (and less well described mathematically) when passivating alloys are involved. Such a schematic polarization plot is shown in Fig. 1.3.3.17. Here, the anodic reaction (blue) is more



• **Figure 1.3.3.17** Evans diagram for the case of a passivating alloy and a reduction reaction.

complicated due to the formation of the passive oxide film. This acts to limit the current passing the interface (kinetic barrier) and the intersection of the reduction reaction with the oxidation reaction defines the corrosion potential and corrosion current (also sometimes called the passive current density). Again, the total behavior of the electrode will be based on the mixed potential theory, and the complex behavior of the anode at the negative potentials will typically not appear in the polarization plot because it is overwhelmed by the cathodic reduction reaction.

Electrochemical Impedance Spectroscopy (an Introduction)

Resistive (Faradaic) and Capacitive (Non-Faradaic) Behavior

From the foregoing discussion of a single half-cell reaction, it can be seen that there are current densities (charge transfer across the interface) and charge accumulation processes. These

are known as Faradaic (charge transfer) and non-Faradaic (charge accumulating) processes. Since charge transfer results in currents across the interface that depend on the electrode potential, one can see that there is a resistive character to the interface. There is also charge accumulation, which results in a capacitive character of the electrode. This capacitance can arise from several sources, including the electrical double layer that may arise at such metal–electrolyte surfaces, but also from charge accumulation that can arise in the oxide film (so-called space charge layer) and even across the oxide–metal interface. These different capacitive effects act in series and since capacitors in series add as the reciprocal, the smallest of these will dominate the charging-based response. These impedance-based properties are an important element of the electrode behavior.

Basic Impedance Concepts

Since electrode surfaces (even with passive films) have both resistive and capacitive character, and these properties reflect the nature of the surface of the electrode and its activity within the electrolyte, an important tool to assess the surface behavior is known as EIS (Gilbert, 2011). This approach to understanding electrochemical systems has been in place for decades and as a result the basic concepts (MacDonald, 1987) for this are described here.

In EIS, a very small cyclic voltage is applied over some fixed potential (typically the E_{corr}, but could be any potential), with the amplitude of the voltage oscillation around 10 mV and the frequency of the oscillation varying between 1 mHz (sometimes less) and 10^5 Hz (sometimes more). At each frequency the current response is captured and will consist of an amplitude, i_o, frequency, ω, and a phase angle that will depend on the extent of resistive and capacitive character present at the frequency. The phase angle can vary from 0 to –90 degrees depending on the resistive (0) to capacitive (–90) character. That is, in general, the applied potential will be

$$V = V_o \sin(\omega t)$$

and the current response will be

$$I = I_o \sin(\omega t + \theta)$$

From these measurements, one can obtain the real (Z') and imaginary (Z'') part of the impedance, $Z(\omega)$, of the interface over the range of frequencies tested:

$$Z(\omega) = Z' + iZ'' = \frac{V_o}{I_o}(\cos\theta - i\sin\theta)$$

Both I_o and θ are frequency dependent, thus the real (Z') and imaginary (Z'') impedances will vary with frequency. Note, that

$$\tan(\theta) = \frac{Z''}{Z'}$$

To analyze EIS data, equivalent electrical circuits are used. These circuits are not "models" per se of the electrode surface but are electrical analogs that can reproduce the observed behavior. Care must be taken not to ascribe too much meaning to a particular circuit element in terms of the impedance behavior.

To obtain the equivalent circuit impedance, two simple concepts are needed. First is the frequency-based impedance of a simple resistor and capacitor. These are $Z_R = R$ and $Z_C = \frac{1}{i\omega C}$, where i is the imaginary number. The second concept is to recall how resistors and capacitors add in series and parallel. Resistors (impedances) add in series and add as the reciprocal in parallel, while capacitors add as the reciprocal in series and simply add in parallel. Since impedance, Z, is like a resistor, impedances add like resistors. Using these two concepts, the frequency-based impedance response of R–C circuits can be readily obtained.

The simplest R–C circuit is the series sum of R and C. Here, the impedance is just

$$Z = R + \frac{1}{i\omega C} = R - i\frac{1}{\omega C}$$

where $i = \sqrt{-1}$, $Z' = R$ and $Z'' = 1/i\omega C$, and $\tan\theta = 1/\omega\tau$, where τ is the time constant (RC) for the circuit.

The most typically used electrical circuit analog for an electrode interface is the Randles circuit (Fig. 1.3.3.16), where there is an electrode-based resistor, R_p, and capacitor, C, which are in parallel, and the solution resistance (R_s) in series with this combination. The impedance for the Randle circuit is

$$Z = R_s + R_p\left[\frac{1 - i\omega\tau}{1 + (\omega\tau)^2}\right]$$

where

$$Z' = R_s + R_p\left[\frac{1}{1 + (\omega\tau)^2}\right]$$

and

$$Z'' = -R_p\left[\frac{\omega\tau}{1 + (\omega\tau)^2}\right]$$

where $\tau = R_p C$.

From these results, one can make several different plots. These are known as Bode plots and Nyquist plots. In Bode plots, the $\log_{10}|Z|$ and θ are plotted against $\log_{10}\omega$, while Nyquist plots are a plot of Z'' versus Z'. Each provides some insight into the overall behavior of the electrode circuit and can assist in determining the values of the circuit elements (R_s and C). Typically, the software used for fitting these functions to the obtained data relies on an iterative nonlinear least squares fitting algorithm contained in the software that depends on the starting values chosen and the quality of the data. The solution resistance in a Randles circuit is found

from the high-frequency response, where the capacitor acts like a short circuit and all of the voltage drop is across R_s (i.e., $R_s = |Z|$ as $\omega \rightarrow$ infinity), while the R_p can be found at very low frequency (i.e., $R_p + R_s = |Z|$ as $\omega \rightarrow 0$).

Equivalent circuit impedance models can be more complicated to include defected coated models, where additional R–C elements are added into the Randles circuit. In addition, electrode surfaces often do not behave as ideal capacitors and in these cases a nonideal capacitive element, known as a constant phase element (CPE), is used to replace the capacitor in the circuit. The CPE element is of the form

$$Z_{CPE} = \frac{1}{(i\omega)^{\alpha} Q}$$

where Q is the capacitive-like element and α is the CPE exponent that can range between 0 and 1. When α is 0 the element acts like a resistor ($R = 1/Q$), and when α is 1, the CPE element acts like an ideal capacitor and $Q = C$. Typically, passive film-covered alloys exhibit α between 0.7 and 0.95 and have mostly capacitive behavior. There is some thought that increased heterogeneity of the surface impedance over the area of the electrode contributes to the nonideality of this circuit element.

When a CPE element is used in a Randles circuit, the equation for Z is

$$Z = Rs + Rp\left[\frac{\left(1 + (\omega\tau)^{\alpha} cos\left(\alpha\frac{\pi}{2}\right) - i(\omega\tau)^{\alpha} sin\left(\alpha\frac{\pi}{2}\right)\right)}{1 + 2(\omega\tau)^{\alpha}\cos\left(\alpha\frac{\pi}{2}\right) + (\omega\tau)^{2\alpha}}\right]$$

where $\tau^{\alpha} = R_p Q$.

This comes about using the identity

$$i^{\alpha} = e^{i\alpha\frac{\pi}{2}} = \cos\alpha\frac{\pi}{2} + i\sin\alpha\frac{\pi}{2}$$

Semiconducting Oxide Impedance (Mott–Schottky Analysis)

With the passivating alloys typically used in biomaterials, the semiconducting properties of the oxide are at times of interest. One impedance-based technique used is the Mott–Schottky analysis. Here, the capacitance of the surface is measured across a range of potentials and a plot of $1/C^2$ versus potential is constructed. The capacitance measured is directly linked to the semiconducting space charge region, and, based on an analysis similar to the electrical double layer analysis for ionic electrolytes adjacent to charged surfaces, the Mott–Schottky equation comes from a similar approach (i.e., analysis of the Poisson equation (Gilbert, 2011)):

$$C^{-2} = \frac{2}{A^2\varepsilon\varepsilon_o e^{-} N_D}\left(V - V_{fb} - \frac{kT}{e^{-}}\right)$$

where A is the area, ε is the dielectric constant of the oxide, ε_o is the permittivity of free space, $e-$ is the charge on an electron, N_D is the number of charge carriers in the oxide, k is Boltzmann's constant, T is temperature, and V_{fb} is the flat-band potential of the semiconductor (i.e., the potential where there is no band bending taking place (Gilbert, 2011)). This equation shows that the square of the reciprocal of capacitance is a linear function of voltage rising from the flat band potential. The slope of the line depends on the dielectric constant and the number of charge carriers. More defective films will have higher numbers of charge carriers.

The impedance of passive oxide-covered alloys (Ti and CoCr alloys) tend to show very high-resistance films in the most simplified, yet physiologically representative solutions (e.g., Ringer's, Hanks balanced salt solution, phosphate-buffered saline, etc.). The resistance can reach upwards of 10^7 Ωcm^2 and, because these films are thin, they exhibit significant capacitive effects as well. This latter property is an important one to understand in that significant charging/discharging of the surface can arise and these capacitive charging currents may affect polarization data and other voltage-changing measurements of the electrode. That is, passive films have significant capacitive charging currents that depend on the voltage scan rate and these electrodes can store significant amounts of charge over time. EIS is an important tool for understanding electrode interfaces and new methods are being developed to make such analyses more facile and better understood in terms of the electrochemical properties of these surfaces.

Questions

1. For the titanium–TiO_2 surface, find the Pilling–Bedworth ratio for this system. Would you expect this alloy–oxide film system to result in a passive behavior based on this result? Why or why not?
2. For a metal–solution interface with properties of the solution resistance of 100 Ωcm^2, polarization resistance of 10^6 Ωcm^2, and constant phase impedance $ZCPE = 1/((i\omega)^{0.89}\ 10^{-5})$, plot the Bode diagrams (for $\log|Z|$ and θ. Also, plot the Nyquist diagram and the Z'' vs. log ω, A'' vs. log ω. Finally, find the frequencies (in rad/s) associated with the reciprocal of the time constants, $\tau_1 = (R_s Q)^{1/\alpha}$, $\tau_2 = (R_p Q)^{1/\alpha}$, and identify these on the $\log|Z|$ versus $\log\omega$ Bode plot. Where do these sit?
3. For an oxide film-covered surface, plot the Mott–Schottky plot for $N_D = 10^{22}$ carriers/cm^3 and 10^{12} carriers/cm^3. How does the change in carrier density affect the plot and the ability of the charge to transit the oxide?
4. Explain how shot peening results in the development of compressive residual stresses in the surface of a metal and how these stresses enhance the fatigue crack initiation resistance of the alloy?
5. Using the Butler–Volmer equation (see equation in the section "Electrochemical Currents [Evans Diagrams]") recreate the plot in Fig. 1.3.3.17 (use Excel or Matlab). Using this diagram show an additional plot and explain why increased cathodic reaction exchange current density will shift the corrosion current and corrosion potential for the anodic reaction.

Introduction

Metals, polymers, ceramics, and composites can all be used as biomaterials (Martz et al., 1997). When compared with ceramic and polymeric biomaterials, metallic biomaterials stand out for their high strength, ductility, fracture toughness, hardness, and formability in addition to their reasonable biocompatibility (Nouri et al., 2010). Metallic biomaterials have a long history of use, dating back to antiquity; considering only modern surgical implants, stainless-steel and cobalt (Co)-based alloys have found use since the 1930s (Niinomi, 2002), with titanium (Ti) and its alloys subsequently finding applications in these areas due to their excellent properties (Niinomi, 1998). Ti alloys, which have become indispensable for the biomedical industry (Abdel-Hady Gepreel and Niinomi, 2013; Niinomi, 2008; Niinomi and Nakai, 2011), are also used in the aviation (Peters et al., 2003), maritime (Candel et al., 2010), armored vehicle (Moxson et al., 2000), chemical (Cui et al., 2011), and sports materials (Moxson and Froes, 2001) industries due to their high specific strength and corrosion resistance; furthermore, their usage area is expanding daily (Ozan and Ipek, 2012). Ti and some of its alloys have become the preferred metallic biomaterials for orthopedic implant applications because of their excellent mechanical, physical, and biological performance in comparison with other metallic biomaterials (Long and Rack, 1998; Niinomi, 1998; Rack and Qazi, 2006).

The need for these materials is increasing, with expected major orthopedic surgeries in the United States showing large increases over the period of 2005–30; total hip arthroplasties are predicted to increase by 174% to 572,000, with revision hip arthroplasties increasing by 137% (Kurtz et al., 2007). Meanwhile, total knee arthroplasties are predicted to grow by an enormous 673%, up to 3.48 million, with a similar 601% increase in knee revisions (Kurtz et al., 2007). Taken together, it is thus apparent that joint replacement biomaterials may profoundly influence the lives of millions of patients. To this end, it is vital to avoid the use of implant materials with low wear and corrosion resistance, low fracture toughness, low fatigue strength and a high elastic modulus, and/or use of poorly biocompatible alloying elements in the alloys, as any or all of these may lead to incompatibility between the bone tissue and implant materials (Geetha et al., 2009).

The primary consideration in designing new biomedical Ti alloys is to select alloying elements with a known, high degree of biocompatibility, e.g., without any biological concerns (Abdel-Hady Gepreel and Niinomi, 2013; Geetha et al., 2009). In the event that the elements chosen are inherently poorly biocompatible, it would then be possible that the implant material as a whole may be nonbiocompatible, causing severe problems in the physiological environment (Abdel-Hady Gepreel and Niinomi, 2013). Following this step, the designers should also consider the criteria of yield strength, elastic modulus, fatigue strength, fracture toughness, wear resistance, corrosion resistance, and surface bioactivity parameters based on the area of use of Ti alloys (Geetha et al., 2009). The development of new Ti alloys for biomedical applications have attracted increasing attention in recent years (Cui and Ping, 2009; Cui et al., 2010; Miyazaki et al., 2006; You and Song, 2012; Zhang et al., 2011a). Biomedical Ti-based materials with both biomechanical and biological compatibility pose an important necessity for orthopedic implant applications.

Biocompatibility

As defined earlier in the Introduction chapter of this book, an important question in biocompatibility is how the device or material "transduces" its structural make-up to direct or influence the response of proteins, cells, and the organism to it. As such, it is clear that the cytotoxic, genotoxic,

mutagenic, carcinogenic, allergenic, and neurological effects must all be taken into consideration, along with corrosion tendencies, when evaluating the biocompatibility of metallic biomaterials (Biesiekierski et al., 2012a).

Nickel (Ni), Co, chromium (Cr), and iron (Fe) ions were released to the physiological environment by stainless steels and Co-Cr alloy implants (Okazaki and Gotoh, 2005). There are serious concerns regarding the carcinogenic effects of Ni and Co (Beyersmann and Hartwig, 2008). In addition, Cr and Fe are not listed as biocompatible elements (Biesiekierski et al., 2012a).

Implant materials may also cause allergic reactions (Biant et al., 2010; Granchi et al., 2008; Rushing et al., 2007; Sesia et al., 2013; Shah et al., 2014; Zhubrak and Bar-David, 2014). Metal allergy due to ion release has become a significant modern issue (Niinomi, 2002), with 20% of young European women and 4% of young European men affected by Ni allergy (Niinomi, 2002). For orthopedic biomaterials specifically, it is estimated that allergic reactions take place in between 1% and 5% of orthopedic cases (Zhubrak and Bar-David, 2014). Figs. 1.3.3A.1 and 1.3.3A.2 show the allergic reactions of patients to the Ni content of stainless-steel screws (Fig. 1.3.3A.1) and bars (Fig. 1.3.3A.2); in both cases, the allergic reaction seems to be caused by the implant, but disappears shortly after removal/substitution for a Ti alloy implant (Zhubrak and Bar-David, 2014; Sesia et al., 2013).

These responses are not limited to stainless steel; even though the wear and corrosion resistance of Co-Cr-based alloys are better than stainless-steel alloys, some of the Co-Cr-based alloys contain high amounts of Ni (Niinomi, 2002). Furthermore, Co and Cr are also potentially concerning (Biesiekierski et al., 2012a), with metal allergies observed in patients even when Co-Cr alloys with less than 1% Ni are used as biomedical materials in total knee arthroplasty, leading to revision surgery (Gao et al., 2011).

These case studies highlight the importance of designing biocompatible materials that are comprised fully of elements without major physiological concerns; coupled with biomechanical problems, this has increasingly contributed to the replacement of stainless steels and Co-Cr alloys in orthopedic implant applications (Abdel-Hady Gepreel and Niinomi, 2013). Beyond stainless steels and Co-Cr-based alloys, some Ti alloys are increasingly considered unsuitable, in part because they contain nonbiocompatible alloying elements (Abdel-Hady Gepreel and Niinomi, 2013). For instance, one of the most commonly used Ti alloys, Ti-6Al-4V, contains vanadium (V) and aluminum (Al). V and its compounds are noted to be carcinogenic (Beyersmann and Hartwig, 2008), while Al displayed neurological side effects (Flaten, 2001) and genotoxicity (Lima et al., 2011).

Related to this topic is the development of novel shape-memory alloys (SMAs). SMAs are alloys that display the

Case Rep. 1 (6), 152–155, Copyright (2013), with permission from Elsevier.)

desirable thermomechanical shape-memory and superelasticity effects (SMEs and SEs, respectively); while SMAs are desirable for a range of biomedical applications (Otsuka and Ren, 2005), the SMA currently displaying the strongest SME and SE is nitinol (NiTi), with recoverable strains of 8% in polycrystalline forms (Buehler et al., 1963). This is increasingly a subject of concern due to the high Ni concentrations, and so there is a push to develop comparable, Ni-free SMAs (Cui et al., 2010; Kim et al., 2006; Li et al., 2012; Xiong et al., 2008; Zhang et al., 2011a).

The biocompatibilities of the transition elements were comprehensively reviewed based on the carcinogenic, mutagenic, genotoxic, cytotoxic, allergic, hemolysis, and neurological effects of alloying elements as well as their corrosion resistances (Biesiekierski et al., 2012a). It has been indicated that Ti, gold (Au), tin (Sn), tantalum (Ta), niobium (Nb), ruthenium (Ru), and zirconium (Zr) are biocompatible (Biesiekierski et al., 2012a); however, Sn has a tendency for pathogenic bacterial adhesion, thus its concentration in Ti alloys should be limited and this should be taken into consideration during the design stage (Mediaswanti et al., 2012). Hafnium (Hf) and rhenium (Re) are promising Ti-alloying elements; however, their carcinogenic, genotoxic, mutagenic, allergenic, and neurological effects are still not well known and need further in-depth study (Biesiekierski et al., 2012a); the remaining elements of the 3d, 4d, and 5d d-blocks, as well as Zn and Al, were deemed insufficiently biocompatible (Biesiekierski et al., 2012a).

Biocompatible Titanium Alloys

Ti and some of its alloys are promising metallic biomaterials due to their excellent biocompatibility and corrosion resistance as well as relatively low elastic moduli (Long and Rack, 1998). Ti alloys can be classified as α-, α-β-, and β-type alloys based on their room temperature microstructures. The strength of α-type Ti alloys does not increase with heat treatment since it is a stable phase (Boyer et al., 1994). This is also a fundamental property that distinguishes the α-type Ti alloys from α-β- and β-type Ti alloys (Boyer et al., 1994). In addition, the cold-forming capabilities of β-type Ti alloys that have attracted significant attention in recent years as orthopedic implant materials are much better than those of α-β-type Ti alloys (Boyer et al., 1994). This superior cold-forming ability of β-type Ti alloys decreases the production cost for the use of such alloys, thereby providing advantages for transforming them into commercial products (Abdel-Hady Gepreel and Niinomi, 2013).

To reduce the number of revision surgeries, it is desirable that the orthopedic implants exhibit long service life and have a rigidity (elastic modulus, E) close to that of bone tissue (Abdel-Hady Gepreel and Niinomi, 2013). However, designing orthopedic implant materials with both high mechanical strength and low elastic modulus is challenging, and it appears that the β-type Ti alloys are a promising candidate for orthopedic applications, as can be seen in Table 1.3.3A.1 (Abdel-Hady Gepreel and Niinomi, 2013).

Recent Efforts in Fabrication Processes

Ti alloys may be produced via casting and powder metallurgy (PM) methods (Nouri et al., 2010). Items made of Ti-based alloys have a much higher cost compared with other metallic biomaterials such as stainless steels due to a combination of high reactivity and poor machinability. This has resulted in an increasing preference for manufacturing methods such as PM, which enables the production of net shape or near net shape parts without needing to melt the alloy, so as to minimize the production costs (Biesiekierski et al., 2012b; Moxson and Froes, 2001; Peter et al., 2012; Qian et al., 2012).

Many powder compaction methods such as die pressing, vacuum hot pressing, cold isostatic pressing, and hot isostatic pressing (HIP) are used to produce compacts with high density (Peter et al., 2012). PM methods have especially been sought for usage in industries such as aviation, where mechanical performance is of utmost importance and where the products used are subject to cyclic loading (Peter et al., 2012). HIP can be used to produce Ti alloy parts with near theoretical density and low porosities, but is very costly (Dewidar et al., 2006). It is one of the most frequently used methods in producing high-density Ti alloys (Donachie, 2000).

The fundamental properties expected from artificial joint prostheses are as follows: restoration of patient ability/mobility, biocompatibility, sufficient mechanical performance, ease of production, ease of implantation, and economic advantage (Dewidar et al., 2006). Thus economics is typically the last factor considered, since cost cannot be a significant factor when human health is taken into consideration (Dewidar et al., 2006).

The mechanical performance indicators include the mechanical strength, elastic modulus, toughness, and fatigue strength since load-bearing implants are generally subjected to cyclic load. For example, the femoral stems of hip prostheses are subject to serious cyclic loading because people may walk several thousands of steps daily (Vadiraj and Kamaraj, 2006). Biomedical materials subjected to cyclic loading may be damaged with the occurrence of fatigue (Buttaro et al., 2007; Chen et al., 2005; Ramos and Simões, 2009).

While modern-day bioengineers use solid and nonporous materials in their designs for load-bearing structures, nature makes use of porous structures that adapt properties such as elastic modulus and strength according to the situation faced in its own cycle (Ashby, 1983). A 100-m-tall alder tree with a weight of around 2500 tons is an excellent example of a load-bearing, naturally porous structure (Ashby, 1983). Coral, fungi, and trabecular bone tissues are also examples of natural porous materials (Ashby, 1983).

To eliminate the mechanical incompatibility between the osseous tissue and the implant material (de Vasconcellos et al., 2010; Dewidar et al., 2008), porous structures may be used, yielding decreased moduli as a function of increasing porosity (Ashby, 1983). But as these pores also aid implant

TABLE 1.3.3A.1 Mechanical Properties of Titanium Alloys

Ti Alloy (wt%)	Microstructure	Young's Modulus (GPa)	Yield Strength (MPa)	Tensile Strength (MPa)	References

Hence, β-type Ti alloys with lower elastic moduli than those of α-β Ti alloys are being developed for orthopedic applications by numerous researchers. Hao et al. (2007), Kuroda et al. (1998), Li et al. (2012), Matsumoto et al. (2005), Miyazaki et al. (2006), Ozaki et al. (2004), Yang and Zhang (2005), Ozan et al. (2015).

fixation via bone ingrowth into the implant (Dewidar et al., 2006), research efforts in developing porous Ti and its alloys have gained significant attention in recent years (Ahn et al., 2014; Asik and Bor, 2015; Rao et al., 2014; Rivard et al., 2014). Some negative aspects include: (1) the presence of porosity will compromise the mechanical strength of these implants with low moduli (Li et al., 2009b; Wang et al., 2009, 2010), and (2) the corrosion resistance and fatigue life of foam alloys are generally lower than nonporous materials (Ryan et al., 2006).

Ti foam materials can be produced by PM in a number of different ways. It is possible to create a porous structure simply by sintering loose powders, but it is difficult to produce parts with high porosity using this method. When higher porosities are desired, methods such as space-holder sintering are more effective method choices, for they provide some degree of choice over pore morphology (Biesiekierski et al., 2012b). Porosity, pore shape and size, and interconnectivity, in addition to appropriate mechanical properties, are important factors determining the bone ingrowth and the biological fixation of an implant material (Ryan et al., 2006).

Carbamide (Bhattarai et al., 2008; Bram et al., 2000), magnesium (Mg) (Asik and Bor, 2015; Esen and Bor, 2007), ammonium bicarbonate (Nouri et al., 2011; Wang et al., 2011), tapioca starch (Mansourighasri et al., 2012), sodium chloride (Ye and Dunand, 2010), and sodium fluoride (Bansiddhi and Dunand, 2007) have all been used as space-holders in the production of porous Ti materials. It should also be taken into consideration that the space-holder materials used may contaminate the porous Ti materials, thereby resulting in degradation of mechanical properties, corrosion resistance, and biocompatibility.

Porous materials with the desired porosity and pore size may also be produced directly, without the use of any space-holders, via additive manufacturing (AM) methods, such as selective laser sintering (SLS) (Shishkovsky et al., 2008; Xie et al., 2013), selective laser melting (SLM) (Chen et al., 2017), and electron beam melting (EBM) (Heinl et al., 2007; Horn et al., 2014; Springer et al., 2014). Fig. 1.3.3A.3 shows a porous Ti-6Al-4V alloy scaffold produced via EBM (Li et al., 2009a) and Fig. 1.3.3A.4 shows the schematic of the SLS process (Yang and Evans, 2007).

The manufacturing process varies somewhat depending on the method chosen. For instance, in the SLS method, powdered material is first spread out as a layer, then sintered in a targeted manner by a computer-controlled laser beam, resulting in metallurgical bonding between metal powders in shapes that may be defined based on CAD or equivalent software files (Munir et al., 2017). When the process is completed, the platform at the base is lowered by a layer thickness and a new powder-bed layer is deposited and then sintered, with this repeating until the target part is produced

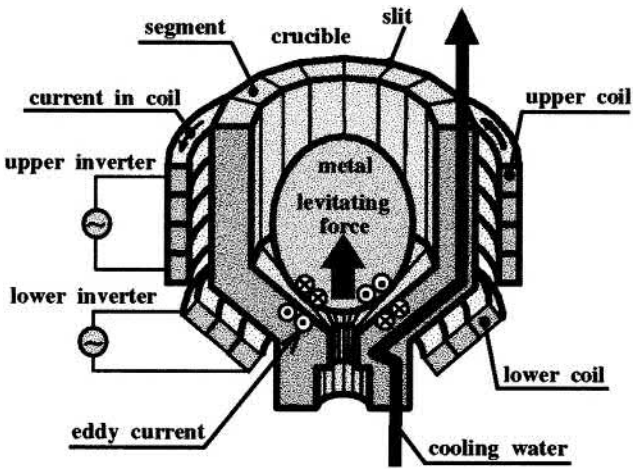
Metering and dispensing of powder; the quest for new solid freeforming techniques. Powder Technol. 178 (1), 56–72, Copyright (2007), with permission from Elsevier. AM has emerged as a promising method for producing biomedical implants with complex shapes. AM is so named because, unlike traditional methods such as machining or forming, production is carried out by systematically adding materials. Comprehensive studies have been carried out examining the use of AM for production of porous bone scaffolds (Ataee et al., 2018; Eldesouky et al., 2017) and dental implants (Jamshidinia et al., 2014, 2015). SLS, SLM, laser-engineered net shaping (LENS), and EBM are the most frequently used AM methods for manufacturing biomedical implants (Harun et al., 2018).)

(Liu et al., 2006). The SLM method is an evolution of the SLS method that allows the metal powder to fully melt to produce a homogeneous part, in contrast to the SLS process where the raw powder is only partially melted or heated to the sintering point (Harun et al., 2018). Similarly, the EBM method also employs complete particle melting, but unlike the SLM method, it uses an electron beam instead of a laser.



• **Figure 1.3.3A.5** Schematic illustration of cold crucible levitation melting method. (Reprinted from Morita, A., Fukui, H., Tadano, H., Hayashi, S., Hasegawa, J., Niinomi, M., 2000. Alloying titanium and tantalum by cold crucible levitation melting (CCLM) furnace. Mater. Sci. Eng. A 280 (1), 208–213, Copyright (2000), with permission from Elsevier.)

Notably, this limits the EBM method to be operable under high vacuum due to the inherent characteristics of the electron beam (Harun et al., 2018). Atmospheric control is also required for the SLM and SLS methods, typically an argon (Ar) atmosphere throughout the entire work area, due to the high reactivity of Ti powders. This can be avoided in the LENS method, however, as the powders are fed through Ar-pressurized nozzles using a high-power laser. The use of pressurized nozzles acts as a local shield to keep potential contaminants out of the melt pool without requiring evacuation of the entire work area (Harun et al., 2018).

Aside from the PM and AM methods, casting also finds use as a near net shape method. However, it is not an easy process to melt and cast Ti, Nb, and/or Ta metals, as these elements have both very high melting points and chemical reactivities (Morita et al., 2000). The density difference between those elements also makes it more difficult to obtain a homogeneous microstructure by traditional casting methods (Morita et al., 2000).

To overcome this challenge, the cold crucible levitation melting (CCLM) method, shown schematically in Fig. 1.3.3A.5, proves to be a very useful method in casting Ti alloys (Morita et al., 2000). In CCLM, both heating and effective mixing are carried out via electromagnetic forces, thereby yielding a uniform microstructure even for metals with high melting points and differences in density (Morita et al., 2000). As the magnetic fields used to heat the material also induce levitation, contamination resulting from crucible contact is also avoided (Morita et al., 2000).

Mechanical Properties of Titanium Alloys

The elastic moduli of Ti alloys (55–110 GPa) are lower than those of stainless steels (~210 GPa) and Co-based alloys (~240 GPa) (Geetha et al., 2009), but their corrosion resistance is higher than that of the aforementioned materials

(Liu et al., 2004), thereby making Ti alloys promising candidate materials in orthopedic implant applications. The fatigue strength should also be high for Ti alloys as implant materials (Niinomi and Nakai, 2011). Since fatigue limit is related to tensile strength (Pang et al., 2014), orthopedic implant materials should have a low elastic modulus and high mechanical strength so that they can be used as implant materials such that the implant can have a longer service life without a need for revision surgeries (Abdel-Hady Gepreel and Niinomi, 2013). In addition, long fretting fatigue life and high wear resistance are two other important characteristics expected from orthopedic implant materials (Niinomi, 2008). Fig. 1.3.3A.6 shows a schematic illustration of the expected locations of fretting motion as a result of cyclic loading experienced by a total hip prosthesis or bone plate (Vadiraj and Kamaraj, 2006).

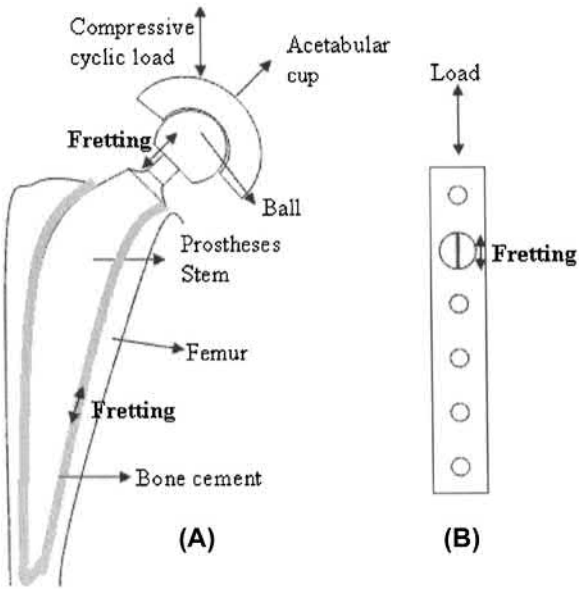
Inadequacy in these mechanical properties may lead to revision surgeries even when biocompatible alloying elements are used. This was seen in the recall of the Stryker modular hip replacements, made of Ti-12Mo-6Zr-2Fe, in 2011 (Yang and Hutchinson, 2016). In addition to the significant economic burden resulting from those revision surgeries, they show poorer success rates than primary surgeries (Geetha et al., 2009). Therefore the wear resistance, fatigue strength, and elastic modulus of the orthopedic implant material used should be mechanically sufficient for minimizing revision surgeries of Ti implants designed using biocompatible alloying elements (Geetha et al., 2009).

Elastic Modulus

It is inevitable that the number of revision surgeries will increase when biochemically and biomechanically incompatible materials are used for implant applications (Abdel-Hady Gepreel and Niinomi, 2013). Stress shielding may develop in cases where an implant material exhibits an elastic modulus exceeding that of the surrounding bone (Huiskes et al., 1992). Stress shielding occurs due to the applied stresses being taken by the stiffer implant rather than the surrounding tissue, and as a result it leads to bone atrophy via the adaptive remodeling process of bone (Torres et al., 2011). Fig. 1.3.3A.7 shows the right hip radiographies for a 63-year-old female (Kawate et al., 2009). Excessive stress shielding can be observed in Fig. 1.3.3A.7C (Kawate et al., 2009), and it may result in implant loosening, increased susceptibility to bone fracture, and worsened revision surgery prognoses due to insufficient bone structure for subsequent implant fixation (Heinl et al., 2007).

The use of Ti alloys as orthopedic implant materials is becoming increasingly popular due to their high compatibility with bone (Geetha et al., 2009). However, stress shielding remains an open issue. The elastic moduli of Ti alloys, at 40–110 GPa, are still high in comparison with the elastic moduli of osseous tissue, which range between 0.1 and 30 GPa (Wang et al., 2011). For femoral and knee prostheses in particular, it is worth noting that human femur has an elastic modulus of 16–18 GPa (Rogers and Zioupos, 1999).

As seen in Table 1.3.3A.1, while the Young's moduli of β-type Ti alloys are lower than those of α + β-type Ti alloys, they are still higher than that of bones. By contrast, the most used biomaterial, the Ti-6Al-4V alloy, has a Young's modulus value that is ~6–7 times higher than that of femur bones.



• **Figure 1.3.3A.6** Fretting fatigue of (A) total hip prosthesis and (B) bone plate. (Reprinted from Vadiraj, A., Kamaraj, M., 2006. Characterization of fretting fatigue damage of PVD TiN coated biomedical titanium alloys. Surf. Coat. Technol. 200 (14–15), 4538–4542, Copyright (2006), with permission from Elsevier.)

Wear Resistance

Ti alloys are known for their poor tribological characteristics (Budinski, 1991). Low thermal conductivity, low strain hardening, and inadequate covering of surface oxides are indicated as reasons for the low wear resistance of Ti alloys (Molinari et al., 1997; Straffelini et al., 2004). If the high wear resistance needed for long service lifetimes cannot be attained, wear debris forms on the material, which may lead to inflammation, osteolysis, metallosis, and bone resorption, leading to the loosening of the implant material (Geetha et al., 2009). Notably, it is not suggested at this stage to use metal-on-metal hip prostheses until they are confirmed as reliable (van Raay, 2012). Fig. 1.3.3A.8 shows schematically the formation of the wear particles (Geetha et al., 2009).

Co-based alloys have better wear resistance when compared with Ti alloys (Long and Rack, 1998). However, the higher elastic moduli and elemental toxicity of Co-based alloys make Ti alloys the preferred option (Long and Rack, 1998). Therefore it is necessary to improve the wear resistance of Ti alloys for implant applications (Niinomi, 2008). While there are many different surface-hardening procedures available for enhancing the tribological properties of biomedical Ti alloys, two methods are of particular note due to their ease of application: oxidation and gas nitriding. The wear resistances of Ti-29Nb-13Ta–4.6Zr and

Ti-6Al-4V were improved significantly in Ringer's solution by the nitriding process as compared to those of their as-solutionized counterparts (Niinomi, 2008).

Fatigue Behavior

The use of implant materials with high fatigue strength is as crucial as that of low modulus for achieving a long service life (Niinomi and Nakai, 2011). The strength of Ti alloys may be improved by different methods such as strain hardening, grain refinement, and aging (Niinomi and Nakai, 2011). When orthopedic implant materials are evaluated regarding the location of failures due to fatigue, fractures mostly occur near the hole of plates and bars, on screws and spinal implants, and on joints of hip prostheses (Okazaki, 2012). Orthopedic implant materials may fail as a result of fatigue (Buttaro et al., 2007; Chen et al., 2005; Ramos and Simões, 2009). Fig. 1.3.3A.9 (Buttaro et al., 2007) shows a total hip prosthesis failure due to fatigue.

One of the methods for improving the fatigue strength of the β-type Ti alloys is aging treatment after solution treatment, which allows α- and/or ω-phases to precipitate. This provides increased mechanical strength, as the secondary phases interfere with dislocation movement (Helth et al., 2017). However, the increase in mechanical strength also coincides with increased elastic moduli of the material, since the elastic moduli of the precipitating secondary phases is significantly higher compared with that of the β-phase (Helth et al., 2017).

Assuming equal yield strength, fatigue strength is generally lower for the β-type Ti alloys with lower elastic moduli than that for the α-β Ti alloys (Long and Rack, 1998; Rack and Qazi, 2006). Taking the Ti-6Al-4V ELI alloy, the most common Ti alloy for biomedical applications due to its satisfactory tensile (listed in Table 1.3.3A.1) and fatigue properties (varying between 610 and 800 MPa; Akahori et al., 2000), as a reference point, it is crucial for β-type Ti alloys to possess improved fatigue strength, but it is quite difficult to improve fatigue strength without also raising modulus (Niinomi and Nakai, 2011). For this purpose, short-term aging at low temperatures, excessive cold rolling, and trace addition of ceramic particles may keep the elastic modulus as low as possible while improving fatigue strength (Niinomi and Nakai, 2011).

Effects of Interstitial Atoms on Mechanical Properties

Precipitation hardening is commonly used to produce Ti alloys with satisfactory strengths, but at the cost of substantially increased elastic moduli (Helth et al., 2017). Thankfully, however, other mechanisms to improve the strength of metallic materials are possible, notably the use of interstitial atoms for strengthening (Cho et al., 2013).

For commercial Ti alloys, one of the major avenues of interstitial or solid-solution strengthening is via controlled oxygen content (Liu et al., 2015). The α- and/or β-phase in Ti have a high capacity for oxygen or other interstitial elements, hence encouraging the use of interstitial elements for solid-solution strengthening (Ouchi et al., 1998). Indeed, commercially pure Ti and Ti alloys generally contain oxygen levels in excess of 0.06% (wt%), while the oxygen content of pure Ti produced via the Kroll method varies between about 0.02% and 0.04% (Ouchi et al., 1998). This mechanism has been shown to contribute to strengthening Ti alloys (Liu et al., 2015; Ji et al., 2018), and it has also been reported that this strengthening can be achieved with no increase in the elastic modulus value of β-type Ti alloys when oxygen content is maintained under 0.33% (wt%) (Geng et al., 2011). That said, care must be taken, as excessive oxygen could degrade the ductility of Ti alloys (Yan, 2014). It is therefore crucial for the strengthening of the β-type Ti alloys: the amount of oxygen must be controlled to just provide a solid-solution strengthening effect to improve the tensile and fatigue properties, and at the same time keep the elastic modulus value almost constant.

Surface Modification of Titanium Alloys

Ti and its alloys have good biocompatible characteristics due to their protective surface oxide layer (Yamamuro, 1989). Implant materials with good biocompatibility have traditionally been preferred to eliminate undesirable tissue reactions such as necrosis after implantation. One issue with this class of biomaterial is that fibrous tissue formation may occur at the bone/implant interface (Liu et al., 2004), which could lead to implants loosening due to the greater compliance of the fibrous tissue (Frenkel et al., 2004). This fibrous tissue also limits bone growth by isolating the implant from the surrounding bone tissue. Fibrous tissue formation can be minimized when excessive micromotion of the implant can be avoided or prevented, e.g., using a bone-like apatite layer directly on the surface of the implant to bond the implant to the surrounding bone (Liu et al., 2004). This process is known as osseointegration, and is defined as a direct contact between bone and implant with no interfering fibrous tissue (Carlsson et al., 1986). While this leads to more rigid fixation than fibrous encapsulation, it has been acknowledged that a better degree of fixation may be achieved with the latter case (Anselme, 2011). As such, there is increasing interest in the property of osteoconductivity or bioactivity, that is, the ability of a material to promote the development of hydroxyapatite (HA) directly onto the implant surface (Skripitz and Aspenberg, 1998).

Integration between bone and implant has importance with respect to clinical requirements (Hanawa, 2012). It is expected that these artificial joints integrate easily with the bone tissue and preserve this integration (Simka et al., 2013a). Because artificial joints are often used in patients with damaged joints to restore bodily functions lost by the damaged natural joints, implants that do not promote new osseous tissue are at best a temporary measure. These patients will need artificial joints throughout their lives. Consequently, an artificial joint that can successfully bond with bone is crucial for the patient to be able to carry out daily activities comfortably throughout life (Fujibayashi and Nakamura, 2004). Alkali heat treatment (Xiong et al., 2008), acidic procedures (Wen et al., 1997), anodic oxidation (Simka et al., 2013b), hydrogen peroxide (Karthega and Rajendran, 2010), plasma spray (Roy et al., 2011a), sandblasting (Kim et al., 2011), and sol-gel (Domínguez-Trujillo et al., 2018) are among the primary methods used to improve the bonding between the implant and bone. Anodic oxidation stands out among those methods for improving surface bioactivity due to its cost effectiveness and ease of application.

Recent Efforts in the Anodization Process

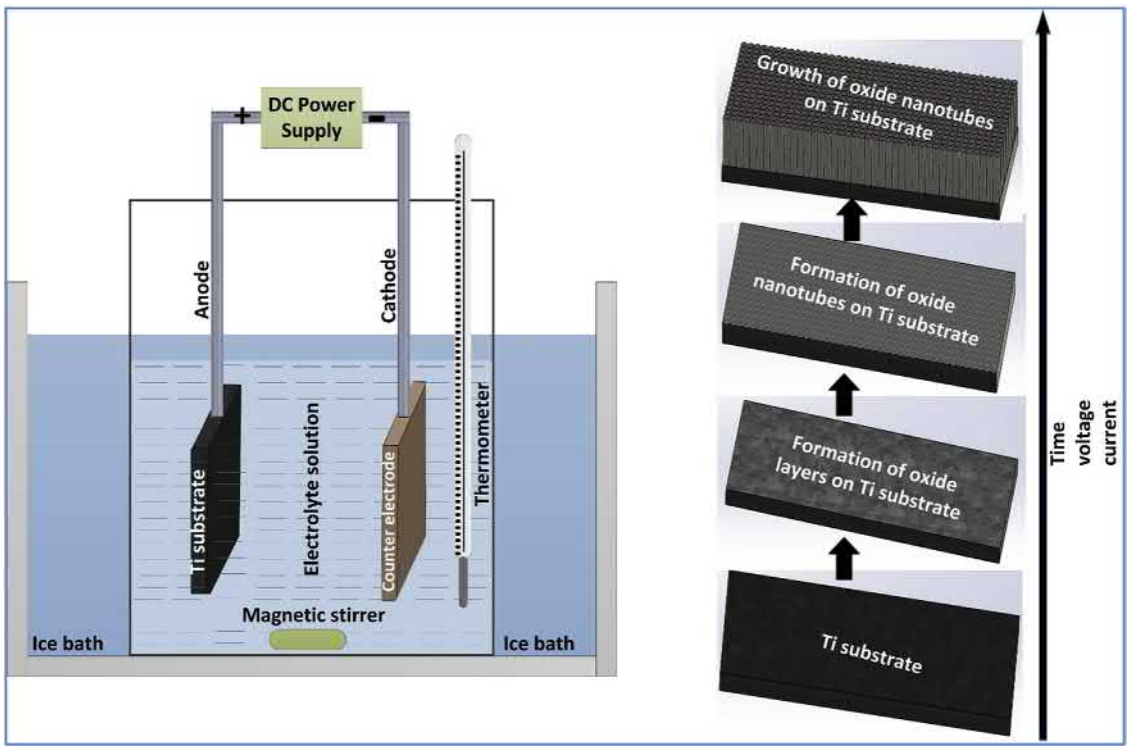
Recent progress in the development of Ti implants has shown that clinical success of such implants relies on the degree of osseointegration in the host environment (Cheng et al., 2010). In this context, biocompatibility of such implants preferentially depends upon the structure,

morphology, and composition of oxide layers on their surfaces. Thus additional surface treatments are essential to ensure formation of stable passive films on the surface of Ti implants with desirable surface chemistry (Liu et al., 2017; Minagar et al., 2012). Anodization has emerged as a promising electrochemical surface modification technique for Ti implants to achieve faster, more secure bonding to the host bone (Minagar et al., 2012; Yao and Webster, 2006). Anodization results in the formation of the desired surface by manipulating its ability and tendency to tailor a self-protective oxide layer. In the presence of fluoride-containing electrolyte solutions and an applied electrical potential, controlled oxidation–reduction reactions form a characteristic, patterned, nanoporous, tubular structure on the surface of the oxide layer, with a conical closed-bottom configuration (Kapusta-Kołodziej et al., 2017; Michalska-Domańska et al., 2018). Fig. 1.3.3A.10 shows schematically a typical anodization set-up and events during the anodization of Ti-based substrates.

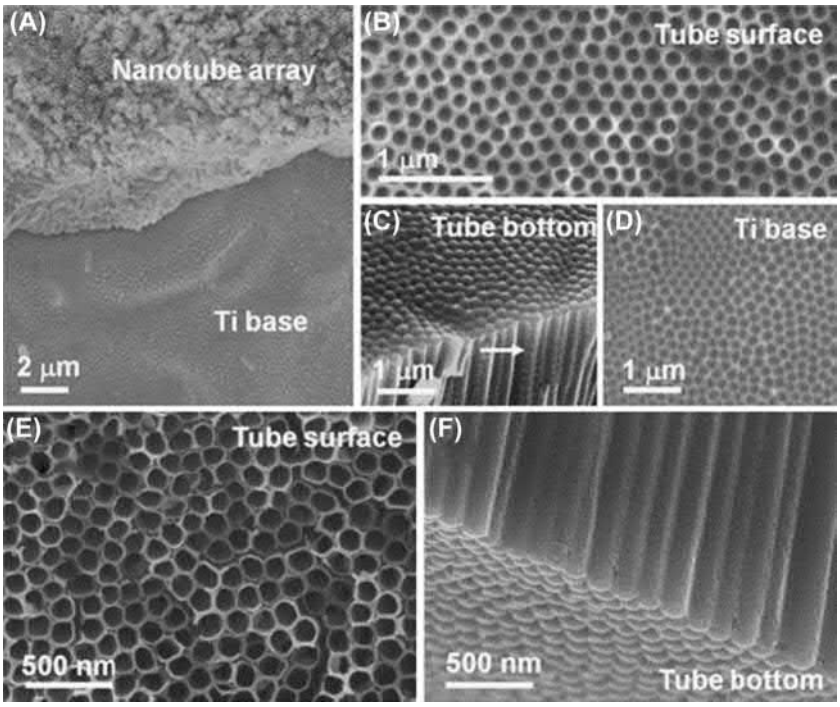
In similar studies (Crawford and Chawla, 2009; Crawford et al., 2009), the anodization technique was used to modify the surfaces by fabricating a dual-porous, hierarchical structure on Ti substrates. The characteristic hierarchical structure consisted of a dual-porous structure of TiO_2 nanotubes and randomly distributed microscale pores. Fig. 1.3.3A.11 shows microscopic images of typical configurations of TiO_2 tubes grown on Ti substrates via anodization at different applied potentials. It has also been established that electrochemical conditions such as applied potential, current density, electrolyte type, time, and temperature govern the characteristic dimensions of these nanotubular configurations, such as diameter, length, and wall thickness (Kapusta-Kołodziej et al., 2017; Ozkan et al., 2018; Roy et al., 2011b). In contrast to the study by Bauer et al. (2009), which indicated that the nanotube length does not affect the cell behavior, other studies suggest that the characteristic length and wall thickness of grown TiO_2 nanotubes on Ti substrates could affect cell adhesion, proliferation, and differentiation because the resultant wettability and surface energy of a Ti substrate are subject to change with changing characteristic dimensions of growth nanotubes on them (Bai et al., 2018; Minagar et al., 2013). Also, compared with surface modification of commercially pure (CP)-Ti, anodization of other β Ti alloys containing different weight fractions of niobium (Nb), zirconium (Zr), and tantalum (Ta) in Ti results in different reaction rates because of the differing electrochemical properties of these alloying elements in Ti (Allam et al., 2010; Jha et al., 2010). Such differences in oxidation rates lead to formation of a more selective and regular, self-organized pattern of anodic nanotube layers, which grow to different sizes in diameters and lengths. Table 1.3.3A.2 summarizes recent efforts in the anodization of Ti alloys.

Effects of Anodization on Corrosion and Surface Mechanical Properties

Corrosion resistance of implants in a human body environment is a critical factor, as the biocompatibility and mechanical integrity of implants can be adversely affected by a low corrosion resistance (Jacobs et al., 1998). Corrosion and dissolution of surface films introduce metal ions



• **Figure 1.3.3A.10** Schematic of a typical anodization set-up for surface modification of Ti implants.



• **Figure 1.3.3A.11** Microscopic images of TiO_2 nanotubes grown on Ti substrates via anodization under different applied potentials, times, and electrolyte types: (A–D) 60 V for 16 h in ethylene glycol/0.3% NH_4F/2% H_2O and (E–F) 120 V for 1 h in ethylene glycol/0.5% NH_4F/1% H_2O. (Reprinted from Su, Z., Zhang, L., Jiang, F., Hong, M., 2013. Formation of crystalline TiO_2 by anodic oxidation of titanium. Prog. Nat. Sci. Mater. Int. 23, 294–301, Copyright (2013), with permission from Elsevier.)

from metallic implants into the physiological medium; extensive release of metal ions from these implants causes adverse biological reactions, which may lead to complete failure of the implanted medical devices (Brunette et al., 2012). It has been established that the corrosion resistance of metals can be improved by anodic oxidation via electrochemical techniques. This is mainly attributed to the formation of stable, adherent, and protective oxide films on the surfaces during anodization (Shabalovskaya, 2002; White et al., 1985). Despite the adherence of an oxide layer to its metal substrate and its self-healing ability when damaged, traces of Ti can nevertheless be observed in tissues adjacent to implant prostheses (Ducheyne et al., 1984). Addition of alloying elements in Ti such as Nb, Zr, and Ta improves the corrosion resistance of these alloys by stabilizing the surface oxide films in the human body environment (Okazaki et al., 1997).

This is particularly important in Ni-containing alloys such as NiTi. Though with high corrosion resistance, NiTi contains a high Ni content, which makes the use of NiTi debatable due to the allergenic and toxic nature of Ni (Morgan, 2004). For this reason, modification of the surfaces of NiTi to further improve the corrosion resistance of NiTi to reduce Ni ion releasing to surrounding tissues has been attempted. It was found that the anodization behavior of NiTi in acetic acid differs markedly from that of Ti, with a much lower value for the steady-state potential and thinner oxide film thickness at similar anodizing current densities. As such, surface modification of NiTi significantly enhanced the corrosion resistance of NiTi with reduced Ni concentration on the surface.

It has also been established that in comparison with bare Ti, anodized Ti containing porous TiO_2 oxide layers enabled them to support more stable sputter-coated HA films (Lee et al., 2010). Subsequently, the corrosion resistance of HA-coated/anodized Ti was found to be higher than nonanodized Ti in Hank's solution. Karpagavalli et al. (2007) also reported enhanced corrosion resistance of anodized Ti-6Al-4V containing nanostructured TiO_2 films as compared with nonanodized substrates. Table 1.3.3A.3 summarizes the recent efforts by different research groups to evaluate the effects of anodization on corrosion and surface mechanical properties of Ti alloys.

Coloring Methods for Titanium Alloys

Coloring of Ti is beneficial for a variety of biomedical applications, as many biomedical-grade metal products in the medical industry require color coding to streamline surgical operations (Kobayashi et al., 1992). The characteristic TiO_2 films on Ti substrates exhibit a wide range of colors as the thickness of the oxide layer approaches the wavelength of visible light, which also makes them potential candidate materials to be used in jewelry and decorative applications to enhance the aesthetics (Suzuki, 2000). This occurs due to constructive and destructive interference between light waves reflected from the air–oxide and oxide–substrate interfaces. Several techniques have been used for coloring Ti substrates via this principle, including high-voltage discharge

methods (Suzuki, 2000), AC polarization (Jerkiewicz et al., 1996), plasma and thermal oxidation (Teng et al., 1998), pulse 1aser treatment (Lavisse et al., 2007), and anodization (Lausmaa et al., 1990). Among these techniques, anodization has emerged as the most commonly used commercial technique for the coloring of Ti. During anodization, the nature and type of electrolyte, along with the characteristics of oxide films themselves, determine the surface coloration. These colors in turn can be manipulated to measure the oxide thicknesses on the metallic substrates. It has also been reported that difference in composition in the Ti substrates can give rise to different colors within the same specimen due to the presence of various oxide phases (Langlade et al., 1997). A previous study (Kobayashi et al., 1992) on anodization of Ti in phosphoric acid (H_3PO_4)-based electrolytes has shown that the color of Ti changes to blue tones by applying a voltage of 25 V. Increasing the voltage from 25 V formed thicker oxide films and their progressive transformation into

a wide range of colors on Ti surfaces. Similarly, relationships between the pulse energy of the laser beams, during laser oxidation, and coloring of oxide films on NiTi substrates can also be identified (Wong et al., 2007). It was found that the surfaces of NiTi remained metallic gray when the pulse energy was kept below 400 mJ, and turned to uniform yellowish and then red–purple colors upon increasing the laser energy to 500 and 600 mJ, respectively. Table 1.3.3A.4 summarizes the recent efforts by different research groups for the coloring of Ti via anodization and laser oxidation.

Compared with coloring of Ti via thermal oxidation techniques, coloring via oxidation of Ti by electrochemical anodization is advantageous as the oxide films can be more accurately controlled by the applied potentials. Another advantage of using anodization techniques for coloring Ti is that it changes the colors of Ti without significantly altering the metallurgical properties of the substrates. Fig. 1.3.3A.12 shows the typical morphology of Ti substrates after their coloring via anodization and laser oxidation techniques.

Conclusions

NiTi alloy, which is attractive with its shape memory and superelasticity, contains carcinogenic and allergic nickel

TABLE 1.3.3A.4 Recent Efforts in Coloring of Ti via Anodization and Laser Oxidation Techniques

Substrate	Surface Coloring Technique	Processing Conditions	Colors of Oxide Films on Ti Substrates	References
Ti	Anodization	Electrolyte: acetic acid Voltage: 0–100 V	Golden, purple, blue, light blue, yellow, pink, green	Del Pino et al. (2004)
	Laser oxidation	Nd:YAG laser with average laser intensity of 55 kW/cm^2	Golden, Purple, yellow–green, pink–golden, green–pink	
NiTi	Laser oxidation	Nd:YAG laser with average nominal pulse energy = 400–600 mJ	Yellow, red–purple	Wong et al. (2007)
Ti-6Al-4V	Anodization	Electrolyte: H_3PO_4/H_2SO_4 Voltage: 10–130 V	A wide range of color saturation observed, depending on jewel surface finishing	Diamanti et al. (2012)
Ti	Laser oxidation	Yb:glass fiber laser (1062 nm) with average output power 20 W, laser scanning speed = 25–200 mm/s	Yellow, orange, red, purple, blue, light blue, silver, black	Antończak et al. (2014)
Ti	Laser oxidation	Yb:glass fiber laser with average output power 20 W	Yellow, orange, red, purple, blue, light blue	Antończak et al. (2015)
Ti	Anodization	Electrolyte: NH_4NO_3 Voltage: 80 V	Black	Kaneko et al. (2018)

elements, thus making it necessary to design and manufacture nickel-free Ti alloys. In this regard, it is necessary to design and manufacture Ti alloys possessing mechanical properties close to those of NiTi alloys.

This chapter aimed to inform readers about the strategies in designing new Ti alloys for orthopedic implant applications. The first and most important step in a design process is to start designing with the biocompatible alloying elements. Following this step, designers should target not only lower elastic modulus, but also higher tensile strength, fatigue strength, wear resistance, corrosion resistance, and surface bioactivity.

SLS, SLM, EBM, and LENS methods are the most effective methods for the production of biomedical implants with complex shapes. On the other hand, the ability to achieve a higher mechanical strength in powder metallurgical methods depends on minimizing the pores originating from the nature of the PM method.

Ti alloys exhibit higher corrosion resistance and lower elastic modulus than many other metallic biomaterials (e.g., austenitic stainless steel and Co-Cr alloys). Although the use of Ti and its alloys as a biomaterial exhibits many advantages over other metallic alloys, chemical bonding to bone tissue, biochemical interaction, and incompatibility between the elastic modulus of bone and the Ti implant material are the three most challenging problems to be solved for the use of Ti alloys as orthopedic implant materials. The elastic modulus of β-type Ti alloys is closer to the elastic modulus of cortical bone tissue than the elastic moduli of other metallic alloys, thus making β-type Ti alloys a more suitable implant material in terms of minimizing the stress-shielding phenomenon. It is of great importance to use implant materials that match the mechanical properties of the target bone tissue. The high fatigue strength of the implant materials subject to cyclic loading is crucial for long-term, problem-free use. With the increase in tensile strength, fatigue strength is also improved. β-type Ti-alloys have a lower elastic modulus than α + β-type Ti alloys, but also display lower mechanical strengths.

The mechanical strength of Ti alloys can be increased via solid-solution strengthening using oxygen or other interstitial elements. It is advisable, however, to add small amounts of interstitial elements to minimize the increase in elastic modulus, while still providing high mechanical strength. Hardening mechanisms (e.g., precipitation hardening and work hardening) are also effective in increasing the mechanical strength. It is worth noting that phases formed during aging and cold-working processes may cause an increase in elastic modulus.

Alkaline heat treatment, acidic processes, anodic oxidation, hydrogen peroxide, plasma spray, sandblasting, and sol-gel are used as methods for increasing the surface bioactivity of Ti and its alloys. The anodic oxidation method for increasing surface bioactivity is widely used because of its effective role in enhancing surface bioactivity in addition to cost effectiveness and ease of application.

Acknowledgments

The authors acknowledge the financial support for this research by the National Health and Medical Research Council (NHMRC), Australia, through grant GNT1087290; and the Australian Research Council (ARC) through the discovery grant DP170102557. YL is also supported through an ARC Future Fellowship (FT160100252). Part of this chapter was originally published in the Ph.D. thesis titled "Investigation of mechanical properties of Ti-alloys developed for bone-tissue engineering applications" (in Turkish), Ege University, Turkey (2015) by SO. SO would like to acknowledge the Council of Higher Education (CoHE) of Turkey for a Ph.D. scholarship.

The authors declare that there are no conflicts of interest.

Chapter Exercise 1

1. Explain the term "biocompatibility" in metallic biomaterials.
2. What are the two unique behaviors of NiTi alloys that make them promising for a variety of implant applications?
3. Which of the following alloys contain allergic and carcinogenic elements?
   (a) Ti-13Nb-13Zr
   (b) Ti-6Al-7Nb
   (c) Co–20Cr–15W–10Ni
4. Explain "stress shielding" in metallic hip implants and its potential consequences.
5. Which of the following implant materials can possibly exhibit the stress-shielding effect when implanted as hip prostheses?
   (a) Ti-15Mo (annealed)
   (b) Ti-13Nb-13Zr (aged)
   (c) Co-Cr-Mo (ASTM-F75)
6. What are the advantages of using Ti alloys over other metallic biomaterials for orthopedic implant applications?
7. Sort the elastic modulus of the following biomaterials in a descending order: (1) AZ91D magnesium alloy (AZ91D), (2) CP-Ti, (3) Co-Cr-Mo alloy (ASTM-F75) (Co-Cr-Mo), and (4) stainless steel (316L).
   (a) AZ91D > CP-Ti > Co-Cr-Mo > 316L
   (b) CP-Ti > AZ91D > Co-Cr-Mo > 316L
   (c) 316L > AZ91D > CP-Ti > Co-Cr-Mo
   (d) Co-Cr-Mo > 316L > CP-Ti > AZ91D
8. What are the advantages of using β-type Ti alloys over α-type Ti alloys for orthopedic applications?
9. Which of the following sets of properties should load-bearing implant materials have?
   (a) High elastic modulus, high fatigue strength, high tensile strength, high wear resistance, and high corrosion resistance
   (b) Low elastic modulus, high fatigue strength, high tensile strength, high wear resistance, high corrosion resistance
   (c) High elastic modulus, high fatigue strength, high tensile strength, low wear resistance, high corrosion resistance

Chapter Exercise 2

1. Explain the term "osseointegration" in metallic biomaterials.
2. Which of the following biomaterials exhibit the lowest wear resistance?
   (a) CP-Ti (Grade 1)
   (b) Co–20Cr–15W–10Ni
   (c) Stainless steel (316L)
3. What is the effect of interstitial oxygen atoms on the mechanical properties of Ti alloys?
4. Which of the following Ti alloys exhibit better cold-forming ability?
   (a) α-type Ti alloys
   (b) β-type Ti alloys
5. Why is fatigue strength important for metallic biomaterials?
6. Why do surface properties of Ti alloys differ from their bulk properties?
7. Which of the following contains information on critical anodization parameters?
   (a) Applied potential, type of electrolyte, time, temperature
   (b) Laser pulse intensity, laser energy, exposure time
8. What are the most commonly used coloring methods for Ti alloys?
9. What are the key steps involved in the additive manufacturing of Ti structures?

Chapter Exercise 3

1. Which of the following materials exhibit shape memory property?
   (a) CP-Ti (Grade 1)
   (b) NiTi alloy
   (c) Stainless steel (316 SS)
   (d) Co-Cr-Mo (ASTM-F75)
2. Which of the following techniques can fabricate complex Ti geometrical shapes?
   (a) Powder metallurgy
   (b) Additive manufacturing
   (c) Casting
3. What are the complications of using stainless steels for orthopedic applications?
4. Why cannot α-type Ti alloys be strengthened by heat treatment?
5. Porous Ti alloys with the desired porosity ratio and pore size may be produced in the required geometric shape without the use of any space-holder material via:
   (a) Casting
   (b) Selective laser sintering
   (c) Powder metallurgy
6. Which of the following is an additive manufacturing process?
   (a) Cold rolling
   (b) Hot isostatic pressing
   (c) Electron beam melting
7. Co-based alloys have higher wear resistances than Ti alloys?
   (a) True
   (b) False
8. Which of the following methods is commonly used to grow oxide nanotubes on Ti alloys?
   (a) Forging
   (b) Anodization
   (c) Additive manufacturing
9. What are the key strategies to avoid stress shielding in orthopedic surgeries?

1.3.3B
Stainless Steels

PHILLIP J. ANDERSEN

Andersen Metallurgical, LLC, Madison, WI, United States

Overview

Stainless steel refers to the family of iron-based alloys having appreciable concentrations of nickel and chromium alloying elements. The term stainless derives from the corrosion resistance afforded by the protective surface oxide layer attributable to these alloying elements. Specific stainless steels are useful for biomedical applications due to their desirable shaping, joining, and mechanical properties, acceptable corrosion resistance, durability, and manufacturing economics.

History

Iron-based tools and weapons have been used since the end of the Bronze Age and the beginning of the historical record. Iron is a particularly advantageous material because material hardness and tensile strength are readily controlled by appropriate heating and quenching. A major disadvantage of iron is its propensity to react with oxygen to corrode (rust) and lose desirable mechanical properties. Humans recognized these characteristics for more than two millennia and this limited use of iron for many applications (prohibited it for biomedical use).

Discovery within the past century, showing that adding appreciable amounts of chromium and nickel to iron produced a new alloy (now known as stainless steel), was an extraordinary technological development enabling many new uses of iron-based alloys in almost every area of human endeavor, especially biomedical. While there are a large number of different types of stainless steels available commercially, only a few of these alloys have properties that enable their use as biomaterials for implantable devices. Use of stainless-steel implants began in the 1920s and 1930s and applications for stainless steels expanded as new medical procedures and material refinements were developed.

Composition and Types

Stainless steel is an iron-based alloy that contains an appreciable percentage of chromium and nickel. There are three main classes of stainless steels: austenitic, ferritic, and martensitic. These classes are differentiated by their microstructure. Austenitic stainless steels have austenite (gamma-phase iron) as their primary phase and contain chromium and nickel (sometimes manganese and nitrogen also). The 300-series of stainless steels, i.e., Types 301 to 304, Type 316 and Type 347, are those most commonly used for biomedical purposes because of their toughness, durability, ability to be joined by welding, corrosion resistance, and manufacturing economics (ESPI Metals, 2019).

The basic composition of austenitic stainless steels is exemplified by Type 302 stainless steel. This alloy is composed of iron with 18% chromium and 8% nickel added. Austenitic steels are amenable to work hardening but cannot be hardened by heat treatment. In addition to favorable corrosion resistance and mechanical properties, austenitic stainless steel is desirable for implanted devices because it is nonmagnetic and thus has minimal or no interactions with the intense magnetic fields used in magnetic resonance imaging (MRI). The most familiar austenitic stainless steel used for surgical implants is Type 304, which contains 18%–20% chromium and 8%–10% nickel (National Specialty Alloys, 2011). Ferritic and martensitic stainless steels, as well as precipitation-hardened and cast stainless steels, lack the desirable corrosion and mechanical properties of austenitic stainless steels. For these reasons, they are not commonly used for biomedical applications and will not be discussed further.

Composition of stainless steels used for biomedical applications is closely controlled because under some processing conditions, it is possible to form different phases within the austenitic stainless-steel alloys, e.g., delta ferrite (which is magnetic). Modest amounts of heating and material displacement can occur for delta ferrite phases when exposed to the large magnetic fields accompanying MRI. Such localized heating or material motion in implants in patients exposed to high magnetic fields during MRI is deleterious, hence the need to control the composition of stainless-steel alloys used for implants.

Structure

Metals, including stainless steel alloys, are characterized by a high percentage of crystallinity. The constituent crystalline structures in metals have one of three basic types of unit cells: face-centered cubic, body-centered cubic, or hexagonal close packed. Stainless steels used for implants are face-centered cubic (Fig. 1.2.3.2, Chapter 1.2.3). Table 1.3.3B.1 shows the ranges of chemical compositions specified for several common implantable stainless steels. Chromium is present in these alloys and its primary purpose is to form a protective Cr_2O_3 surface layer (passive film) that confers corrosion resistance. Since chromium stabilizes the ferrite (body-centered cubic) phase, other alloying elements are added to stabilize the desired austenite phase. This objective is attained by addition of nickel, manganese, and nitrogen. Nitrogen added as an alloying element to stainless steel also increases mechanical strength and corrosion resistance. Molybdenum additions have a beneficial impact on the pitting corrosion resistance of stainless steels.

Carbon content in stainless-steel alloys must be limited to small percentages (the "L" in 316L designates low carbon) to prevent formation of chromium carbides. Formation of these carbides can result in a phenomenon known as sensitization. If sufficient carbon is available, chromium carbides can form when austenitic stainless steels are held at temperatures in the range of 450–815°C. The time required to form these carbides depends on temperature. Under select time and high-temperature conditions, carbides tend to form preferentially along grain boundaries, leaving the adjacent areas with depleted chromium levels. Such chromium-depleted areas then become prone to corrosion and this can lead to macroscopic material (implant) failure. Slow cooling after welding is a classic means by which sensitization can occur when time and cooling rates are unmanaged.

Examination of the chemical compositions of surgically implantable stainless steels (Table 1.3.3B.1) shows variability with time and alloy selection. While 316 and 316L stainless steels have been used successfully for implants for many decades, stronger and more corrosion-resistant alloys have subsequently been developed. The alloys, e.g., Rex 734 (also known as Ortron 90) and 22-13-5, were developed in the 1980s. They contain higher levels of chromium, manganese, and nitrogen compared to 316L, leading to improved mechanical properties and enhanced corrosion resistance. Recent concerns for adverse (allergic) patient responses to nickel (see Orthopedic Applications, Chapter 2.5.4 for additional discussion of this topic) have led to the development of stainless steels that are essentially nickel free. One example is BioDur 108 (BioDur, 2008), a stainless-steel alloy that uses manganese and nitrogen instead of nickel to stabilize the austenite phase. The nitrogen level in this alloy is much greater than the level found in the Type-300 family of stainless steels.

Structure, Composition, and Processing Effects on Mechanical Properties

The mechanical properties of metals and alloys depend on their structure, chemical composition, and processing history. To understand how these factors influence mechanical properties, consider the mechanisms involved when permanent (plastic) deformation occurs. Plastic deformation results from mechanical stress-induced movement of atoms within the crystalline structure of a metal. These movements result in irregularly distributed atoms that cause defects or disturbed regions in the crystal lattice. These disturbances are known as "dislocations." Subsequent strain-induced movement of atoms in the presence of dislocations is typically more difficult, and in this event the mechanical properties of the material change. Typical changes accompanying increased dislocation density include increases in yield strength and decreases in ductility.

Chemical composition of an alloy influences mechanical properties by a process known as solid solution strengthening. Metallic alloying elements in stainless steels, i.e., chromium, nickel, etc., replace iron atoms at random locations within the crystal structure. Since the replacement atoms differ in size compared to iron atoms, the crystal lattice can be distorted. This distortion makes material deformation via dislocation movement more difficult and this also increases yield strength as well as generally decreases ductility. Smaller atoms, such as nitrogen, fit within the gaps between the larger metallic atoms and for this reason they are often referred to as interstitials. Additions of these chemical species leads to substantial strength increases due to interactions between solute atoms and dislocations.

Processing also affects the mechanical properties of stainless steels. While processes are commonly used to alter mechanical properties of other iron-based alloys, e.g., aging reactions during heat treatment, such processes are not applicable to austenitic stainless steels. Instead, material strengthening mechanisms such as work hardening, also known as "cold working," are used. Work hardening involves repeated mechanical stresses applied to an unheated material. Work hardening occurs by mechanical stress-induced introduction of increasing amounts of dislocations. As the percentage of dislocations increases, motion of these dislocations becomes more difficult as more dislocations interact within the material. As the material continues deforming by the applied mechanical stress, increasing quantities of dislocations develop within the grains of the alloy. If the deformation process takes place at high temperatures typical of the large-scale processes used to produce metal products, or if the material is heated above its recrystallization temperature after deformation, then the dislocations are removed by formation of new, annealed grains (recrystallization). Deformation at lower temperatures does not eliminate dislocations. As the density of dislocations within the material increases, they interact causing increasing difficulty for further dislocation motion. This leads to increases

TABLE 1.3.3B.1 **Compositions of Common Implantable Stainless Steels (Weight Percent)**

Alloy	Cr	Ni	Mn	Mo	C	N	Nb	V	Si	Cu	P	S
316L ASTM F138, ISO 5832-1	17–19	13–15	<2 max	2.25–3	<0.030	<0.10	–	–	<0.75	<0.5	<0.025	<0.010

• **Figure 1.3.3B.1** Microstructures of annealed 316L (*left*) and ~30% cold-worked 316L (*right*). Deformation within many of the grains of the cold-worked material is evident.

in strength and reductions in ductility. More information on solid solution strengthening and work hardening can be found in materials science textbooks (Hosford, 2005; Meyers and Chawla, 2008).

Evidence of mechanical stress-induced deformation within the grains of a moderately cold-worked 316L sample is shown in Fig. 1.3.3B.1. This compares the structure of annealed and ~30% cold-worked 316L. The amount of cold work is routinely specified by the percentage reduction of area, i.e., $(A_i - A_f/A_i) \times 100$, where A_i is the initial cross-sectional area of the product and A_f is the final cross-sectional area. As the amount of cold work increases, strength parameters (yield strength and ultimate strength) increase (along with hardness), while ductility decreases. This behavior provides designers with the ability to specify a wide range of mechanical properties by proper selection of alloy composition, processing temperature, and amount of cold work. Table 1.3.3B.2 lists approximate tensile and fatigue strength properties for some implantable stainless steels produced under different conditions. These data show the influence of chemical composition and amount of cold work on mechanical properties of stainless steels.

There are limits to the uniformity of the cold-working response of a material. This limit is a function of the material cross-sectional area. Practically speaking, this means that a large cross-section may have a cold-work gradient such that the exterior regions of the material may be more heavily worked than the interior regions. Another effect of cold working is that heavily worked stainless steels, such as Types 304 or 305, can become magnetic due to a stress-induced transformation of crystal structure from austenite (nonmagnetic) to martensite (magnetic). This can have pronounced negative results if fragments of these alloys, routinely used as guide wires, fracture and separate during an invasive clinical procedure (FDA Public Health Notification, 2008). It is also important to realize that elevated temperature processes such as welding will result in softening of a cold-worked material and reduction of mechanical properties to annealed levels.

A high level of fatigue strength is necessary for many stainless-steel medical devices (see Chapters 1.2.3 and 1.3.3 of this volume for more information on mechanical fatigue). The fatigue properties of metallic materials depend on a number of factors, including composition, grain size, processing history, surface finish, and test method. The fatigue data shown (Table 1.3.3B.2) provide approximate relative values; these data should not be used for implant design purposes since the properties of specific devices are strongly influenced by manufacturing processes, product design features, heterogeneities in raw materials, and variability in device manufacturing processes.

Corrosion

Corrosion (oxidation) is a persistent materials-engineering consideration because this ubiquitous process causes loss of desirable electrical, chemical, mechanical, or thermal properties. Corrosion is even more important for biomedical applications because in addition to loss of desired material properties, adverse cellular responses may occur when metal ion corrosion products interact with biological tissues. Corrosion-related loss of properties or adverse cellular responses to corrosion-released metal ions may cause failure of the implant.

Except for noble metals such as gold or platinum, commonly used implantable metals and alloys rely upon protective oxide films to limit corrosion to acceptable levels. These oxides are commonly referred to as passive films. They are thin (typically less than 100 microns), dense, adhere strongly to the metal alloy substrate, and limit transport of corroding metallic ions to the implant surface and into the body. Alloys containing substantial amounts of chromium (austenitic stainless steels and implantable cobalt base alloys) form a Cr_2O_3 passive film, while alloys rich in titanium (titanium alloys and Nitinol) form a TiO_2 passive film.

The internal milieu of the human body presents a hostile environment to artificial biomaterials. Given the highly corrosive nature of most body fluids, additional corrosion resistance beyond that afforded by Type 304 stainless steel is frequently needed. For such applications, Type 316 or Type

TABLE 1.3.3B.2 Approximate Mechanical Properties of Stainless Steels

Alloy	Material Condition	Ultimate Tensile Strength (MPa)	Yield Strength (MPa)	% Elongation	10^7 Cycle Endurance Limit (MPa)	References
316L	Annealed	550	240	55	180	Shetty and Ottersberg (1995)
316L	30% cold worked	896	827	20	380	Shetty and Ottersberg (1995)

316L stainless steel is appropriate. Alloy Type 316 or 316L is an austenitic stainless steel typically composed of iron and 12% nickel, 17% chromium, 2.4% molybdenum, 2% magnesium, and less than 0.08% carbon. The higher nickel and molybdenum content in Type 316 stainless steel provides superior overall corrosion resistance compared to Type 304, especially with regard to pitting and crevice corrosion in chloride environments. In addition, Type 316 or 316L provides excellent mechanical properties as well as outstanding formability and weldability. High-temperature benefits of Type 316 stainless alloys are also useful for manufacturing bone drill bits and bone saw blades.

In general, austenitic stainless steels are not as corrosion resistant as either cobalt–chromium alloys or titanium alloys. The more recent stainless-steel alloys, e.g., 22-13-5, Rex 734, and BioDur 108, exhibit improved corrosion resistance compared to 316L, due to their greater concentrations of Cr and N. A metric for relative corrosion resistance is the pitting potential; this is measured by an anodic polarization test. Pitting potentials vary depending on testing conditions, but one study observed 346 mV for 316L, 1030 mV for 22-13-5, and 1120 mV for BioDur 108 (Zardiackas et al., 2003). Another factor influencing corrosion of stainless steels is the presence of foreign particles (inclusions). Inclusions are typically oxide particles, such as alumina or silicates formed during the initial melting of the alloy, which become trapped within the material during subsequent processing. Since these inclusions have different corrosion behavior compared to the host alloy, they can act as corrosion initiation sites if they occur on the implant surface. Careful control of alloy melting and subsequent processing, as noted in standardized specifications (e.g., American Society for Testing and Materials, ASTM) for stainless steels, is required to minimize inclusions within these alloys.

Corrosion occurs by several specific mechanisms, i.e., uniform corrosion, pitting corrosion, crevice corrosion, intergranular corrosion, stress corrosion cracking, and galvanic corrosion. The most familiar everyday experience is a relatively even layer of rust on the surface of an iron bar exposed to the elements—this is a form of uniform corrosion. Pitting corrosion, a separate mechanism, deserves special attention due to the difficulty of predicting, detecting, and characterizing this form of corrosion. Pitting corrosion occurs when the protective oxide layer fails in a localized region on the surface of a metal. The oxidation that preferentially occurs in this region can lead to the formation of a focal deficit (hole) in the material. Even small amounts of pitting corrosion-induced material defects can ultimately lead to gross failure of the implant, particularly those subjected to repetitive mechanical loads.

To quantify the potential for pitting corrosion, an empirical relationship estimates the contribution of alloying elements to pitting corrosion resistance of austenitic stainless steels. This relationship, i.e., the pitting resistance equivalent number or PRE, depends on the percentage of chromium, molybdenum, and nitrogen in the alloy. For low nitrogen levels an appropriate approximation of the PRE is PRE = % Cr + 3.3 × % Mo + 16 × % N; at nitrogen levels nearing 1% an appropriate approximation is PRE = % Cr + 3.2 × % Mo + 8 × % N (Gebeau and Brown, 2001). Higher PRE numbers indicate improved resistance to pitting corrosion.

Crevice corrosion is another localized form of corrosion, but occurs chiefly due to a stagnant microenvironment that in turn causes a difference in ion concentration between two areas of a given metal. Here, corrosive agents may enter a given local microenvironment, but oxygen is prevented from entering this microenvironment thereby preventing repassivation (reformation of the protective oxide layer). The potential for crevice corrosion can be minimized by careful attention to implant design and consideration of all local microenvironments.

Galvanic corrosion occurs when two dissimilar metals are in electrical contact in an electrolytic (fluid-conducting) environment. Galvanic corrosion may occur even when two ostensibly similar corrosion-resistant alloys are in electrical contact in the body if such alloys have different alloying elements, different concentrations of the same alloying elements, or different processing methods. Galvanic corrosion can be avoided by careful management of stainless-steel alloy composition and processing.

Summary

Iron-based alloys were unsuitable for human implantation because rapid oxidation in vivo deteriorated their mechanical properties and released excessive quantities of corrosion products. The introduction of engineered quantities of chromium and nickel to iron for the creation of corrosion-inhibiting oxide layers revolutionized biomaterials by the creation of new "stainless-steel" alloys for human implants. A select group of austenitic stainless steels is especially suitable for human implantation in biomedical devices because these alloys offer favorable corrosion resistance, MRI compatibility, and desirable mechanical properties that collectively support long-term implant use in the human body. The favorable biological performance (Black, 2005) of these stainless-steel alloys is not only conferred by the types and concentrations of particular alloying elements, but also by the processing of these alloys, which collectively produces a desirable material structure conferring these favorable material properties. Although 316L is one of the oldest and most common alloys used for human implants, recent developments have led to newer stainless steels with improved mechanical strength and enhanced corrosion resistance. Alloy element type and concentration, as well as postprocessing, permits the resulting material to have a wide range of properties engineered for a specific biomaterial application. A soft, ductile, annealed condition is useful for implants requiring intraoperative contouring by the surgeon, while a higher strength, less ductile, work-hardened material can be specified for implants exposed to high amplitude fatigue loading. While ASTM and ISO standards provide valuable guidance for alloy composition, processing, machining, sterilization, and use, information obtained from retrieval studies attending long-term human usage is also important for advancing the design and biomedical applications of stainless-steel alloys for human use.

CoCr Alloys

AMIT BANDYOPADHYAY, KELLEN D. TRAXEL, JOSE D. AVILA, INDRANATH MITRA, SUSMITA BOSE

W. M. Keck Biomedical Materials Research Laboratory, Washington State University, Pullman, WA, United States

Introduction

Degenerative joint disease and rheumatoid arthritis are the most common clinical conditions in which cobalt–chromium (CoCr) implants are used. In recent years, arthroplasty has seen a significant jump in numbers and is projected to grow in the future, increasing the number of implants and technological improvements needed for future patients. From 2005 to 2030, the demand for total hip arthroplasty (THA) and total knee arthroplasty (TKA) is projected to increase by 174% to 572,000 total, and 673% to 3.48 million total, respectively (Kurtz et al., 2007). In 2014, in the most recent study released by the Mayo Clinic, it was estimated that 7.2 million Americans were living with knee and hip implants; that is, 4.7 million TKAs and 2.5 million THAs performed on Americans (Maradit-Kremers et al., 2014). In response, orthopedic device manufacturers have made headway in addressing some of the issues that arise from introducing artificial materials into the body for articulating surface applications (relative motion between two surfaces). Namely, there has been significant regulatory development calling for additional bio-tribological, mechanical, and electrochemical testing due to ionic leaching from wear-induced damage. Because of this, extensive studies have been performed to understand the cellular response to ionic release of Co^{2+} and Cr^{3+} depending on particulate size range, concentration, pH, and galvanic potential at the implant site. In addition, new electrochemical testing methods have been developed to better understand the complex reactions that occur at the implant site during wear degradation, the methods of which are presented later in this Introduction. The most common CoCr-based alloys are of the cobalt–chromium–tungsten (Co-Cr-W) and cobalt–chromium–molybdenum (Co-Cr-Mo) types, where chromium provides a passive Cr_2O_3 surface oxide that is the same corrosion-resistant film that forms for "stainless" steels, and W and/or Mo both act as strengthening elements within the CoCr alloy system. The best known Co-Cr-Mo ternary system is the Co27Cr6.1Mo (ASTM-designated "F75") alloy owing to the excellent combination of properties that it exhibits for biomedical applications. Because of its widespread success, it has seen little change in the composition except for strict regulation on the carbon content, which affects the amount and nature of the intergranular carbide formation. Tables 1.3.3C.1 and 1.3.3C.2 outline some of the common grades and compositions, as well as their general properties.

Among the various characterization techniques for biomedical devices in articulating surface applications, electroanalytical methods (EMs) have provided a simple and standardized way to analyze and quantify the electrochemical performance of many biocompatible materials. These techniques fall within the field of analytical chemistry or the branch of chemistry that identifies and quantifies matter. EMs examine an analyte–the species of interest in an analytical test–by quantification of current and/or potential within an electrochemical cell. Specifically, in tribocorrosion testing, the analyte is generally the metal or metal–composite sample. In performing a tribocorrosion test the typical setup is of a three-electrode convention as seen in Fig. 1.3.3C.1A. The different electrodes are the reference electrode (RE), the working electrode (WE, or the analyte), and a counterelectrode (CE)–most commonly made of platinum due to its high electrochemical stability. The working electrode provides the surface for the electrochemical reactions to take place and thus allow quantification of the reacting matter–the material that corrodes. A potentiostat instrument controls the potential between the WE and RE, and subsequent data acquisition. The combination of the electrolyte, three electrodes, and the potentiostat gives rise to a specific type of EC termed a "corrosion cell" and measures the corrosion properties of an analyte surface. A corrosion cell is often configured to work in biologically relevant media and can be combined with tribological (wear) testing to study tribocorrosion (Fig. 1.3.3C.1B); this is done by implementing a counter wear material, applying a load, and allowing relative motion between the WE and counter material. An example potentiodynamic polarization curves for CoCrMo alloys are shown in Fig. 1.3.3C.2.

TABLE 1.3.3C.1 Common Biomedical CoCr Alloy Grades and Their Alloy Composition

ASTM Designation	Main Alloying Elements								
	Co	*Cr*	*Mo*	*W*	*Si*	*Mn*	*C*	*Ni*	*Other*
F75 (CoCrMo)	Bal.	27.0–30.0	5.0–7.0	–	0.0–1.0	0.0–1.0	0.0–0.35	1.0	Fe
F799 (CoCrMo)	Bal.	26.0–30.0	5.0–7.0	–	0.0–1.0	0.0–1.0	0.0–0.35	0.0–1.0	Fe, Al, N, La
F90 (CoCrW)	Bal.	19.0–21.0	–	14.0–16.0	0.4	1.0–2.0	0.05–0.15	9.0–11.0	Fe (3.0 max)
F562 (CoNiCrMo)	Bal.	19.0–21.0	9.0–10.5	–	0.0–0.15	0.0–0.15	0.0–0.025	33.0–37.0	Ti, B, Fe, S, P
F90 (CoCrWNi)	Bal.	19.0–21.0	–	14.0–16.0	–	–	–	9.0–11.0	–

All properties originate from each respective ASTM standard related to the designation.

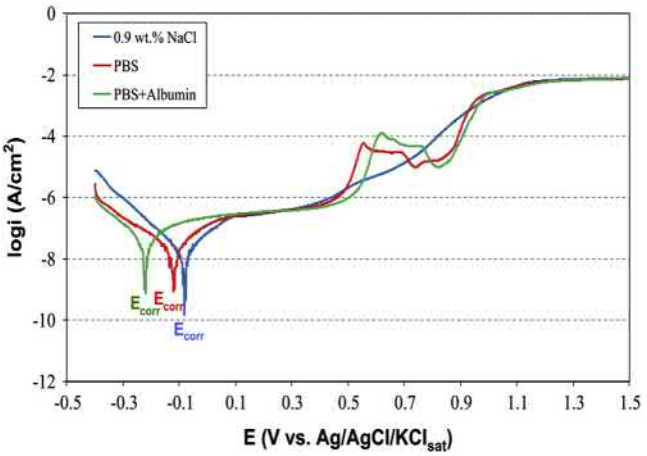
Microstructure, Mechanical Properties, and Manufacturing of CoCr Alloys

In CoCr alloys, cobalt serves as the base FCC (face-centered-cubic, α-Co) crystal structure of these alloys. On its own, it is known to have low stacking fault energy that results in relatively high strength and work-hardening rates, low damage under cyclic loading, and the ability to absorb stresses through an FCC-HCP (hexagonal closed-packed) phase transformation. These characteristics lead to its excellent wear and corrosion resistance as well as strength. Chromium provides oxidation and corrosion resistance in the form of an oxide surface layer, Cr_2O_3, as well as a major metal-carbide source, typically forming carbides in the form of Cr_7C_3 and $Cr_{23}C_6$. Chromium also provides strength to the larger solid solution when dissolved in the Co matrix, stabilizing the HCP (ε-Co) phase when present in amounts up to 30 wt.%. Tungsten and molybdenum provide general substitutional and interstitial solid-solution strength to the cobalt matrix due to their large atomic size, which significantly impedes dislocation motion. These elements also contribute to the metal carbide formation along the grain boundaries of the Co-base matrix, when present in large enough amounts. Typically, these carbides are reported as being of the M_7C_3 and $M_{23}C_6$ types, where M denotes metal and is usually considered to be taken as Cr, Mo, or W, depending on the specific alloy composition and processing route, and any secondary solution treatments. Examples of different phases that form within these microstructures are shown in Fig. 1.3.3C.3.



• **Figure 1.3.3C.2** Example of potentiodynamic polarization curves of CoCrMo alloy in varying media. Testing was conducted at 37°C in 9 g/L NaCl, PBS and PBS + albumin solutions (Espallargas et al., 2016).

The mechanical properties of CoCr alloys generally depend upon the alloying elements, processing route, as well as the thermomechanical post-processing that is used to achieve specific microstructures. As shown in Fig. 1.3.3C.4, the microstructure of cold-swaged (cold-rolled) F75 depends heavily on the heat treatment (annealing) time as well as the temperature. High-temperature annealing results in the formation of large, equiaxed grains, whereas lower temperature annealing resulted in highly refined grains. The finer grained material results in higher hardness and tensile strength, whereas the larger grained material maintains high ductility under loading. Also of note are the intergranular twins caused by the stress-induced phase transformation from γ-(FCC) to ε-(HCP). These annealing and/or solution treatments can result in microstructural homogeneity within both the Co-rich dendritic phases as well as the carbides that form along the grain boundaries of the main Co phase. It was shown that solution-annealing treatment to a hot-pressed F75 microstructure results in carbide-free grains which are prone to higher abrasive wear when compared with simply hot-pressed microstructures that contain large amounts of intergranular carbides (Chen et al., 2014). The microstructure of the hot-pressed condition can be seen in Fig. 1.3.3C.3A, where the darker phase represents the γ-(FCC) structure, and the lighter phases correspond to the carbides. It was also shown that the initial formation of an intermetallic σ phase, as shown in Fig. 1.3.3C.3B, and lamella precipitates can be removed from the microstructure after appropriate solution annealing treatments to force diffusion back into the Co-based grain structure (Giacchi, 2012). The σ phase is known to negatively affect the mechanical properties of these alloys, therefore removing it during solution treatment is of great importance within

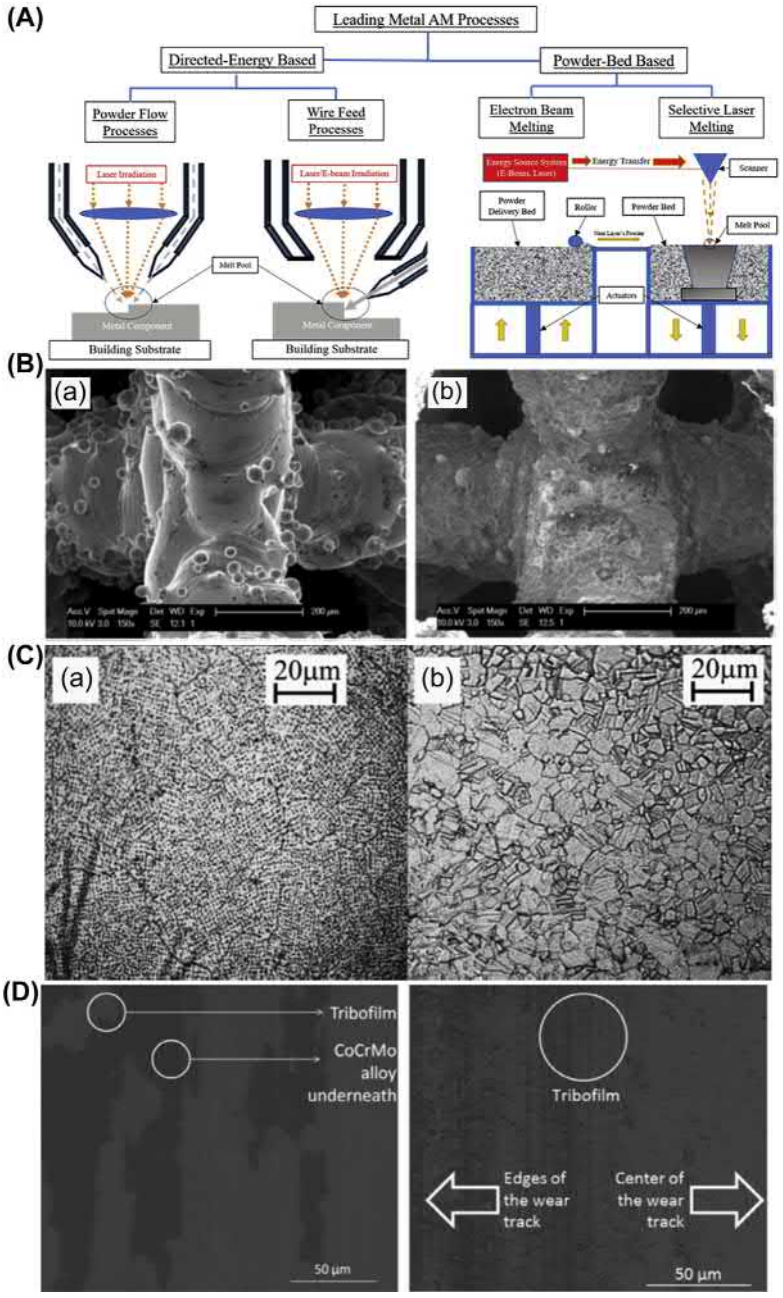
low-carbon CoCrMo alloys. Often, a compromise must be made in regard to the desired final properties in comparison with ASTM standard values.

Most CoCr implants are traditionally manufactured using investment casting or wrought processing, although alternative methods have been investigated for reducing production cost, increasing patient specificity, and enabling advanced design capabilities to increase implant longevity and performance. Castings are formed from wax molds that represent the final geometry of the implant component when the mold is covered with ceramic and hot fired with access ports, the wax burns out and a void is created where liquid metal can be cast into shape. Wrought materials are formed from ingots and shaped through various techniques. Casting alloys, while ideal for high-production volumes, are typically known for their variation in microstructure, difficulty in final machining and variations in mechanical properties in comparison to wrought materials. As shown in Table 1.3.3C.2, the mechanical properties of wrought versus cold-worked and aged F562 are significantly different when comparing the wrought versus annealed processing route. The annealing heat treatment results in larger, equiaxed grains that provide better ductility (50% elongation) at the expense of both tensile yield strength (241–248 vs. 1586 MPa) and tensile (ultimate) strength (793–1000 MPa). Note that the range is highly dependent on the annealing temperature and time (as systematically demonstrated in Fig. 1.3.3C.4). Powder-based metal injection molding has also been investigated for manufacturing F75 and demonstrated comparable fatigue properties with increased tensile strength (1000 MPa) and ductility (40%) due to the more homogeneous microstructure in comparison to casting after post-processing and hot isostatic pressing (HIP). While these methods have shown success in producing materials that are biocompatible with adequate mechanical properties, the increase in implant failure after 10–15 years has stimulated the development of new manufacturing techniques that can simultaneously increase implant life and reduce costs for patient-matched implants.

3D Printing of CoCr Alloys

The advent of additive manufacturing or 3D printing technology has provided a layer-by-layer processing route that can introduce patient specificity as well as surface modification that are not possible using traditional methods (Bose et al., 2018). Metal-additive manufacturing processes applicable to



• **Figure 1.3.3C.5** Additive manufacturing for biomedical CoCr alloys and aspects associated with process evaluation. (A) Different AM-based processing techniques (Bandyopadhyay and Traxel, 2018). (B) Comparison of nonetched (left) to etched (right) microstructures of interconnected pores in SLM-F75 material (Van Hooreweder et al., 2017). (C) Grain size comparison of EBM F75 to wrought-processed F75 (Bordin et al., 2014). (D) Materials innovation using DED-processing (Sahasrabudhe, 2018).

biomedical applications (as shown in Fig. 1.3.3C.5A) can be combined into two distinct categories, the first being powder-bed based and the second being directed-energy-deposition (DED) methods. The DED methods utilize a powder or wire feedstock material that is melted, cooled, and rapidly solidified in a defined manner to create a layer of a component, with the deposition head moved upward to deposit subsequent layers. The DED process was utilized to make CrCo alloys for load-bearing implants and showed that a compositional gradient can be established from Ti alloys to CoCr alloys during the direct digital manufacturing (España et al., 2010). Powder-bed methods utilize a powder delivery bed and roller system to provide a thin layer of powder which is melted by a laser or electron beam and creates a single layer. After the layer is traced out by the heat source, the powder-bed side drops a layer thickness, and the next layer of powder is rolled over from the powder delivery-bed side (Bandyopadhyay, 2018). In general, powder-bed processes utilize lower layer thickness and can create finer features than the DED processes, lending themselves well to designed porosity and internal features within patient-specific implants. Directed-energy processes are known for their ability to quickly change feedstock material as well as process metal–matrix composites, which lends them well

toward material development and testing for implants (Stenberg et al., 2018). While additive manufacturing techniques are envisioned to be the future of low-volume, patient-specific implant fabrication, challenges such as defects, residual stress, and surface roughness play a vital role in the successful implementation of this process. When parts are produced, excess powder around the parts must be removed as well as partially melted particles on the surface of the component, to ensure that no particles are loosened from the surface and put the patient's health at risk from infection or other complications. The effects of chemical etching were studied on powder removal of selective-laser-melted (SLM-processed) F75 scaffolds with interconnected pores (see Fig. 1.3.3C.5Ba and 1.3.3C.5Bb) (Van Hooreweder et al., 2017). As shown in the pre-etching images (Fig. 1.3.3C.5Ba), free particles have a tendency to sintering onto the surface of the melted and resolidified component. Etching using a combination of HCl and H_2O_2 (Fig. 1.3.3C.5Bb) resulted in a smoother surface finish without a significant compromise in fatigue performance, a property that is known to be highly dependent upon surface condition. For the same F75 material, it was demonstrated that using the SLM-processing route, changing the layer thickness from 30 to 60 µm resulted in no effect on the fatigue properties despite lower resolution and higher surface roughness, indicating that streamlining this process is possible for manufacturers of CoCr alloys in multiple different patient-specific geometries and applications (Cutolo et al., 2018). Furthermore, because of the high cooling rates that are inherent during laser-based additive manufacturing, the grain structure can vary significantly from wrought or other traditionally processed alloys and can have an effect on the machinability of the material in the as-processed condition. It has been reported that these differences (see Fig. 1.3.3C.5C) can make machining more difficult for additively processed parts than a wrought specimen of larger grain size (Bordin et al., 2014). The EBM-processed material exhibited extensive adhesive wear on the tool and resulted in cracking within the printed material. This study helps to demonstrate the importance of controlling processing parameters as well as post-processing conditions in order to achieve appropriate microstructures for machining of additively manufactured implant materials.

Materials innovation is also capable of using additive manufacturing, particularly in the case of DED systems. The ability to deposit both premixed powder compositions as well as dynamically change the composition during printing can result in unique microstructures and properties that are advantageous for improving the biomedical relevance of these materials. It was demonstrated that premixing 1–3 wt.% calcium phosphate powder into CoCrMo alloy during laser-additive manufacturing results in an in situ tribofilm on the surface of the printed component during wear testing (Sahasrabudhe, 2018). This film contributed to a lower coefficient of friction and wear debris during testing, providing a surface that is less prone to ion release during the lifetime of the implant material, and therefore decreasing the likelihood of a required secondary procedure to alleviate complications between the patient's tissue and the implant material. This concept demonstrates a combination of materials development, design innovation, and cost reduction, to provide the best possible implant for the patient, which is truly the future of biomedical materials manufacturing.

Bio-Tribocorrosion of CoCr Alloys

One of the more relevant tests using the corrosion cell setup is measurement of the equilibrium potential or open-circuit potential (OCP). Once material is placed in the corrosion cell with its respective media, a spontaneous potential difference between WE and RE exists and may be measured. A typical setup is demonstrated in Fig. 1.3.3C.1A. For this test, an idle time is implemented to allow the potential to reach an equilibrium (Fazel et al., 2015), which is dependent on the coupled half-cell/redox reactions and can fluctuate depending on environmental factors such as oxygen, salt concentration, temperature, and the pH of the testing media. The spontaneous potential can be correlated to the chemical reactions taking place by the Nernst equation, thus allowing the proportional chemical activity to that of potential change or monitoring of the OCP. In OCP testing, the circuit is considered open with no current flow, allowing for the equilibrium potential to exist under nonpolarized conditions. Shifting from the equilibrium potential is considered "polarizing the sample," and is achieved by introduction of a counterelectrode and control of the potential difference between the WE and the CE, as shown in Fig. 1.3.3C.1B. As the potential is varied, it gives rise to the concept of potentiodynamic polarization (PDP) Fig. 1.3.3C.3. The applied potential can allow for further reaction of the surface and is used to measure the corrosion potential (E_{corr}) and the corrosion current (I_{corr}), identifying passive and active states at varying potentials. Potentials below E_{corr} are classified as the cathodic domain, where reduction of water and dissolved oxygen determine the current, as shown in Fig. 1.3.3C.2. The second domain is characterized when a shift from cathodic current takes place to anodic current at E_{corr}, varying the applied potential in a more positive direction relative to the WE. The third domain is the passivation region; steadier current values are observed and succeed the E_{corr} peak. Certain shifts can be interpreted as the material exhibiting a lower resistance to corrosion if in the presence of the physiological environment, which has strong implications for biomedical applications. As observed in Fig. 1.3.3C.2, for example, a negative shift in E_{corr} is observed. The CoCr alloy displays a lower resistance to corrosion in a physiological environment. This displays the importance of EM for better understanding the behavior of such materials in biomedical applications–simple salt-based media testing will not suffice.

A typical tribocorrosion OCP curve for a CoCrMo alloy tested in phosphate buffered solution (PBS) and bovine serum albumin (BSA) was shown by Gil and Muñoz (2011). A sudden drop in potential by 200 mV and stability at a more negative potential occurs due to mechanical wear. The reduction in potential occurred due to the destruction of the passive layer of the WE, exposing the CoCrMo surface to the PBS and thereby activating dissolution of CoCrMo alloy. Similar results have also been reported for other biocompatible alloys (Fazel et al., 2015).

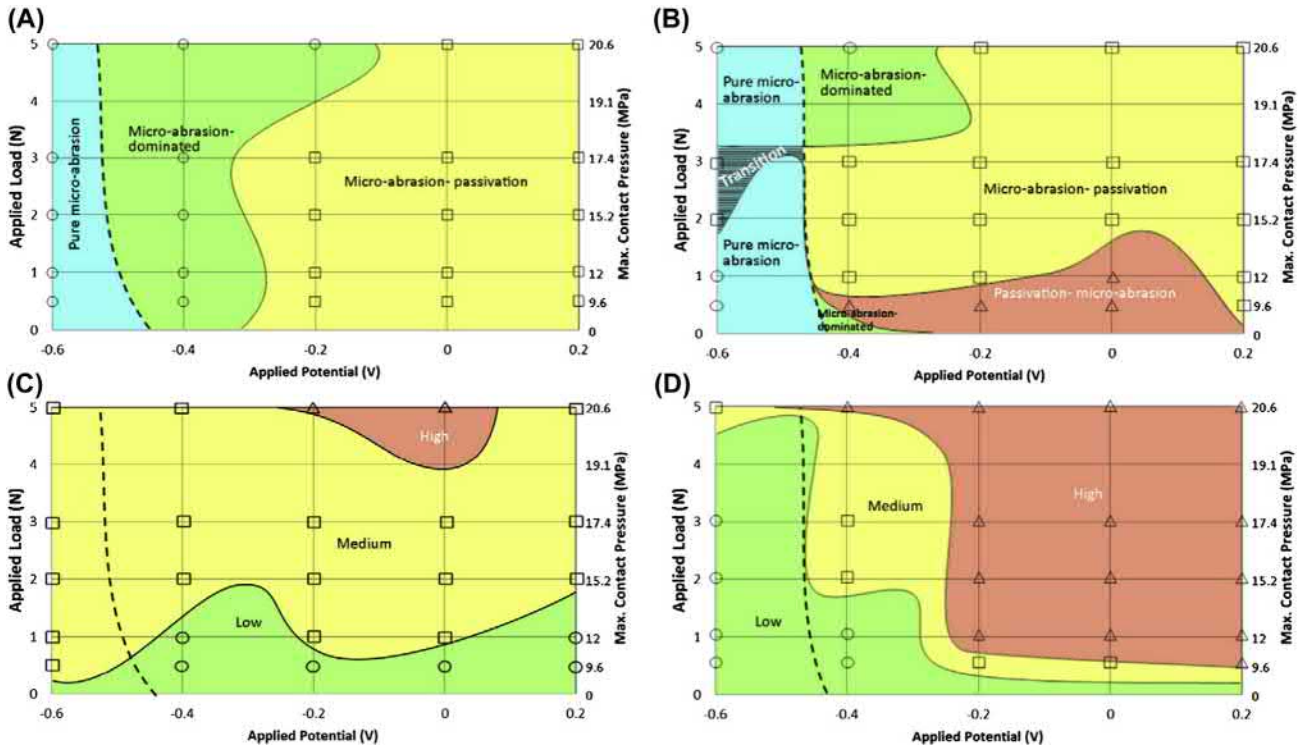
Reported results under PBS + BSA display an initial drop in OCP (depassivation) and a subsequent increase in OCP, meaning that the surface's electrochemical response is dictated by mechanical factors applied to the surface. The upward shift in OCP is due to the mixed potential of the active and unstable passive surface area attempting to reach an equilibrium. In comparison, for Ti6Al4V (Ti64), an overall negative shift in the OCP curve occurs. This shift in the OCP may be seen in Table 1.3.3C.3 for reported OCP values of Ti64. The exception is LENS processed Ti64, which at idle state exhibits a higher potential when compared with CoCr alloys but falls below during mechanical wear. The negative shift is interpreted as an increase in dissolution kinetics and results in reduced corrosion resistance at idle state and under mechanical wear conditions.

Another typical EM is performed under nondynamic polarization when a constant potential is applied and current values are measured, which are typically normalized by the exposed surface area. Unlike the potentiodynamic polarization curves, which only display the electrochemical properties of the material at idle, i.e., no mechanical wear, holding the potential constant and performing mechanical wear can display the evolution of the anodic current over time. In one example, CoCrMo alloy was tested initially at rest and then under mechanical wear with a constant applied passive potential of 0.05 V in a base solution of 0.14 M NaCl, 0.5 g/L BSA, and bovine serum (BS) (Casabá N Juliá and Muñ Oz, 2011). Upon the initiation of mechanical wear, a rise in current is observed which is due to removal of the passivation layer. Corrosion of the exposed material occurs as the passive film is regenerated but is subsequently removed. This cycle is known as depassivation/repassivation, and results in wear-accelerated corrosion, or synergistic wear. It was observed that the protein-containing solutions allowed for a third body layer to adhere to the surface, protecting the underlying metal and therefore reducing wear and corrosion by lower current values.

The application of different normal loads can allow for microabrasion corrosion (MAC) and wastage mapping. These maps are similar to a typical metal phase diagram, or Pourbaix diagram, as the stable ionic phase is identified via a potential versus pH diagram. Wastage maps are the result of weight loss as a function of applied load and potential and are derived by



• **Figure 1.3.3C.6** (A, B) MAC wear maps of CoCrMo alloy against UHMWPE ball in FCS solution at 25°C; (C, D) wastage maps (Sadiq, 2015).

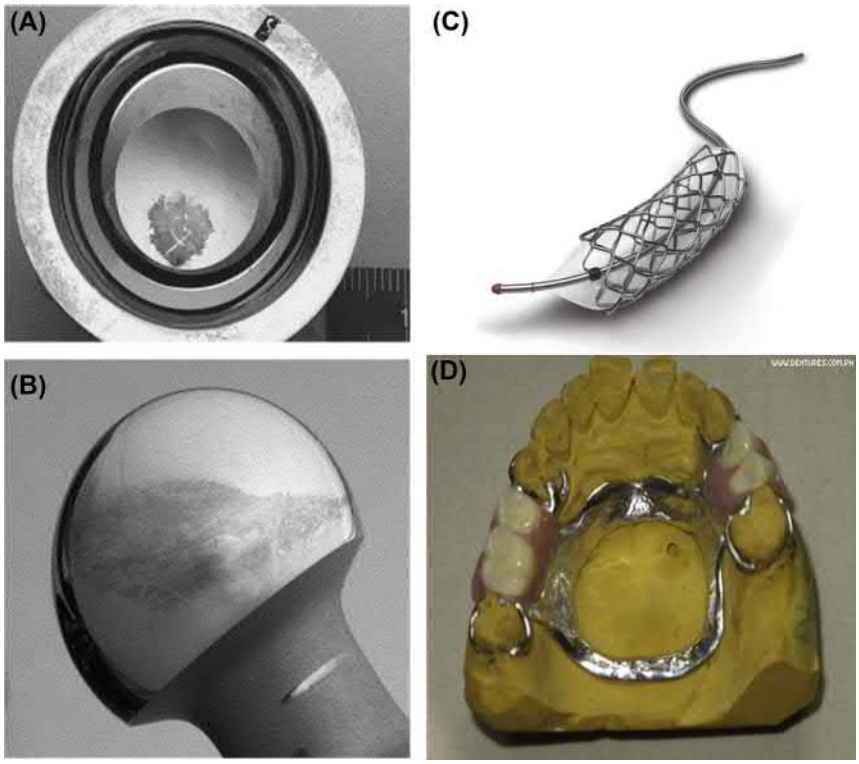
taking the ratio of weight loss due to corrosion or microabrasion corrosion. Depending on the magnitude of the ratio, regimens such as "micro–abrasion," "micro–abrasion passivation," or "passivation microabrasion" may be established (Sadiq et al., 2015) and can be seen in Fig. 1.3.3C.6. Wear regimens and transition zones are defined by the MAC maps within the testing parameters. The severity of material loss is defined by the wastage maps. Being able to develop these maps can prove useful when considering the fabrication of a medical device for load-bearing articulating applications. A major contributor to the development of these maps is volume loss. CoCr alloys have been reported to exhibit less wear volume than Ti64, and a summary of the reported wear rate values is displayed in Table 1.3.3C.3.

A final bio-tribological metric, electrochemical impedance spectroscopy (EIS), relates the effect of adsorbed species on the surface of the material as well as characterization of the passive film formed. The manner in which EIS is performed is by application of an alternating current (AC) potential signal through the material, current signal measurement, and calculation of the impedance of the system. Larger impedance values signify greater resistance to corrosion across a frequency range. In one example of a high-carbon CoCrMo alloy, higher impedance is reported in NaCl-based solutions and not so much in protein-based bovine serum (Igual Muñoz and Casabán Julián, 2010). The reason for this is the higher dissolution occurring in the NaCl solution, enhanced at a higher passive potential.

The general and most important take-away from CoCr alloys is the significant reduction in volume loss and positive shift in equilibrium potential. In comparing reported wear rates from Table 1.3.3C.3 with comparable wear tests, the results display lower wear rate values associated with CoCr alloys across the board. The reported wear rates when using UHMWPE as the counter material are approximately six times lower for a CoCr alloy than they are for Ti64. This is directly proportional to the working life of an implant and reduction of wear debris. Moreover, the positive shift in the OCP is ideal for CoCr alloys. It was previously discussed that a negative shift is indicative of reduced corrosion resistance, therefore a positive shift means increased corrosion resistance. The reason for this is the phenomenon of cathodic protection—a common electrochemical method for the protection of metals. The method typically involves what is referred to as a "sacrificial metal," which must exhibit a lower equilibrium potential than the metal needing protection. The greater the potential difference, the faster the corrosion kinetics. CrCo alloys having more positive equilibrium potential, as seen in Table 1.3.3C.3, can allow for a reduction of the drive for the corrosion mechanism to occur.

Application of CoCr Alloys in Biomedical Devices

CoCr as biomaterials were originally introduced by Austenal Laboratories (Stryker, MI) in the early 1930s for dental applications. Since then, this particular class of alloys has seen significant market demand over the past 90 years for their durability and versatility. Under the brand name of Vitallium, this class of alloys was soon adopted by the orthopedic industry because of its excellent corrosion resistance and biocompatibility. Vitallium also found its application in



• **Figure 1.3.3C.7** CoCr alloy based (A,B) McKee-Farrar prosthesis (Wimmer et al., 2003), (C) cardiac stent (Confluent Medical Technologies, 2017), (D) orthodontic wire (Cheng et al., 2010).

articulating joint arthroplasty and fracture fixation devices. In the 1970s, the alloy underwent modification in response to reports of fatigue failure in forged Vitallium.

First-generation CoCr THA implants were called Charnley prostheses, and these implants introduced an acetabular cup and small femoral head with low friction design. Later, the Harris Design 2 THA Prosthesis was brought to the market due to several recalls and failure of the Charnley prosthesis. The Harris Design 2 THA implants gained popularity by changing the original Charnley design into a collared prosthesis. These implants were also made both cemented and cementless. Following this, the introduction of tapered stem designs for THA led to better stabilization of the implant within the bony matrix. These implants were called "anatomic stems" because they incorporated an anteroposterior curve to match the bent shape of a patient's femur. The anatomic stems came to market also due to recall of the first-generation Charnley implants and showed >92% stem survivorship along with increased bony growth, reduced stress shielding, and reduced thigh pain.

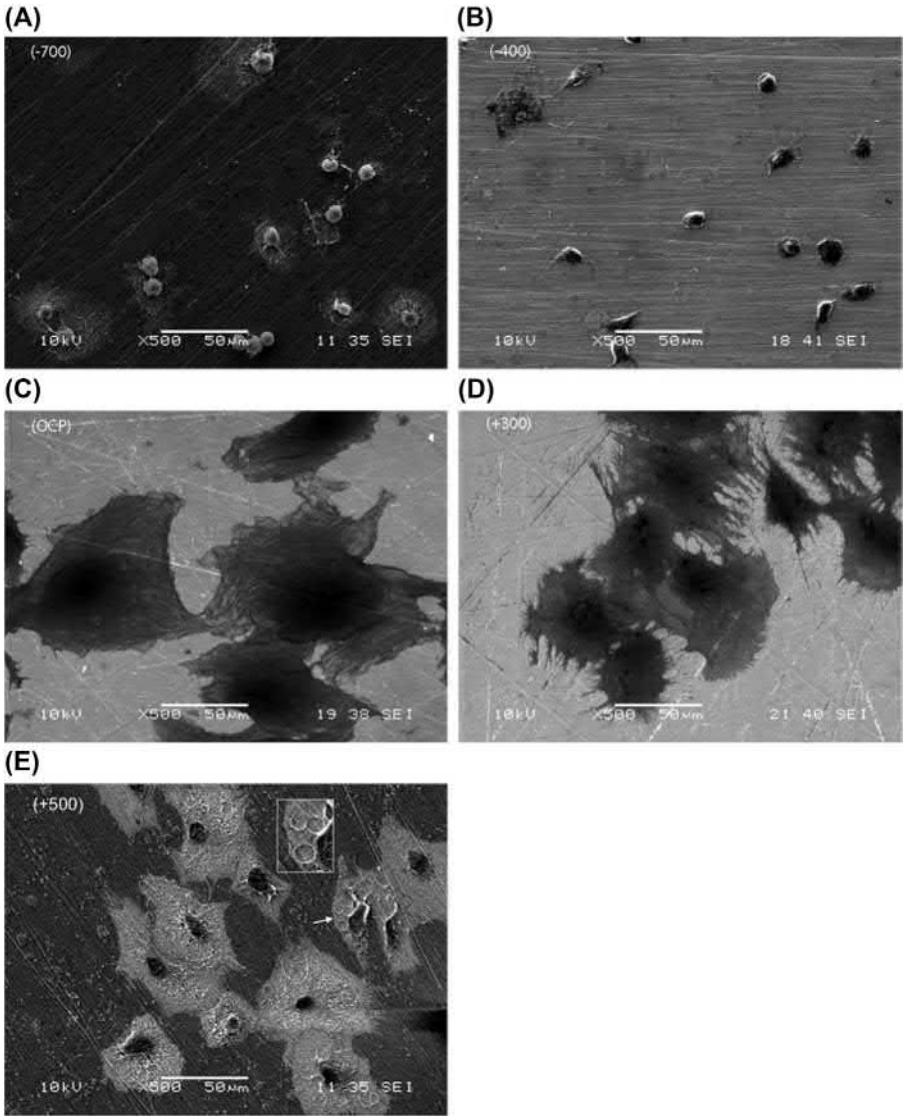
To date, CoCr alloys have been extensively used in dental, spinal, and orthopedic applications. Properties such as excellent wear and corrosion resistance, good castability, strength, and toughness make these materials viable for such applications. The first CoCr prosthetic heart valve was implanted in 1960, and lasted over 30 years due to its high wear resistance. Long-term stability, surface hardness that resists abrasive wear, and good coating properties are other key attractive characteristics for CoCr alloys to be used in biomedical devices. Several rare and noble metals in combination with CoCr possess the desired properties needed for specific applications. For example, CoCrMo (CoCr–molybdenum) alloys are used in cardiac stents (Kereiakes et al., 2003), bone plates/screws/pins (Ogawa et al., 2012) (Fig. 1.3.3C.7), orthodontic wire (Cheng et al., 2010), and some craniofacial applications due to their high wear resistance. Their application as load-bearing ankle implants, however, have been fashioned out of CoNiCrMo alloys.

CoCr alloys have comparable mechanical properties to stainless steel (another material used for biomedical orthopedic applications). Heat treatment can increase tensile and fatigue strength. However, CoCr alloys have low ductility, which can result in component failure, posing a serious concern in load-bearing applications. CoCr alloys in combination with other metals can help overcome this drawback, usually by stabilizing the Ɣ phase. The hardness and tensile strength of CoCr range from 550 to 800 MPa and 145 to 250 MPa, respectively. Table 1.3.3C.2 lists the mechanical properties of CoCr alloys in comparison with other metals used for similar applications. A complete understanding of biocompatibility, which is the most relevant property with respect to safe biological application of these implants, can provide a clear picture of the advantages and disadvantages of CoCr alloys.

Properties Leading to Biocompatibility of CoCr Alloys and Their Applications

Corrosion Resistance

Among the various material properties, corrosion resistance of CoCr alloys has gained the most significant interest in terms of

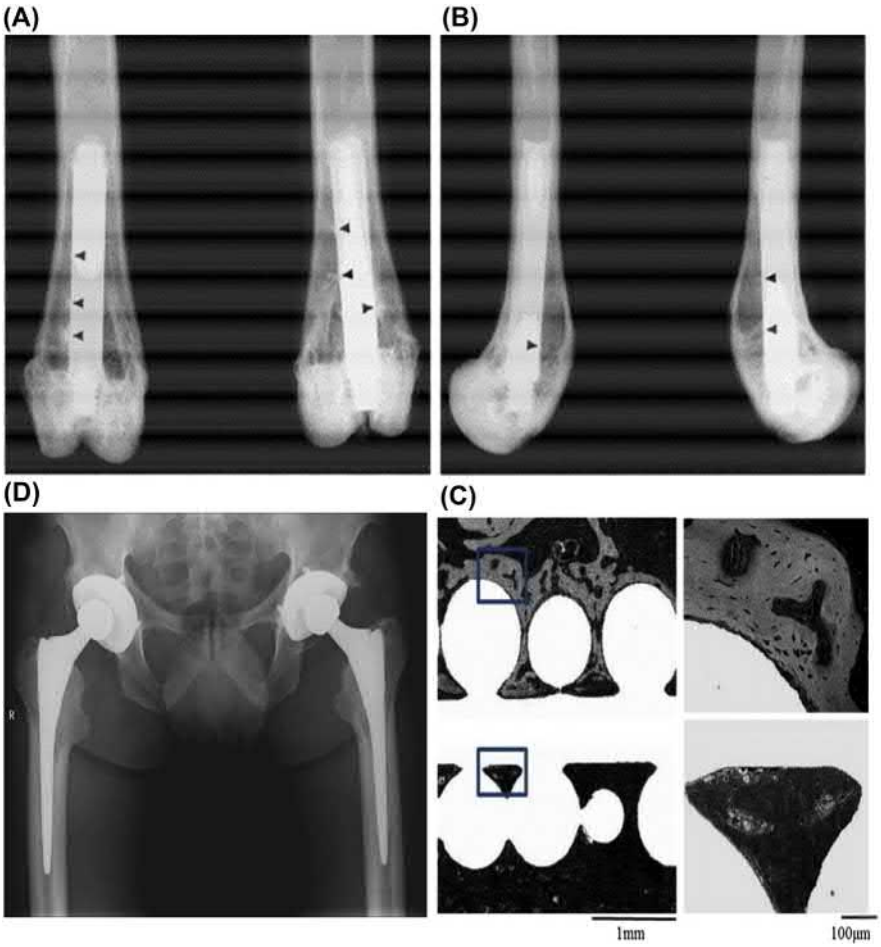


• **Figure 1.3.3C.8** Topography of MC3T3 preosteoblast cells from SEM micrographs exposed to different polarization voltages for 24h. (A, B) Negative polarization voltages show rounded MC3T3 cellular morphology indicating unfavorable conditions for cellular proliferation. (C) The open-circuit potential varies from –400mV to –200mV and shows adequate cellular flattening and attachment. (D, E) Positive/increased circuit potential shows enhanced cellular proliferation and flattened morphology.

host responses. The presence of chromium helps in self-passivation of the alloy surface as mentioned above, thereby providing corrosion resistance in devices such as dental prosthetics. Under low pH conditions, Cr ions remain associated with the alloy and are responsible for the development of the corrosion-resistant surface oxide layer (Haynes et al., 2000). Dental crown and other prosthetics run the risk of getting damaged due to chemical reactions from food and enzymes. The self-passivating chromium oxide layer on the surface of CoCr prosthetics provides resistance to such damage, thereby increasing the service life. Corrosion resistance of CoCr alloys also plays an important part in medical implants by reducing complications with irritation and immune response in the surrounding tissue.

CoCr Alloys in Biological Environments

CoCr alloys under different pH conditions result in Co^{2+} particulate leaching for at least the initial 24 h compared with Cr^{3+} ions. These alloys show markedly lower cellular toxicity at pH 4.5 due to corrosion resistance from the self-passivating oxide layer (Haynes et al., 2000). Electroactive metals, in close apposition to cellular structures, influence electrochemical processes related to cellular adhesion, proliferation, membrane transport, and other cellular redox reactions. Electrical stimulation on these materials results in cell–electrode interactive effects. Materials such as CoCr alloys, owing to their proneness to mechanically assisted corrosion, undergo large shifts in positive and negative voltage during redox reactions in a corrosive environment such as body fluid/cell culture media. The effect of these voltage changes has been shown to have positive effects on cell–material interactions between CoCr alloys and MC3T3-E1 preosteoblast cells (Haeri et al., 2012). Fig. 1.3.3C.8 shows enhanced MC3T3-E1 cell attachment and proliferation with increased circuit potential.



• **Figure 1.3.3C.9** (A,B) MicroCT images of Ti6AL4V (left) and CoCr (right) showing multiple localized bone apposition regions after 12 weeks post-implantation (Jinno et al., 1998), (B) first-generation DePuy CoCr hip implant at 10-year follow up (Learmonth, 2007), (C) electron microscope image of bone growth around CoCr implants after 3 weeks post-surgery (Ogawa et al., 2012), (D) first-generation Co-Cr implant called "anatomic stems."

CoCr implants bypass the disadvantages often encountered with the use of NiCr implants in dental prosthetic applications, which is primarily due to cytotoxic Ni ion release. CoCr femoral prostheses have also been shown to be effective for load-bearing applications in terms of stability. In in vivo conditions, CoCr alloys have good biocompatibility characterized by new bone formation as early as 3 weeks post-implantation. Lamellar contact and bony-bridge formation are characteristic responses of CoCr alloys in vivo (Fig. 1.3.3C.9A,B) (Jinno et al., 1998). Tissue engineering has also been explored with CoCr alloys using mesenchymal stem cells and differentiated osteoblasts on the surface of the implants prior to implantation, which has been shown to improve bone interlocking as early as 3 weeks (Fig. 1.3.3C.9C) (Ogawa et al., 2012).

Clinical Concerns Related to Metal Ion Release From CoCr Alloys

Although load-bearing implants are popular, revision surgeries are also common. Some of the main reasons for revision surgeries include wear-induced osteolysis, aseptic loosening, metal ion release, and mismatch of modulus between the implant and the bone. Moreover, it is worth noting that wear- and corrosion-induced metal ion release from CoCrMo alloys from devices used in articulating joints can potentially cause cancers and metallosis (Sansone, 2013). A recent study, with 8343 patients over 9 years, showed that the risk of cancer in tissues including bone, prostate, kidney, and skin, is higher for patients with THA that have either metal-on-metal (MOM) or metal-on-polymer (MOP) devices (Levašič, 2018). In almost all cases, these cancers were linked to release of Co^{2+} and Cr^{3+} ions due to wear and biocorrosion of metal implants. Moreover, toxicity from Co^{2+} may cause symptoms related to neurological (deafness and blindness), endocrine (hypothyroidism), hematological, and cardiological (Posada et al., 2015) damage. Due to some of these concerns, use of CoCr alloys has declined significantly in recent years for may load-bearing implant applications. However, it is still one of the best alloys available today that can provide excellent strength as well as both wear and fatigue resistance for in vivo applications.

Conclusions

CoCr–base alloys are widely used in dental, hip, knee, and spine arthroplasty applications because of their unique combination of strength, and wear and corrosion resistance, along with excellent fatigue properties. Although CoCr alloys are well-known in the biomedical field, recent developments in manufacturing capabilities and biologically relevant testing methods have provided new insights into how these base materials can be implemented in different applications. In this chapter, details are given on fundamental relationships between the main alloying elements, microstructure, mechanical and electrochemical properties, and in vitro as well as in vivo cellular responses of CoCr alloys. These aspects are crucial to building a foundational understanding of the material system, how it has been used previously, and the challenges that lie ahead for future engineers and physicians.

Questions

1. Describe the advantages and disadvantages of CrCr alloys for biomedical applications.
2. What are the typical processing routes for CrCo alloys?
3. Why is additive manufacturing becoming popular for making CoCr alloy-based implants?
4. Describe typical biocorrosion testing methods for CoCr alloys. What parameters can influence biocorrosion of CoCr alloys?
5. What kind of microstructures are preferred for CoCr alloys and why? What is the purpose of adding Mo or W in CoCr alloys? What is the role of Cr in CoCr alloys?

1.3.3D
Biodegradable Metals

FRANK WITTE

Professor for Bioactive Implants, Department of Prosthodontics, Geriatric Dentistry and Craniomandibular Disorders, Berlin, Germany

Introduction

The current definitions of biodegradable metals are:

> *A pure metal, alloy, or metal matrix composite that is intended to degrade in vivo. (Ai et al., 2019).*

or

> *Metals are expected to corrode gradually in vivo, with an appropriate host response elicited by released corrosion products, which can pass through or be metabolized or assimilated by cells and/or tissue, and then dissolve completely upon fulfilling the mission to assist with tissue healing with no implant residues. (Liu et al., 2019).*

The majority of metal implants are designed on the assumption that the device will remain in the human body for the patient's lifetime or until the device's service life has ended and requires surgical removal. However, there are some situations where permanent implants are not needed and in fact it would be beneficial if an alternative biodegradable device could be utilized. This is especially the case when load-bearing tissues are accidentally or surgically injured and complete healing is intended by the use of auxiliary implantable devices, which provide mechanical support of the healing tissue until sufficient repair or regeneration is achieved.

In these cases, biodegradable metals are advantageous due to their specific strength (strength/density), which allows the design of thin and low-volume biodegradable metal implants with higher strength than alternative biodegradable polymers. Such mechanical properties are attractive to minimize the necessary strut thickness for cardiovascular stents or for low-volume fixation screws in small bones. An advantage of the low implant volume achievable with biodegradable metals is that less material needs to be cleared or diffused from the healing site. Moreover, more space is available for the increasingly strong healing tissue, and there is a lower release of ions and secondary formed material that could potentially interact locally or systemically with the body.

A principal question when considering the use of a biodegradable metal in a medical device is which element should be chosen as a base metal? From a toxicological perspective, all obviously nontoxic elements that can form a technical metal could be selected from the mass elements (>50 mg/kg body weight), e.g., Mg or Ca, or from trace elements (<50 mg/kg body weight) in our body, e.g., Mn, Fe, or Zn. All other elements could be candidates as alloying elements. To understand which base metal might be suitable for large- or small-volume implants, the concentration of an administered element at which no adverse response is recognized (NOAEL = no observable adverse effect level) might provide some guidance (EFSA Journal, 2009; ATSDR, 2012).

According to these guidelines, the daily dosage of Mg is 6.7 mg/kg/day making Mg suitable for larger-volume implants compared to Fe (0.28 mg/kg/day) or Zn (0.07–0.23 mg/kg/day), where the NOAEL is an order of magnitude lower than for Mg-based implants and thus might be suitable for small-volume implants such as coronary stents. From the regulatory perspective, good advice is the use of minor amounts and low diversity of alloying elements (so-called lean alloys), to achieve the intended corrosion rate and mechanical strength as well as processing properties of newly designed biodegradable metals. Further selection criteria for the choice of metal or alloy may be based on the local anatomical situation, which may limit the dimensions of the implant, but also overall toxicity levels of the released ions, or the requirement for the service lifetime of the intended implant, may lead to the choice of the base metal and alloying elements.

A general agreement is that temporary implants should provide sufficient mechanical support until healing of the tissue is completed. Both loading pattern over the healing period and the time until the tissue is healed are meaningful parameters, but sound data for many clinical applications in humans are rare. Moreover, most data refer to physiological situations while implants are placed in pathological situations—or data from similar pathological situations in animals are available. Thus, one is still left alone with the scaleup

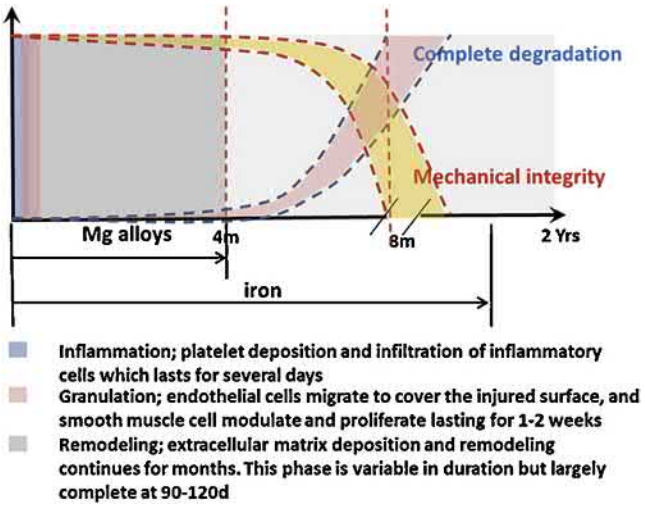
problem from animals to humans. Moreover, changes in loads at the tissue level, structural level, or whole-body level may also be considered within the various loading phases after implantation and the recovery phase for the patient. Good estimations can be drawn from biomechanical textbooks and further references (Verheul et al., 2019; Van den Bogert, 1994).

A basic truth in biomaterials is the appearance of an inflammatory phase after any implantation. This phase might be longer and more intense if degradation products need to be locally cleared, but if this reaction is only temporary and local, and the mechanical support function of the implant for the healing tissue is not compromised, the injured tissue might be completely repaired or regenerated without a persisting device made of a permanent implant material. This concept should receive more attention especially when the biological response to biodegradable metals is histologically or clinically evaluated.

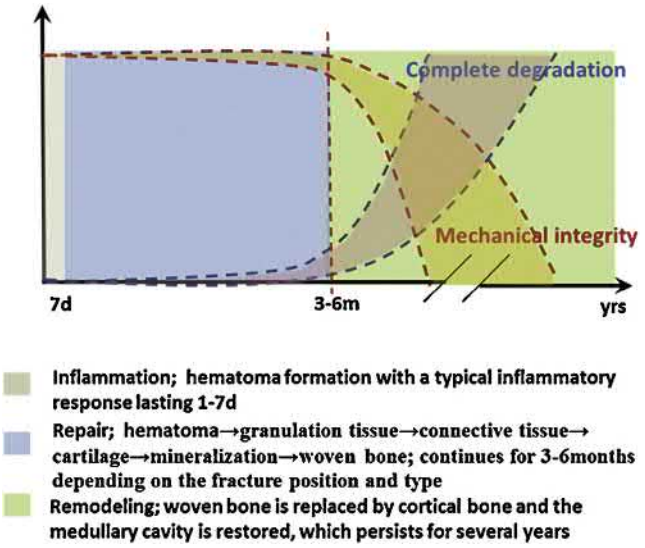
General Considerations of Corrosion Design of Biodegradable Metals

Some very general considerations on the design of the corrosion rate of temporary metal implants will be discussed. Based on standard electrode potential, reactivity, and galvanic series (corrosion potential), all the metallic elements with standard electrode potential lower than zero exhibit the potential to initiate corrosion in a neutral aqueous environment. Furthermore, metals with an electrode potential slightly higher than zero may be degraded under certain microenvironments inside the human body. In general, electrode potential and galvanic series show the tendency for corrosion, but the corrosion kinetics or extent of the degradation process is dependent on certain specific aspects such as the surface film condition and environmental parameters such as pH and flow of the media or tissue fluid around the implant (Li et al., 2014). To prevent local accumulation of corrosion products and to estimate the initial corrosion attack, the local tissue perfusion needs to be considered. In particular, changes in local perfusion after trauma or operation can dramatically reduce tissue perfusion (more than 80%) for several days after implantation (Melnyk et al., 2008). Moreover, the general pathological situations of patients (e.g., cardiovascular or metabolic diseases) may also influence local perfusion.

A "holy grail" remains the prediction of cyclic fatigue of biodegradable metals in vivo, since there are still many unknown values for parameters such as local loads, changes of these loads over time, changes in perfusion and tissue coverage (corrosive environment) over the healing period, mechanical capacity of the healing tissue, time point when tissue is considered to be healed/repaired, number of cycles until tissue healing/repair is accomplished, and frequency and amplitude changes over time. A general idea of the service lifetime for corroding implants in a healing tissue situation (either cardiovascular or musculoskeletal) is given in Figs. 1.3.3D.1 and 1.3.3D.2.



• **Figure 1.3.3D.1** Vascular injury after following balloon angioplasty is often observed in three overlapping phases: inflammation, granulation, and remodeling. The vessel remodeling phase, which is usually completed at 90–120 days, and the minimal luminal diameter tend to stabilize after the 90th day. Even though experts still debate whether full mechanical support in stented lesions is mandatory during the first 4 months after implantation, it would certainly be wise to use this clinical opinion as a safety design parameter and a benchmark for market approval evaluations based on the fact that there are insufficient human in vivo data available especially for mechanical vessel wall properties during the healing/remodeling phase (Zheng et al., 2014). (Reprint with permission from Elsevier.)



• **Figure 1.3.3D.2** Bone fracture healing occurs in three stages: inflammation, repair, and remodeling phases. A similar illustration is valid for absorbable bone implants, but the mechanical integrity should remain high for the first 3–6 months to allow bone repair processes to take place (Zheng et al., 2014). (Reprint with permission from Elsevier.)

It might be wise to consider a very low corrosion rate in some situations. Therefore, either a very corrosion-resistant metal/alloy can be used, but the implant may not completely dissolve, or a surface treatment or coating could be employed to protect the base material from initially high corrosion attack; however, the coating needs to dissolve/degrade as well, leaving no remnants of the implant or coating behind.

General Ideas on the Influence of Alloying Elements, Corrosion Behavior, and the Biocompatibility of Zn and Mg

It is well known that the mechanical properties, corrosion behaviors, and biocompatibility of metallic alloys are strongly influenced by alloying elements as well as by microstructure. Another effective way to improve the mechanical and corrosion properties of biodegradable metals is the use of mechanical deformation techniques such as rolling (hot/cold), extrusion, equal-channel angular pressing, high-pressure torsion, or drawing. While these techniques are known for Mg, they can also be adopted for Zn-based biodegradable metals (Zheng et al., 2014).

Materials with amorphous, nano-, or quasicrystalline structure can exhibit very promising physical, mechanical, and chemical properties, e.g., high corrosion resistance, about one to two orders of magnitude higher than polycrystalline alloys with the same alloy composition (Zberg et al., 2009; Zberg et al., 2009). In general, nanocrystallinity is assumed to improve the mechanical behavior as well as the corrosion resistance of an alloy as compared to its conventional counterpart. A reason for such a behavior might be a higher diffusivity due to the high ratio of surface to volume due to the presence of a high number of grain boundaries, thus improving the formation of a protective layer. Furthermore, the higher homogeneity allows better distribution of contaminants because of the increased area of grain boundaries, thus reducing local segregation (Liu et al., 2019; Zheng et al., 2014).

Iron-Based Biodegradable Metals

Introduction to Fe-Based Implants

Iron-based biodegradable metal implants can provide high strength (up to 1450 MPa) and high ductility (up to 80% elongation), and thus make them favored candidates for biodegradable stents (Li et al., 2014). Iron stents are characterized by high radial strength, which enables the fabrication of thin struts, while the high ductility of the Fe stents allows good plastic deformation during vascular deployment (Davim, 2019). Other attempts to use Fe-based biodegradable metals in clinical applications such as bone substitutes or osteosynthesis material have not yet been very successful (Wegener et al., 2011; Ray et al., 2018; Kraus et al., 2014). For further reading regarding the biological role of Fe in the human body, please see the following references (Yiannikourides and Latunde-Dada, 2019; Coates and Cazzola, 2019).

Modifications to Accelerate the Corrosion Rate of Fe-Based Biodegradable Metals

The advantage of a biodegradable iron implant is limited when incomplete corrosion leads to residual implant material, as has been reported with pure Fe stents. A solution to accelerate corrosion of Fe implants but maintain mechanical strength is alloying. Among such attempts, alloying with elements such as manganese and palladium has been successful. Alloying with manganese turns the ferromagnetic iron into nonmagnetic, as a single austenitic phase is formed (Feng et al., 2016; Hufenbach et al., 2017), which is beneficial for magnetic resonance (MR) compatibility of the Fe-based device.

The alloying elements, including Mn, Co, W, B, C, and S, were found to improve the yield tensile stress and ultimate tensile stress (UTS) of iron, whereas the alloying element Sn led to a severe reduction in mechanical properties (Liu and Zheng, 2011; Liu et al., 2011). However, techniques such as silver ion implantation using a vapor vacuum arc technique, or by making composites with its oxides or bioceramics, have also been investigated (Li et al., 2014; Moravej and Mantovani, 2011). A more promising approach seems to be enhancing the surface of the implant and utilizing iron in its porous structure for potential scaffold applications, which has been achieved by creating a nanoporous surface via a dealloying zinc-diffused process on Fe–Mn alloys or electroforming (Li et al., 2014; Moravej et al., 2010a,b). The smaller grains of electroformed iron provide a higher grain boundary area and are more susceptible to corrosive attack. The high density of microstructural defects in electroformed iron is another reason for the higher corrosion rate with a more uniform morphology (Moravej et al., 2010a,b). The mechanical properties can be adjusted by thermomechanical treatment (Moravej et al., 2010a,b, 2011). For more details on properties of Fe-based biodegradable materials, please refer to the following references (Li et al., 2014; Moravej and Mantovani, 2011).

The Proposed Degradation Process of Fe-Based Biodegradable Metals

Iron-based biodegradable devices undergo local corrosion in the presence of dissolved oxygen with a lower tendency to dissolve relative to other biodegradable metals. This is based on the formation of a protective oxide layer that acts as a barrier to the rapid degradation. An explanation for the corrosion processes in vivo follows from the electrochemical processes found in the literature (Schinhammer et al., 2013). The anodic partial reaction (oxidation) usually proceeds rapidly in physiological media:

$$\mathrm{Fe} \rightarrow \mathrm{Fe}^{2+} + 2\mathrm{e}^{-} \qquad \textbf{(1.3.3D.1)}$$

The cathodic partial reaction (reduction) in oxygen-containing aqueous solutions with a pH range between 4 and 10 is:

$$\mathrm{H_2O} + \frac{1}{2}\mathrm{O_2} + 2\mathrm{e}^{-} \rightarrow 2\mathrm{OH}^{-} \qquad \textbf{(1.3.3D.2)}$$

This pH range is representative for most of the potential implantation sites in a living body, except, e.g., for implantation in the gastrointestinal tract. The reaction kinetics of

the coupled reduction (2) and oxidation reaction (1) are dependent on the locally dissolved oxygen reaching the Fe metal surface. The critical factor for the local degradation of Fe-based implants is the local availability of oxygen in the surrounding tissue. This consideration explains the different corrosion rates of Fe stents in blood vessels and Fe pins in bone (Kraus et al., 2014; Schinhammer et al., 2013).

The degradation mechanism of Fe-based alloys and the formation of degradation products is schematically illustrated in Fig. 1.3.3D.3. This degradation process could be applied for all iron-containing alloys. In detail, the Fe ions, which are usually formed in the corrosion process, react with hydroxyl ions (OH^- ions) to form hydrous ferrous oxide ($FeO \bullet nH_2O$). Dissolved oxygen causes the ferrous (Fe^{2+}) oxides to be further oxidized to ferric (Fe^{3+}) oxides according to the following reaction:

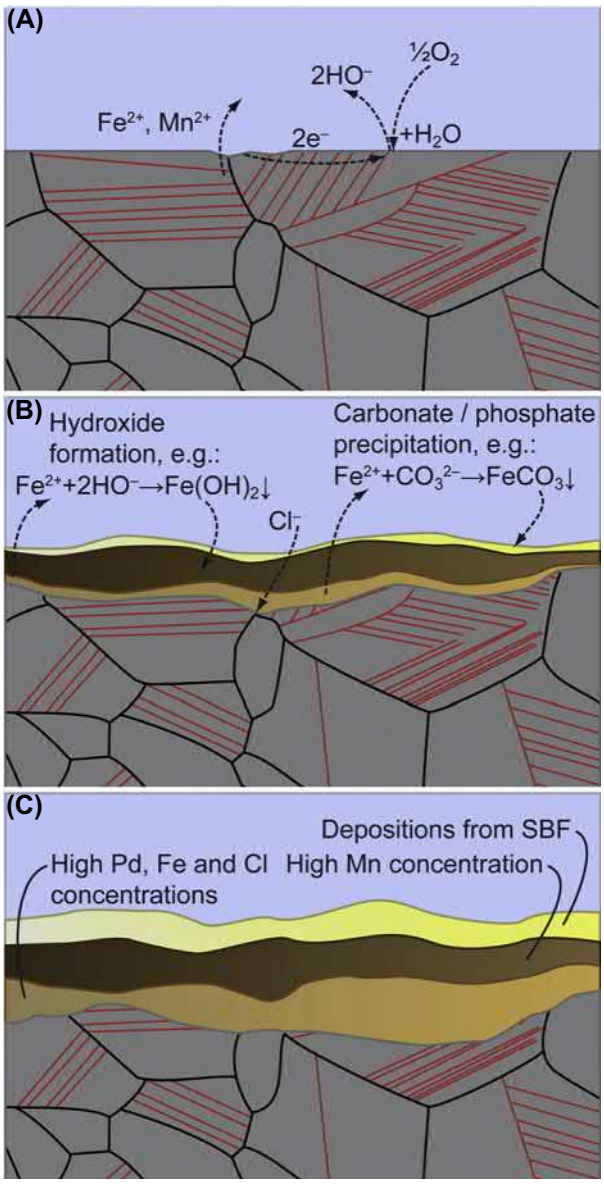
$$Fe(OH)_2 + 1/2H_2O + 1/4O_2 \rightarrow Fe(OH)_3 \quad \textbf{(1.3.3D.3)}$$

Based on the oxygen gradient in the corrosion layer, oxidation to the ferric form usually commences in the outer layers and subsequently progresses toward the *metal* surface. The formation of such Fe- oxide degradation products has been observed in vitro (Li et al., 2014), but also in vivo by Peuster et al. (Peuster et al., 2006; Peuster et al., 2001).

Another important factor influencing the degradation rate in vivo is the formation of degradation products on the implant surface, especially the formation of a complex iron phosphate layer (Schinhammer et al., 2013). The precipitation of carbonates and phosphates comprises the formation of hydroxides/oxides in the oxide layer, which allows Cl^- ions to diffuse to the metal surface, causing localized corrosive attacks (Schinhammer et al., 2013).

Biocompatibility Evaluations

Several animal tests have been reported, but one of the first in vivo experiments with Fe-based materials was performed by Peuster et al. who implanted a pure Fe stent into the descending aorta of New Zealand white rabbits that showed a moderate local macrophage infiltration and complete neointima coverage after 18 months (Peuster et al., 2001). In further studies, a biodegradable stent in a minipig model could maintain mechanical properties during the implantation without failure. However, these results also clearly demonstrated the need for faster-degrading Fe-based implants (Peuster et al., 2006; Peuster et al., 2001). Today the appropriate corrosion rate for Fe implants remains unclear since the formation of by-products of iron oxide degradation as well as the controlled release of Fe ions into the surrounding tissues is concomitant. In this regard, the biological role of Fe, especially its role in oxygen transport, needs to be considered (Silva and Faustino, 2015). Its ability to mediate electron transfer, changing between the +2 and +3 oxidation states, may elicit the production of reactive oxygen species responsible for cellular and tissue damage. To avoid those negative effects, iron is usually found coupled with proteins. In serum, it is mainly associated with transferrin, while within the cells it is driven by chaperones or stored within ferritin (Silva and Faustino, 2015). The role of Fe ions for inflammation and healing tissues has to be carefully considered. For further reading on Fe metabolism and its disorders, please refer to the following references (Andrews, 1999; Ponka et al., 2015).



• **Figure 1.3.3D.3** The degradation process and formation of degradation products for TWIP-1Pd alloys. Schematic illustration of the degradation process and the formation of degradation products for TWIP-1Pd alloys. (A) Initiation of the corrosion reaction: the anodic partial reactions are metal oxidation, whereas the cathodic partial reaction is oxygen reduction. (B) Formation of hydroxides/oxides, and precipitation of carbonates and phosphates that comprise the degradation products. Cl^- ions diffuse to the surface, causing localized attacks. (C) Further build up of degradation products. The Pd remains in the layer close to the sample surface and acts as a macrogalvanic element to increase degradation. *SBF*, Simulated body fluid; *TWIP* = twinning-induced plasticity. Current Perspective on Fe-Based Degradable Implants

Fe-based biodegradable metals are a challenging choice for temporary implants. Research efforts address very interesting potential clinical applications such as triggering drug release by using external magnetic fields, using the heat generated locally for thermal therapy of cancer, or treating implant-associated infections. Given the biocompatibility considerations, small volume implants seem to be most feasible for Fe-based alloys, such as biodegradable stents. Their main design characteristics can be given as: (1) high strength approaching 316L SS alloy with sufficient remaining ductility; (2) biocompatibility, including MR compatibility; and (3) controlled degradation within a reasonable period (1–2 years) (Moravej and Mantovani, 2011; Francis et al., 2015).

Zinc-Based Biodegradable Metals

Introduction to Zn-Based Implants

Zn-based biodegradable metals have been applied in tissues with high tolerances to Zn ions, such as vessels and muscles, but mainly in cardiovascular stent applications. The predominant processes responsible for the corrosion of zinc are the cathodic reduction of the oxygen dissolved, anodic dissolution, and pH level of the surrounding environment. The corrosion rate of Zn is comparatively lower than that of pure Mg, but higher compared to Fe-based alloys. Enhanced corrosion resistance as well as improved mechanical properties are obtained by combining Zn with Mg (Heiden, 2015). Zn-based biodegradable stents do not lead to extended inflammatory responses, which was evident when Zn stents were implanted into rat arteries. Zn and its alloys have also been explored for fixation of fractures, besides their applications for stents (Bowen et al., 2016). The locally released concentration of zinc ions needs to be critically discussed since this essential element serves as a cofactor of many enzymes and regulatory proteins. For further reading regarding the biological role of zinc in the human body, please see the following references (Sandstead, 2015; Coleman, 1998; Vallee, 1988).

Zn-Based Materials Under Investigation

Zinc has been widely used as an alloying element in Mg-based biodegradable metals. However, the limitation of pure zinc as an implant material is based on its low strength (UTS 30 MPa) and plasticity ($\varepsilon < 0.25\%$), which are inappropriate for most clinical devices. Therefore, a higher strength and hardness are the main focus of current zinc research. This can be achieved by metallurgical engineering of the zinc alloy's chemical composition and microstructure by solid-solution and second-phase strengthening as well as thermomechanical deformation techniques to improve the mechanical and corrosion properties. Currently investigated zinc alloys exhibit a wide range of ultimate tensile strengths and elongations, from 87 to 399 MPa and from 0.9% to about 170% (Katarivas Levy et al., 2017). Even minor alloying can significantly improve the mechanical properties, for example, adding 1.2% Mg to pure zinc improves its ultimate tensile strength from 18 to 362 MPa, and the elongation fraction from 0.32% to 21% (Table 1.3.3D.1). Moreover, hot rolling and hot extrusion contribute to the strength and ductility of zinc alloys, particularly in Zn-based ternary alloys. Thus conventional metallurgical approaches can be used to adjust the required mechanical properties of Zn-based biodegradable metals. Furthermore, Zn-based bulk metallic glasses have been intensively studied for their magnetic

susceptibility, mechanical properties, corrosion behavior, and cytocompatibility, aiming to develop Zn-based alloys for bone repair and fracture fixation. Zn-based metallic glasses ($Zn_{38}Ca_{32}Mg_{12}Yb_{18}$) exhibited higher strength (above 600 MPa) than conventional Mg (about 200 MPa) crystalline materials, much lower magnetic susceptibility than that of commonly used biomedical alloys, and a slower degradation rate than pure Mg. During corrosion immersion testing in Hank's solution for 30 days, minimal hydrogen was generated and its compression fracture strength was retained. Based in part on its slow corrosion, Zn-based metallic glass exhibited good cytocompatibility with MG63 osteoblast cells (Zheng et al., 2014).

The Proposed Degradation Process of Zn-Based Biodegradable Metals

In general, the standard electrode potential (vs. standard hydrogen electrode) for Mg is –2.37 V, for Zn –0.763 V, and for Fe –0.440 V, which means that Zn has a corrosion rate faster than Fe, but slower than Mg. The degradation model for Zn-based biodegradable metals in a neutral physiological environment has been proposed by Zheng et al. (2014) and generally occurs via a cathodic and anodic reaction:

$$\text{Anodic reaction: } 2Zn \rightarrow 2Zn^{2+} + 4e^{-} \quad \textbf{(1.3.3D.4)}$$

$$\text{Cathodic reaction: } O_2 + 2H_2O + 4e^{-} \rightarrow 4OH^{-} \quad \textbf{(1.3.3D.5)}$$

When exposed to body fluid, zinc is oxidized into metal cations following the anodic reaction in Eq. (1.3.3D.4). The generated electrons are consumed by a cathodic reaction, corresponding to the dissolved oxygen reduction in Eq. (1.3.3D.5). The corrosion reaction produces zinc hydroxides and oxides via a number of intermediate species, according to the following:

$$Zn(OH)_2 \text{ formation: } 2Zn^{2+} + 4OH^{-} \rightarrow 2Zn(OH)_2 \quad \textbf{(1.3.3D.6)}$$

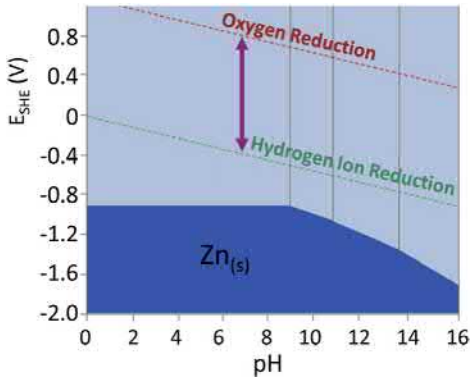
$$\text{ZnO formation: } Zn(OH)_2 \rightarrow ZnO + H_2O \quad \textbf{(1.3.3D.7)}$$

The corrosion products $Zn(OH)_2$ and ZnO are likely to form on the metal surface according to Eqs. (1.3.3D.6) and (1.3.3D.7).

The high concentration of chloride ions in the physiological environment destabilizes the equilibrium between dissolution and formation of the corrosion product layer, which enables chloride ions to convert the corrosion layer into soluble chloride salts as follows:

$$6Zn(OH)_2 + Zn^{2+} + 2Cl^{-} \rightarrow 6Zn(OH)_2 \cdot ZnCl_2 \quad \textbf{(1.3.3D.8)}$$

$$4ZnO + 4H_2O + Zn^{2+} + 2Cl^{-} \rightarrow 4Zn(OH)_2 \cdot ZnCl_2 \quad \textbf{(1.3.3D.9)}$$



• **Figure 1.3.3D.4** Pourbaix diagram of zinc. The *purple arrow* shows the range of biological standard reduction potentials at pH 7.4: from ~820 to ~–670 mV (Katarivas Levy et al., 2017). (Reprinted with permission from MDPI.)

The dissolution of the $Zn(OH)_2$ and ZnO surface film components promotes further dissolution of the exposed metal. With progressing corrosion, irregular particles may be separated from the zinc-based metal and released into the surrounding tissue (Katarivas Levy et al., 2017).

Another important factor that needs to be considered in the corrosion of zinc is the pH value of the physiological solution or surrounding tissue (Katarivas Levy et al., 2017). According to a Pourbaix diagram, shown in Fig. 1.3.3D.4, zinc is present as hydrated $Zn^{2+}(aq)$, over the entire physiological range of pH values and biological standard reduction potentials (~820 to ~ –670 mV) (Fig. 1.3.3D.4).

In vivo experiments by Bowen et al. (Bowen et al., 2013, 2014) demonstrated thin layers of zinc oxide during early stages of implantation (1.5 and 3 months) on the surface of zinc wires (99.99% purity) in the rat aorta. As corrosion progressed (4.5 and 6 months), the corrosion layer thickened and contained three different phases/layers: calcium phosphate, zinc oxide, and zinc carbonate (Fig. 1.3.3D.5). The calcium phosphate layer appeared on the exterior surface without forming a true bulk product. Hence, the calcium phosphate layer was not thought to play a significant role in zinc biocorrosion. The compact corrosion layer included the two other phases, zinc oxide and zinc carbonate, with ZnO appearing in formations isolated from one another by the zinc carbonate phase. This complex corrosion layer is reminiscent of the composition reported for Mg-based biodegradable metals. These ceramic degradation products can accumulate as a function of the local tissue's physiological mass transfer rate and therefore may impact tissue healing and remodeling.

Biocompatibility of Dissolved Zn Corrosion Products

A number of zinc alloys have been developed considering nontoxicity for the choice and amount of the used alloying elements (lean alloys). As an example, for lean Zn alloys, Zn–Mg and Zn–Al with alloying element concentrations of less than 1%, enhanced mechanical properties and

• **Figure 1.3.3D.6** Overview on Mg-based biodegradable implants that are commercially approved (green) in clinical trials (blue) and that may have clinical potential (orange). (Reprinted with permission of Materials Today.)

adequate strength and ductility were achieved to enable use as a structural support for arteries or bone fractures. Preliminary results in cell culture and in small animal models have been promising (Katarivas Levy et al., 2017). More information on the cytocompatibility of Zn-based biodegradable implants can be found elsewhere (Han et al., 2019; Zheng et al., 2014; Katarivas Levy et al., 2017).

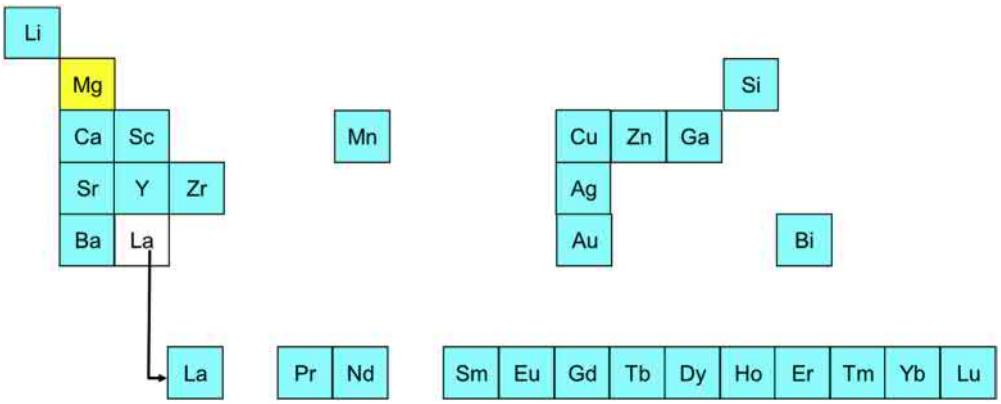
Current Perspective on Zn-Based Degradable Implants

Modification of zinc by alloying and thermomechanical processing is a current research approach to obtain refined grain sizes for optimized mechanical properties applicable in most medical applications. Tailored corrosion rates for Zn-based degradable implants are mandatory for minimized toxicity, reduced inflammatory reactions, and a favorable cell response in the host tissue.

Magnesium-Based Biodegradable Metals

Introduction to Mg-Based Implants

A historical review has shown that Mg-based biodegradable metals were used in humans as early as 1878 (Witte, 2015). Today, Mg-based biodegradable metals have arrived in the clinic and are used as regulatory agency-approved cardiovascular stents (Magmaris, Biotronik AG) and as small bone



• **Figure 1.3.3D.7** Alloying elements for Mg-based implants. (With courtesy from Norbert Hort.)

fixation screws (Magnezix, Syntellix AG) in patients (Fig. 1.3.3D.6). Most interestingly, both implants are made of Mg–Y-RE (WE) alloys, but both have different processing routes and serve in two different clinical applications. The benefit of biodegradable implant materials is enormous when applied in pediatrics, where the patient's tissue often continues to grow after implantation.

Even though successful clinical applications have been proven in humans, the basic understanding of the complex processes at the implant surface and in the surrounding tissue is still not clear, primarily due to the lack of nondestructive and noninvasive methods with suitable spatial and temporal resolution for local perfusion, pH, and osmolality. For the biological role of Mg ions in the human body the reader may refer to established literature for further reading (AIa, 1958). The following text will summarize the general approach to Mg-based implants and specific biological and clinical findings.

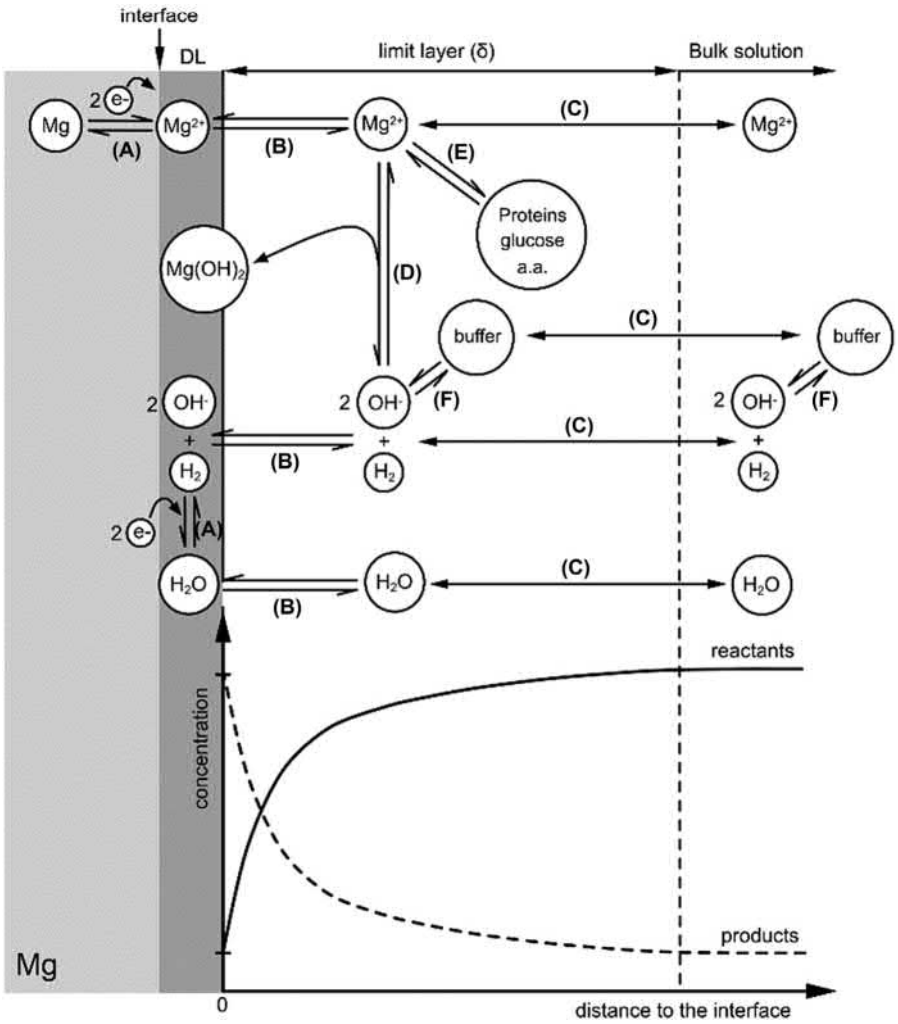
Impact of Alloying Elements on Mg Processing and Microstructure

Critical properties (e.g., corrosive or mechanical) stem from the metal microstructure, which is a result of the combined alloying elements and specific processing routes, including surface conditioning. Therefore, appropriate elements for alloying have to be selected and checked for their suitability in all intended following processing steps. The first processing steps, melting and casting, are already influenced by the selected alloying elements. In a next step, wrought processes such as extrusion, rolling, and forging are often combined with heat treatments that are highly impacted by the alloying elements. However, the processing also influences the microstructure and element distribution. With respect to the biological performance, only a few elements remain as possible alloying elements as depicted in Fig. 1.3.3D.7. Due to improved casting and processing properties, Al is often chosen as an alloying element regardless of the possibility that it may be involved in Alzheimer's disease. Other elements are also under evaluation. Still it is unpredictable which element and at what amount an alloying element can be used to achieve intended corrosive and mechanical properties in the implant material, as well as offering appropriate biocompatibility. Therefore, Mg-based alloy development is based on multiple experiments, even though first principle calculations may be applied to guide the selection of alloying elements and their concentration.

Remarkable progress to achieve improved mechanical and corrosion characteristics has been made by using rare earth elements (REE) as alloying elements (Han et al., 2019). REEs can be categorized depending on their solubility in Mg in a high solid-solubility group (Y, Gd, Tb, Dy, Ho, Er, Tm, Yb, Lu) and a limited solid-solubility group (Nd, La, Ce, Pr, Sm, Eu). To improve the mechanical properties of Mg for cardiovascular stents, REEs may promote grain refinement upon thermomechanical treatment. REEs (e.g., Nd, Gd) may also improve the corrosion resistance of Mg alloys by suppressing microgalvanic coupling between Mg and impurities by precipitating secondary phases with similar electrochemical potentials with respect to the matrix (Chen et al., 2014; Hort et al., 2010). REEs may arouse toxicological concerns due to insufficient in vivo data, but most published preclinical literature report on biocompatible REE systems. As an alternative, Zr can be used as a grain refiner (Chen et al., 2014).

If the solid-solubility limit of Ca in Mg (1.34 wt%) is exceeded, Ca saturation results in the secondary Mg_2Ca phase, which can cause accelerated corrosion (Li et al., 2008). However, the corrosion rate can be controlled by selectively doping Zn into Mg_2Ca to synchronize the corrosion potentials of the two constituent phases (i.e., Mg and Mg_2Ca). Additionally, extrusion processes have been used to break down the connectivity of the Mg_2Ca phases to prevent continuous corrosion and the formation of galvanic circuits. Adjustments to this microstructure have led to an Mg–Ca–Zn alloy (Resomet), which was approved by the Korean government in 2015 for clinical applications (Han et al., 2019).

Bulk metallic glass (BMG) materials have been created from Zn-containing Mg systems. In contrast to conventional metallic materials with crystalline structures, noncrystalline amorphous BMGs are obtained by processes such as extremely rapid cooling, ion irradiation, or physical vapor deposition. Based on their unique irregular atomic arrangement, BMGs provide low elasticity, high strength, and improved corrosion resistance due to the absence of grain boundaries (Zberg et al., 2009). However, BMGs are very brittle and may shatter during implantation or under severe loading (Han et al., 2019). For further reading on



• **Figure 1.3.3D.8** Schematic description of the degradation process involving (A) electrochemical reactions, (B) absorption–desorption processes, (C) mass transfer processes, (D) precipitation reactions, (E) complexation reaction, (F) acid–base reactions (Gonzalez et al., 2018). fundamentals in Mg alloy metallurgy the following reference is recommended (Pekguleryuz et al., 2013).

Current Models of the Corrosion Process In Vitro

When an Mg alloy is immersed in a physiological medium, the contact between the fresh metal surface and an electrolyte-containing aqueous medium initiates high corrosion rates. This process involves the release of hydrogen and the alkalinization of the environment as described by the following reactions:

$$\text{Anodic reaction: } Mg \rightarrow Mg^{2+} + 2e^- \qquad \textbf{(1.3.3D.10)}$$

$$\text{Cathodic reaction: } 2H_2O + 2e^- \rightarrow 2OH^- + H_2 \qquad \textbf{(1.3.3D.11)}$$

$$\text{Product formation: } Mg + 2H_2O \rightarrow Mg(OH)_2 + H_2\uparrow \qquad \textbf{(1.3.3D.12)}$$

The formed $Mg(OH)_2$ is the first product in the degradation process and precipitates on the metal surface due to its low solubility in water (12 mg/L). The consolidation or dissolution of this layer depends on the other elements present in the electrolyte and the immersion time. However, it has been shown that MgO, $Mg(OH)_2$, and $MgCO_3$ are the main degradation products formed with the application of Hank's balanced salt solution, simulated body fluid, and Dulbecco's modified Eagle's medium (Gonzalez et al., 2018). Moreover, the solubility of the various corrosion products is dependent on environmental factors such as temperature, pH, and flow of the electrolyte.

The flow of the electrolyte or media in the in vitro setup—and probably in vivo too—can modulate the kinetics of electrochemical processes. Fig. 1.3.3D.8 displays the surface electrochemical and chemical processes involved in magnesium degradation, including the necessary mass transfer processes between the region of the metal surface and the bulk solution. As a consequence of this mass transfer process and the natural tendency of a fluid to stick to a solid surface,

a gradient of reactants (e.g., H_2O) and products (e.g., Mg^{2+} and OH^-) is stabilized (Gonzalez et al., 2018). Depending on the hydrodynamic conditions, the contribution of the mass transfer can be the major rate-determining parameter of the overall degradation process (Fig. 1.3.3D.8) (Gonzalez et al., 2018).

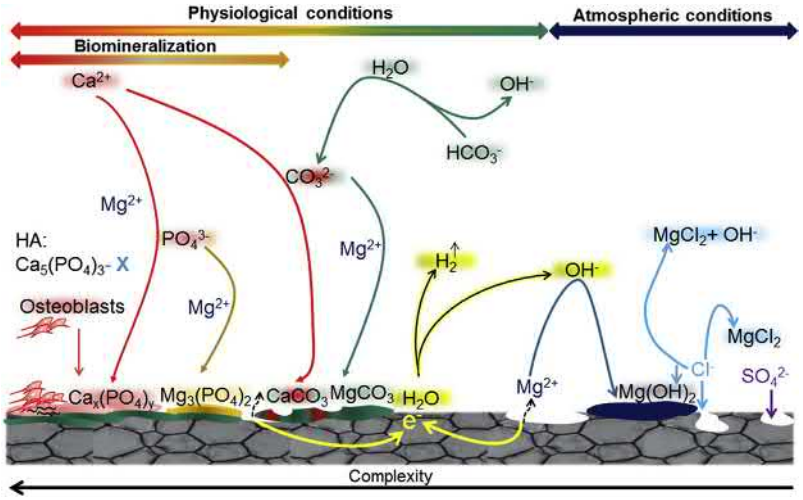
The best explanation for different corrosion rates of Mg-based biodegradable metals in in vitro and in vivo setups is based on different environmental conditions as depicted in Fig. 1.3.3D.9. A study investigating the reported corrosion rates across various publications on Mg-based biodegradable metals has been published by Martinez-Sanchez et al., which showed that the corrosion rate in vitro is about 1–5 times higher than in vivo (Martinez Sanchez et al., 2015).

While under atmospheric conditions, $Mg(OH)_2$ and $MgCl_2$ are the main degradation products, and carbonates (CO_3^{2}) and phosphates (PO_4^{2}) stabilize the corrosion layer under physiological conditions and may interact with further protein and cell adhesion. The cells themselves can influence the condition of the corrosion layer in vitro and in vivo. Especially in vivo the reactive zone influencing the corrosion layer on the implant is increasing and becoming more complex in terms of active parameters (cells, proteins, reactants, loads) and their constituent variations over time compared to the in vitro situation.

Situation In Vivo: Tissue Perfusion, pH, and the Issue of Gas Formation

It is evident that after implantation the perfusion at the implantation site is changing, disturbed by the associated mechanical damage. Ischemic tissues (low oxygen, low perfusion) influence the initial degradation behavior of the material. Generally, the blood flow in bone is rather low (Kane, 1968; Kiær et al., 1989) and after fracture or implantation there are significant changes. First, the direction of blood flow is changing from centrifugal to centripetal, thereby inducing a healing cascade, which includes cells from the periosteum and the surrounding soft tissue (Einhorn, 1995; Rhinelander, 1974). Second, the perfusion at the fracture or implantation site shows a transient diminishing for 3–10 days, depending on the site of implantation. This reduction in perfusion can reach up to nearly 20% of the baseline value (Melnyk et al., 2008). Afterward the blood flow is successively restored and even increases compared to the flow in the healthy counterpart (Retzepi et al., 2007; Vendégh et al., 2012). This implies a highly complex interaction: not only the magnesium degradation shows a variable and time-dependent behavior, but also the tissue environment is far from stable. Consequently, a reduction of blood flow initiates a change in mass transport and oxygen saturation and raises the possibility of pH changes and degradation product accumulation. As an example, in vitro studies revealed that magnesium degradation, oxygen saturation, and pH are interlinked (Feyerabend et al., 2012; Willumeit et al., 2013). From the tissue side, hypoxia is essential for bone regeneration via hypoxia-inducible transcription factors (HIF-1α and HIF-2α) (Araldi and Schipani, 2010; Street et al., 2005) and the vascular endothelial growth factor pathway (Genetos et al., 2010), but can also be a sign of transitional pathological conditions, then upregulating osteoclast activity (Knowles, 2015).

It also seems true that the spontaneous mineralization of the corrosion layer stabilizes the corrosion in vivo. This phenomenon can be reduced if matrix GLA protein is locally present (Hong et al., 2019). Recent research also shows that the calcium ions in the corrosion layer seem to determine also if cells migrate on the implant surface (Amberg et al., 2019). This might lead to a thickening of the corrosion layer, which in turn reduces the velocity of mass exchange at the implantation site leading to an additional phenomenon: the formation of gas pockets around the implant. It is widely believed that these gas pockets indicate high hydrogen formation and an accumulation of hydrogen in the vicinity of the implant. However, it has been demonstrated in in vivo



• **Figure 1.3.3D.9** Degradation products formed under physiological conditions and the corresponding chemical reactions. As an overview, current knowledge on degradation products under physiological conditions is shown.

experiments (Kuhlmann et al., 2013) that these gas pockets do not contain high levels of hydrogen, but a substitution by other gases with a much higher tissue retention than hydrogen (Witte et al., 2008). Although these pockets may be formed by a too high initial hydrogen release, the replacement of hydrogen by other gases (nitrogen, oxygen, carbon dioxide) leads to temporary gas cavities, which can separate tissue layers. However, all in vivo observations demonstrated that these gas cavities are transient. Gas cavity may push the bone marrow locally; however, in long-term observations the final bone healing result is sufficient (Han et al., 2019).

In several clinical reports of Mg-based implants with different Mg alloys, processing and coating background, an early appearance of locally hypomineralized zones around the Mg-based implant could be observed in bone applications (Fig. 1.3.3D.10) 6–12 weeks after surgery. However, these hypomineralized zones disappear on radiographic images at the time of complete bone healing. The scientific understanding of this phenomenon is still pending. It is not clear if the stiffness changes in the hypomineralized zones are critical for the overall mechanical stability of the fracture/osteotomy or if the temporary reduced stiffness in the implant interface could even have beneficial effects on bone healing as reported elsewhere (Weinkamer et al., 2019).

The ability of Mg implants to promote bone growth has been fully validated in various preclinical animal models using computed tomography, fluorescent imaging, and histological analysis (Han et al., 2019) and is evident from various clinical trials (Witte, 2015; Windhagen et al., 2013). The periosteal bone growth is based on the enhanced release of calcitonin gene-related peptide (CGRP) from sensory nerve endings in the periosteum, which promotes osteogenic differentiation of periosteal-derived stem cells. The peripheral release of CGRP in the sensory nerve endings upregulates the CGRP production in the dorsal root ganglion and continues until the Mg^{2+} ion-triggered release of CGRP ends (Zhang et al., 2016). However, in the bone marrow space, Mg^{2+} ions seem to stimulate an osteogenic effect by activating the canonical Wnt signaling pathway, which in turn causes bone marrow-derived stem/stromal cells to differentiate toward the osteoblast lineage (Hung et al., 2019).

X-ray images showing fixation of the distal radius fracture with conventional stainless-steel pin implant and the scaphoid nonunion with Resomet screws at preoperative, postoperative, 6-month follow-up, and 12-month follow-up. Complete degradation of screw and bone healing was observed at 12-month follow-up. (Reprinted from Han, H.-S., et al., 2019. Current status and outlook on the clinical translation of biodegradable metals. Mater. Today 23, 57–71.)

Methods to Measure Mg-Based Implant Corrosion In Vitro and In Vivo

The observed corrosion of Mg-based biodegradable metals (in vitro and in vivo) is highly dependent on the environment. Therefore, samples under atmospheric conditions exhibit a black surface, typically consisting of $Mg(OH)_2$, while samples immersed under cell culture conditions show various precipitates, where the main constituent has been identified as $MgCO_3$. Additionally, the introduction of cell culture conditions accelerates the degradation rate of all Mg-based materials, as monitored by the increase of osmolality. Therefore, the most relevant corrosion setup for prediction of in vivo behavior includes immersion of the Mg-based sample in complex physiological solutions (e.g., HBSS) with the addition of physiological serum levels of Ca^{2+} ions, tested at cell culture conditions (37°C, 95% RH, 5% CO_2, 21% O_2) in at least slow flowing media (Reynolds number <1000) (Gonzalez et al., 2018). The ratio of the media volume to the sample surface should be kept the same for all tested samples and needs to be reported. The level of $NaHCO_3$ in the media should be kept at physiological concentrations, since $NaHCO_3$ and $CaCl_2$ in the media promote the formation of $MgCO_3$, which influences the measured corrosion rate. For cocultures of the material with cells, the required media and additives as well as the cells themselves can interfere with the corrosion process, which needs to be carefully checked and reported (Gonzalez et al., 2018).

Mass loss measurements are the simplest approach to analyze the degradation of Mg-based materials using ASTM standards. Chromic acid treatment (180 g/L in distilled water) facilitates the removal of the degradation layer providing an opportunity to visualize the degraded metal surface morphology (Gonzalez et al., 2018). To prevent surface-entrapped Cl^- aggregates from reacting with chromic acid and continue corrosion locally, compounds such as silver nitrate ($AgNO_3$; 2 g/L in distilled water) are added to the chromic acid. Most of the alloying elements are inert in contact with chromic acid; however, certain elements such as silicon, zirconium, and others may interact with chromates. Therefore, it is of importance to check possible interaction of magnesium alloys with chromic acid treatment. However, if Ag-containing Mg alloys are analyzed, the addition of $AgNO_3$ should be avoided. Another method to determine the degradation rate is with eudiometric measurements of generated hydrogen (Gonzalez et al., 2018; Tie et al., 2013). As under physiological conditions, eudiometric experiments are performed either in a gaseous atmosphere in the incubator or by gassing of the medium (Gonzalez et al., 2018). However, not many studies have been conducted with eudiometric setups. A general concern about the validity of this determination of mass loss/degradation rate should be stated, as (1) magnesium degradation influences directly the amount of O_2 and CO_2 in solution and (2) many ingredients of physiological solutions have hydrogen-binding capacities, including the medium buffering systems as stated before. Therefore, if eudiometric methods are used, the escaped gas should be analyzed (Gonzalez et al., 2018; Agha et al., 2016).

Several analytical methods have been successfully applied to investigate the corrosion of Mg-based biodegradable metals in vivo. Especially, microtomography (lab devices or synchrotron radiation based) seem to be useful to determine nondestructively the remaining metal volume and therefore can be used to estimate the corrosion rate and describe the corrosion morphology (Witte et al., 2006; Witte et al., 2010). Retrieved tissue-implant samples need special sample treatments to minimize artifacts, e.g., histological techniques requiring plastic embedding and thin microtome sections for immunohistology (Willbold and Witte, 2010). These techniques can also be used to prepare samples to analyze the locally dispersed alloying elements or impurities at ultratrace level, e.g., by laser ablation-inductively coupled plasma-mass spectrometry or synchrotron radiation-induced micro-X-ray fluorescence (Gruhl et al., 2009). High-field magnetic resonance imaging technology seems to be promising for functional imaging (Witte, 2013) as well as hydrogen measurements in vivo via hydrogen selective electrodes (Kuhlmann et al., 2013).

Preclinical and Clinical Observations for Mg-Based Biodegradable Metals

Various preclinical studies using different Mg-based materials with various processing histories and different coatings have been published for soft and hard tissue applications. A good summary can be found in the following references (Han et al., 2019; Zheng et al., 2014). In general, a low initial corrosion rate after implantation can reduce or prevent side effects such as gas cavity formation or the observation of locally hypomineralized zones. However, most of the studies provide short- to mid-term postoperative follow-ups and it is hard to predict when the implant is completely degraded. Some of the remarkable results are the effect of Mg on bone healing, but Mg-based implants might also be beneficial for soft tissue repair such as anterior cruciate ligament reconstruction in rabbits (Wang et al., 2018). An accumulation of bone morphogenetic protein-2 and vascular endothelial growth factor and reduction in the expression of matrix metalloproteinase-13 have been found around corroding pure Mg implants, which facilitated early phase healing of the tendon in bone without bone tunnel widening, implying its potential application in clinical settings (Wang et al., 2018). The result seems not to be material specific, since similar results can be obtained with interference screws made of Mg–REE alloys (Diekmann et al., 2016). Another interesting study showed the application of an Mg–6Zn alloy system as a pin stapler to treat intestinal anastomosis leading to stimulation and accumulation of the extracellular matrix and promoting healing of the anastomotic site (Cao et al., 2013).

Clinical data for Mg-based biodegradable metals are abundant for a coronary stent made by the company Biotronik AG, while only a few reports from three companies are available for orthopedic applications. The interested reader may want to study further literature for the fascinating development from preclinical studies to the final Mg stent called Magmaris, which received CE mark approval in

TABLE 1.3.3D.2 Summary of Recent Clinical Trials of Orthopedic Devices Made of Mg-Based Biodegradable Metals (Han et al., 2019)

Device Material/ Trade Name	Study Type and Identifier[#]	No. of Patients	Application	Total Duration	Outcomes
Magnezix	Prospective and randomized controlled (according to EN ISO 14155–1:2009 and EN ISO 14155–2:2009)	26	Mild hallux valgus	6 mo	Outstanding results for ROM, MTPJ, AOFAS. Equivalent performance to titanium screws for treatment of mild hallux valgus deformities.
Resomet (K-MET)	Prospective, single center, single group, open (KFDA clinical trial approval for medical device no. 362), NCT02456415	53	Hand fractures	12 mo	Normal range of grip power. No change in ROM, DASH. At 12 months, screws were completely replaced by new bones.
Pure magnesium	Prospective and randomized pilot (registered in the Chinese Clinical Trial registry), ChiCTR-TRC-13003238	48	Osteonecrosis of the femoral head	2 mo	Increased bone flap stability. Serum levels were normal. Two patients suffered collapse of the femoral head. At 12 months, higher Harris hip score than control.

AOFAS, American Orthopaedic Foot and Ankle Society; *DASH*, disabilities of the arm, shoulder, and hand; *MTPJ*, metatarsophalangeal joint; *ROM*, range of motion.

2016 (Han et al., 2019; Erbel et al., 2007; G et al., 2019; Haude et al., 2013; Haude et al., 2019; Hideo-Kajita et al., 2019; Joner et al., 2018; Verheye et al., 2020). The clinical studies for orthopedic applications are summarized in Table 1.3.3D.2 and briefly introduced as follows:

Orthopedic Devices Based on MgYREZr Alloy (Magnezix)

The first orthopedic application of an MgYREZr alloy screw was to treat patients with a mild hallux valgus (bunion) (Windhagen et al., 2013). In a prospective and randomized controlled study, a chevron osteotomy was performed in 26 patients who were randomly assigned to two groups and treated using either the titanium or MgYREZr alloy screws. No complications during the 6-month follow-up period were reported, but one patient from each group dropped out of the study after surgery for personal reasons. Equivalent performance of MgYREZr alloy screws compared to the conventional titanium screws was demonstrated by the range of motion of the first metatarsophalangeal joint, the visual analog scale for pain assessment, and the postoperative American Orthopaedic Foot and Ankle Society score for hallux. After receiving a CE mark in 2013, a modified chevron osteotomy study with a larger group of patients (44 total) was performed showing similar results (Plaass et al., 2016; Plaass et al., 2018; Han et al., 2019). Moreover, recent case studies have reported the application of MgYREZr alloy systems in the fixation of distal fibular and intraarticular fractures (Biber et al., 2016).

Orthopedic Devices Based on MgCaZn Alloy (Resomet)

In a postmarket approval study (KFDA Clinical Trial Approval for Medical Device No. 362), the Mg–Ca–Zn alloy system was tested in a prospective single group clinical trial in 53 patients to evaluate its performance in the treatment of hand fractures (Lee et al., 2016). All patients revealed normal healing after 12 months with continuity of the cortical bone and a reduced diameter of the Mg–Ca–Zn alloy screws after implantation without any adverse events (Fig. 1.3.3D.10). None of the patients had any indication of pain and reported recovery of their range of motion and grip power. Even though hypomineralized zones could be seen as early as 6–12 weeks postoperatively (Fig. 1.3.3D.10, after surgery), the fracture appeared to be healed at that time point. Furthermore, the Mg–Ca–Zn screws were completely replaced by new bone after 1 year of implantation. Mg–Ca–Zn screws were approved by the KFDA for clinical use in 2015, and various prototypes are currently being developed to utilize this newly approved alloy system (Han et al., 2019).

Orthopedic Devices Based on Pure Mg

Patients with osteonecrosis of the femoral head (ONFH) received a vascularized bone flap that was fixed with screws made of high-purity (99.99%) magnesium (Zhao et al.,

TABLE 1.3.3D.3 Specific Standards Under Development for Absorbable Metals (Han et al., 2019)

Topic of Standard	Title of Standard	Status
Umbrella document	ISO/DTS 20721: Implants for surgery—guidance for the assessment of absorbable metal implants (as revised)	Under development in ISO/TC 150
Material Characterization	ASTM F3160-16: Standard guide for metallurgical characterization of absorbable metallic materials for medical implants	Published 2016
Degradation guidance	ASTM WK52640: Standard guide to in vitro degradation testing of absorbable metals	Ballot approved; expected publication 2018
Fatigue Testing	ASTM WK61103: Standard guide for corrosion fatigue evaluation of absorbable metals	Updated draft review May 2018
Biological evaluation	ISO/NP TS 37137-1: Biological evaluation of medical devices—Part 1: Guidance for absorbable implants	Under development in ISO/TC 194
	ISO/DTR 37137-2: Biological evaluation of medical devices—Part 2: Guidance for absorbable metal implants	Under development in ISO/TC 194

2016). In a prospective, randomized clinical trial (ChiCTR-TRC-13003238) with 48 patients (18–55 years) suffering from femoral head osteonecrosis of the ARCO stage II/III (Association Research Circulation Osseous), 23 patients received the Mg screw fixation of the bone flaps during ONFH and the remaining 25 patients received the vascularized bone grafting without fixation. Computed tomography analysis showed higher mineral density around the Mg screws, and continuous degradation of the Mg screw after implantation from 3.7 ± 0.4% at 1 month postoperative to 25.2 ± 1.8% at 12 months postoperative. A collapse of the femoral head was observed twice in the Mg screw group and six times in the control group. After 12 months, the Mg screw group had a significantly higher Harris hip score than the control group. The Chinese FDA (CFDA now National Medical Products Administration) recently approved high-purity Mg screws as medical devices for various applications, e.g., in fractures of the femoral neck, femoral head, and metatarsals (Han et al., 2019).

Current Perspective on Mg-Based Degradable Implants

Mg-based biodegradable metals have been intensively investigated during the past decades and have finally been introduced as medical devices in the clinic. Further clinical applications, e.g., as clips in general surgery or in oral surgery as barrier membranes or membrane fixation screws, may be available soon.

Summary

Biodegradable metals have been established as a new class of biomaterials. About one decade after rediscovery of this biomaterial class in 2000, Mg-based biodegradable metals were introduced as medical devices in cardiovascular and orthopedic applications. Medical devices based on Fe-based or Zn-based biodegradable metals seem to be promising, but the technology needs to meet the right market and investment situation before it can be seen as medical devices on the market.

In general, it might be advisable for biodegradable metals to look for small volume implant applications that require high-specific strength materials. These applications may be safe and the clinical performance design of these implants seem to be achievable by biodegradable metals.

In this regard, iron-based biodegradable metals may have a challenging future as large-volume, solid, and bulky implants. However, there might be some advantageous applications for very low-volume Fe-based implants in well-perfused tissues. Zinc-based implants seemed to be promising for temporary implants, but they are still mainly used in academic research.

The term "absorbable" has been introduced to "biodegradable metals" in the regulatory language to harmonize the language with already existing guidelines for "absorbable polymers." Even though it seems to be confusing, the terms "absorbable" and "biodegradable" can both be used equally for biodegradable metal implants. The standards and guidelines that are under development by ISO and ASTM (Table 1.3.3D.3) will serve as a platform that allows the comparison of results from different labs. These new standards will certainly promote a faster translation of biodegradable metals toward their clinical use.

Acknowledgment

The author appreciates the intensive discussions and help of Frank Feyerabend and Norbert Hort.

Ceramics, Glasses, and Glass-Ceramics: Basic Principles

JULIAN R. JONES[1], IAIN R. GIBSON[2]

[1]Department of Materials, Imperial College London, South Kensington Campus, London, United Kingdom

[2]Institute of Medical Sciences, School of Medicine, Medical Sciences and Nutrition, University of Aberdeen, Aberdeen, United Kingdom

Introduction

Ceramic, glass, and glass-ceramic implant materials can be broadly grouped as bioceramics. These materials often contain a broad range of hard inorganic components that are generally used to repair, replace, or regenerate bone or teeth, and their applications are becoming broader with time.

This chapter will consider bioceramic implant materials that are designed to be nearly bionert and those that are bioactive (and biodegradable). No material implanted in living tissue is completely inert because all materials elicit a response from living tissues. Nearly-inert bioceramics tend to be used where a robust hard surface is needed, e.g. a joint replacement with articulating bearing surface or dental restoration. Nearly-inert implants are commonly surrounded by fibrous capsules in the body due to the body's inflammatory response to foreign objects. Bioactivity is regarded as the provocation of a beneficial biological response from the body's host environment to the implanted devices. In the case of bioactive ceramics, glasses, and glass-ceramics, this has traditionally been regarded as the ability to form a direct bond with bone tissue without fibrous encapsulation. This chapter will discuss these two types of bioceramics (nearly inert bioceramics and bioactive bioceramics) with a focus on materials that have been utilized in clinical applications.

Nearly-Bioinert Ceramics

Common nearly-bioinert bioceramics are alumina (aluminum oxide) and/or zirconia (zirconium oxide)-based biomaterials. A medical device, or part of it, made of these nearly-inert bioceramics is often formed from fine-grained particulate solids, e.g. by mixing the particulates with water and an organic binder, then pressing them in a mold. Subsequently, the temperature is raised to evaporate the water (i.e., drying) and the binder is burned out. At a very much higher temperature, the part is densified during firing. After cooling to ambient temperature, one or more finishing steps, such as polishing, may be applied.

Without the densification stage, pores will remain in between the particles, which can act as defects under mechanical loads. The process of densification closes those pores in a process commonly known as sintering and for bioceramics this is typically by solid-state sintering. In some systems when the temperature is raised to a certain point at which some liquid phases form at grain boundaries, while the majority of the material remains solid, densification can occur by "liquid-phase sintering." Here, as the liquid penetrates between the grains and fills the pores, it will draw the grains together by capillary attraction, thereby decreasing the volume of the powdered compact (densification). The microstructure resulting from this "liquid-phase sintering" will consist of small grains from the original powder compact surrounded by a liquid phase. As the compact is cooled, the liquid phase will crystallize into a fine-grained matrix surrounding the original grains. A powder compact can also be densified without the presence of a liquid phase by a process called solid-state sintering. In this case, atoms move to fill up the pores and channels between the grains of the powder compact, causing the grains of crystals to bond together more tightly, thereby leading to greatly improved density, strength, and fatigue resistance for the sintered ceramic object. The rate of densification for solid-state sintering is typically slower than that for liquid-phase sintering, because material transport is slower in a solid state than in a liquid state. However, a higher degree of purity and uniformity in fine-grained microstructures can be obtained via the solid-state sintering process, making it a common process for forming many bioceramics.

Alumina and Zirconia Ceramics

Alumina (Al_2O_3) has been used in orthopedic surgery for over 50 years. High-density, high-purity (>99.5%), fine-grained polycrystalline α-Al_2O_3 is used in the articulating surfaces of total joint prostheses because of its excellent corrosion resistance, high wear resistance, and high strength (Chevalier and Gremillard, 2009; De Aza et al., 2002). To form these ceramics, ceramic powder is pressed and sintered at 1600–1700°C. A very small amount of MgO (<0.5%) is used to aid sintering and limit grain growth during sintering. Too much sintering aid would be detrimental (Rahaman et al., 2007).

The strength, fatigue resistance, and fracture toughness of polycrystalline α-Al_2O_3 ceramics are functions of grain size and percentage of sintering aid (i.e., purity) (Chevalier and Gremillard, 2009; De Aza et al., 2002). Al_2O_3 ceramics with an average grain size of ~4 μm and >99.7% purity can exhibit good flexural strength (e.g. 55 MPa) and excellent compressive strength (e.g. 4.5 GPa), which are needed to reach the International Standards Organization (ISO) requirements for alumina implants (ISO 6474).

The use of polished alumina as part of the articulating joint was motivated mainly by its exceptionally low coefficient of friction and low wear rates. The superb tribology properties (friction and wear) of alumina occur only when the grains are very small (<4 μm) and have a very narrow size distribution. These conditions lead to very low surface roughness values (Ra <0.02 μm). If large grains are present, they can be pulled out, leading to very rapid wear of bearing surfaces because of local dry friction.

Yttria-stabilized zirconia was later introduced for articulating applications in hip and knee implants (Chevalier and Gremillard, 2009; De Aza et al., 2002). Specifically, zirconia stabilized with 3 mol% yttria, termed Y-TZP, results in a ceramic with excellent fracture toughness. However, a series of implant failures around the year 2000 resulted in the withdrawal of zirconia for these applications. This is because of unforeseen aging of the ceramic postimplantation, where the crystal structure of the ceramic changed from tetragonal to monoclinic, making the ceramic more brittle. Today, development of zirconia-toughened alumina (ZTA) is used as it has enhanced strength and toughness properties over α-Al_2O_3. Small zirconia grains within the alumina matrix will not only slow down the aging process but also prevent crack propagation. ZTA is now in widespread use for the articulating surfaces of knee implants and trials are currently under way for hip arthroplasty, which could benefit younger patients as it will help preserve much of the underlying bone in the femoral head. Alumina and zirconia ceramics are described in more detail in Chapter 1.3.4B.

Bioactive Ceramics and Glasses

Bioactive ceramics and glasses are designed to elicit a biological response that supports tissue repair, specifically bone formation and integration. The types of biological responses to such bioactive materials, alongside bioinert ceramics, are discussed in detail in Chapter 2.2.2 and the classic descriptions of these are summarized in Table 1.3.4.1.

The responses described in Table 1.3.4.1 are not simply dictated by material type; the physical form that a given material takes will also influence the local tissue response, such as dense or porous, low or high surface area, among others. In the context of bone repair, a bioactive material would be associated with bone formation at the implant surface, but it may also undergo osteoclast resorption (Hasegawa et al., 2003), activation of a proinflammatory response (Zhao et al., 2018), or new blood vessel formation (Arkudas et al., 2013), in addition to being chemically resorbed. Clinical applications of bioactive ceramics and bioactive glasses are quite broad and Table 1.3.4.2 lists some of the example cases.

These different applications require the use of bone grafts. Synthetic bone graft substitutes derived from bioactive ceramics and bioactive glasses offer advantages over other grafts such as autografts, allografts, and demineralized bone matrix (DBM) (Oryan et al., 2014). The properties of these synthetic materials will depend on their chemical compositions, their physical micro- and macrostructures, and the forms in which they are used within an implant. These different attributes of bioactive ceramics and bioactive glasses will now be described separately. It should be noted that bioactive ceramics and glasses also have a role as scaffolds in orthopedic tissue engineering and this is described elsewhere in this book (see Chapters 2.6.3 and 2.6.5).

TABLE 1.3.4.1 Types of Implant-Tissue Response Observed With Bioceramics

Type of Tissue Response to Biomaterial	Description of Tissue Response
Biologically active (bioactive)	An interfacial bond with tissue forms. For bone repair, implants may allow/support the formation of bone (osteoconductive) or may induce the formation of bone.
Biologically inactive (nearly inert, or bioinert)	The material is tolerated by the formation of a fibrous tissue layer for variable thickness
Resorbable	Implant material is resorbed/degraded by chemical and/or biological processes, typically designed to allow new tissue to replace it. Degradation products should be biocompatible.
Toxic	Toxic response, surrounding tissue death (local), with potential systemic toxicity

Bioactive Ceramics

A number of ceramic materials have been shown to be bioactive but the most widely studied group is calcium phosphate-based bioceramics. These materials share a similarity in chemical composition to the mineral component of bone and teeth. A wide range of distinct calcium phosphate phases exist that can be found in mineralized tissue in nature. This family of calcium phosphate phases is typically classed in terms of the molar ratio of calcium-to-phosphorus (Ca/P), their polymorphs (same chemical composition but different crystal structure), the presence/absence of structural water, and whether any crystalline phases can only form at high temperatures (e.g., tetracalcium phosphate). Some of the main phases that are relevant to bioactive calcium phosphate ceramics and bone graft substitutes are listed in Table 1.3.4.3.

TABLE 1.3.4.2 Types of Clinical Indications That Utilize Bioactive Ceramics and/or Glasses as Synthetic Bone Graft Substitutes

Orthopedics	
General	Filling of bone defects, including after removal of bone cysts
Trauma	Long-bone nonunion fractures Tibial plateau fractures Repair of long bone fractures Hand surgery
Spine	Posterolateral spinal fusion Interbody spinal fusion
Craniomaxillofacial/Dental	
Trauma	Cranioplasty Repair of orbital floor fracture
Disease	Sinus obliteration Repair after cyst removal
General oral/dental defects	Ridge augmentation Repair of tooth extraction sites Periodontal regeneration

One of the major differences in the properties of these different calcium phosphate phases is their relative solubility. At physiological pH and at 37°C, the solubility of the CaPs listed in Table 1.3.4.3 has the following order: dicalcium phosphate anhydrous (DCPA) = dicyclopentadiene (DCPD) > α-tricalcium phosphate (α-TCP) > β-TCP > TCP > Ca-deficient apatite (CDA) > octacalcium phosphate (OCP) > hydroxyapatite (HA) (LeGeros, 2002). The application of a number of these phases (DCPA, DCPD, α-TCP, and TCP) is predominantly as reactant phases in calcium phosphate bone cements, due to their inherent high solubility at physiological pH; these cements will be discussed later.

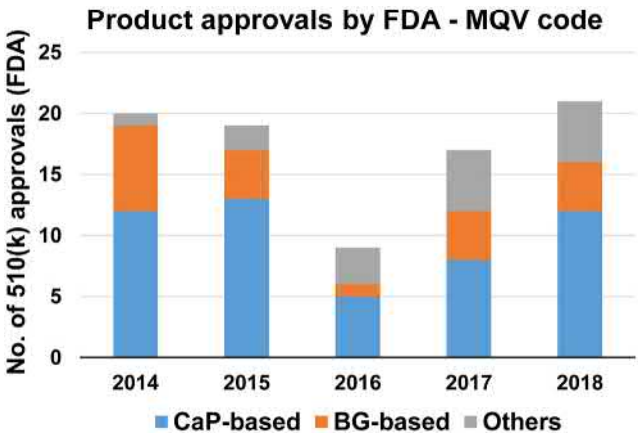
DCPD, DCPA, and OCP, although not traditionally classed as ceramics as they form by aqueous precipitation at or close to room temperature and would transform to different calcium phosphate phases through traditional high-temperature ceramic processing, have been studied as potential bone graft substitutes (Tamimi et al., 2010; Komlev et al., 2014; Sheikh et al., 2017; Kawai et al., 2017).

Calcium phosphates can be used to coat metallic and polymeric implants to provide a bioactive surface on a bulk material that is biologically inert. The most studied coating is HA on metallic implants and it is usually applied to the implant surface using a high-temperature plasma-spraying method. This, along with other coating methods, is described in more detail in Chapter 1.3.4A.

Of the calcium phosphate phases listed in Table 1.3.4.3, HA and TCP are the two compositions that are widely studied as bioactive ceramics. They are mainly used as bone graft substitutes, which sometimes are referred to as bone void fillers (BVFs). They are typically used in the form of porous ceramics, often within a natural (e.g., collagen) or synthetic (e.g., polyethylene glycol [PEG]) polymeric carrier, or as cements. These different forms offer distinct advantages, depending on the nature of the bone defect to be repaired. In the United States, calcium salt BVFs approved for orthopedic use by the Food and Drug Administration (FDA) are classed with a product code MQV, whereas for dental application they have the code LYC. To give some context of the number of synthetic bone graft substitutes available

TABLE 1.3.4.3 Different Calcium Phosphate Phases Relevant to Bioceramics

Chemical Name	Chemical Formula	Ca/P Molar Ratio	Mineral Name
Dicalcium phosphate anhydrous	$CaHPO_4$	1.0	Monetite
Dicalcium phosphate anhydrous	$CaHPO_4.2H_2O$	1.0	Brushite
Octacalcium phosphate	$Ca_8(HPO_4)_2(PO_4)_4.5H_2O$	1.33	
Tricalcium phosphate (α-, β-) (TCP)	$Ca_3(PO_4)_2$	1.50	Whitlockite (β-TCP)
Ca-deficient apatite	$Ca_{10-x}(HPO_4)_x(PO_4)_{6-x}.(OH)_{2-x}$	$0<x\leq1$, $(1.50\leq Ca/P<1.67)$	
Hydroxyapatite	$Ca_{10}(PO_4)_6(OH)_2$	1.67	Apatite, hydroxyapatite
Tricalcium phosphate	$Ca_4O(PO_4)_2$	2.0	Hilgenstockite



• **Figure 1.3.4.1** The number of synthetic bone graft substitutes approved annually by the Food and Drug Administration (FDA) under the MQV product code (calcium salt bone void fillers) between 2014 and 2018; the approvals may be for trauma indications and/or posterolateral spinal fusion indications (CaP based include hydroxyapatite, tricalcium phosphate, and biphasic calcium phosphate-based bone grafts and CaP cements; bioactive glass [BG]-based includes Bioglass containing bone grafts; others include demineralized bone matrices, calcium carbonate-based bone grafts, and polymer-based bone grafts).

commercially, a summary of the number of MQV products approved by the FDA between 2014 and 2018 is depicted in Fig. 1.3.4.1.

Porous Calcium Phosphate Ceramics

Bone graft substitutes produced from porous calcium phosphates usually consist of either HA or β-TCP, or a mixture of these two phases to produce biphasic calcium phosphates (BCPs). The relative solubility of β-TCP is much higher than that of HA. Both of these materials are osteoconductive, providing a surface that encourages new bone formation, with their major difference being the rate of degradation in vivo (Klein et al., 1983). In cases where rapid resorption of the bone graft is required, the use of β-TCP could be preferred to HA, but the challenge could be that the β-TCP resorbs faster than the rate of bone formation. The limited solubility of HA ceramics can result in a material with an osteoconductive surface that, once host bone forms on the surface, shows limited further integration and is not remodeled.

The rationale for BCP compositions with a biphasic mixture of HA and β-TCP is that it provides a material offering a mixture of these biological responses (Bouler et al., 2017). The relative amounts of these two phases has been shown to have an effect on bone formation (Jensen et al., 2009), soft tissue response (Ghanaati et al., 2012), material degradation/resorption (Yamada et al., 1997; Daculsi et al., 1989), and even osteoinduction (Arinzeh et al., 2005; Tang et al., 2017).

Calcium phosphate phases utilized as bioceramics can be synthesized using a number of methods; these are described in detail for the case of HA in Chapter 1.3.4A, and all these methods may also be used to synthesize TCP and BCP bioceramics. Briefly, aqueous precipitation reactions involving calcium and phosphate reactants are preferred methods (Osaka et al., 1991; Jarcho et al., 1976). The Ca/P molar ratio of the product formed can be controlled by the synthesis conditions, principally the pH but also the concentration of reactants and the temperature, and this method can be easily scaled to large volumes for translation to commercial manufacture. In these methods the product formed is described by the composition in Table 1.3.4.2 of a CDA, and the value of x can vary from 0 to 1 depending on the synthesis design. When the formed composition is heated/sintered to temperatures above 750°C and water is lost, the final composition will form with either HA ($x=0$), TCP ($x=1$), or BCP ($1>x>0$, with the amount of TCP relative to HA increasing as x increases). If excess calcium is present, or reaction conditions have allowed large drops in pH to below 7, it is possible that other CaP phases may be present in the product phase (DCPD, DCPA, or OCP) and this would affect the final bioceramic composition on heating/sintering. Aqueous precipitation reactions can also be used to synthesize DCPD, DCPA, or OCP, but these would not involve a heating/sintering step to form the final composition.

There is an increased interest in producing nanoparticles of calcium phosphates, primarily apatites, and these can be produced by aqueous precipitation reactions but can also be synthesized by other methods such as biomimetic synthesis, sol-gel synthesis, and hydrothermal methods (see Chapter 1.3.4A).

Synthesized CaP bioceramics can be characterized by a number of methods and ISO 13175-3 (2012) and ASTM F1185-03 (2014), F1088-18 (2018) standards describe the requirements of characterization methods and the expected parameters for use of these compositions as bone replacement materials. Primary measures of chemical characteristics of these materials include phase composition/phase purity (X-ray diffraction), chemical composition (Ca/P molar ratio, impurity content, using, e.g., X-ray fluorescence and/or inductively coupled plasma-optical emission spectrometry), presence of specific functional groups (Fourier transform infrared and/or Raman spectroscopy), surface area, and density. The identification of different calcium phosphate phases can be achieved by reference to standard powder diffraction files from the International Centre for Diffraction Data. Some of these main CaP phases and the most common impurity phases are listed in Table 1.3.4.4.

Infrared and Raman spectroscopy have been used to characterize naturally occurring calcium phosphates and also synthetic calcium phosphates (Koutsopoulos, 2002), providing a complementary method for distinguishing different CaP phases and small changes that may occur in these materials during synthesis and/or processing, such as the inclusion of carbonate ions or the loss of structural water.

In addition to the chemistry of bone graft substitute ceramics affecting their behavior, the physical form in which they are manufactured is as, if not more, influential. HA, TCP, and BCP ceramics can be produced by typical ceramic approaches such as optimizing the powder properties in

TABLE 1.3.4.4 Powder Diffraction Files (PDFs) for the Main Calcium Phosphate Phases and Most Common Impurity Phases

Chemical Name	Chemical Formula	PDF No.

terms of particle size, surface area, and composition of HA, and the sintering conditions, including compaction pressure, sintering temperature, and sintering atmosphere (Patel et al., 2001; Gibson et al., 2001; Champion 2013). As calcium phosphate ceramics exhibit relatively poor mechanical properties compared with other bioceramics, dense monolithic calcium phosphate ceramics have limited applications. Production of macroporous ceramics as bone graft substitutes from natural sources such as converted coral and bovine bone still relies on the sintering/densification of the calcium phosphate in a structure that contains large macropores, typically 100–1000 µm in size (Seebach et al., 2010). Other methods for producing macroporous ceramics of calcium phosphates are: space holder, e.g., polymer sphere, burnout (Bouler et al., 1996); use of polymer foam templates (Ramay and Zhang, 2003); gas-inducing reactions such as decomposition of hydrogen peroxide (Almirall et al., 2004); mechanically induced foaming procedures (Binner and Reichert, 1996); and more recently using 3D printing methods (reviewed by Yu et al., 2017). The latter provides a significant amount of design control that is not available with other methods, and this opens up the feasibility of making individualized patient-specific scaffolds. Currently, scalable additive manufacturing of large volumes may be limited to more simple architectures.

The characteristics of the porosity produced by these different methods, such as pore size, pore size distribution, total porosity, and pore interconnectivity, can be controlled and they have significant effects on bone ingrowth and integration (Gauthier et al., 1998). Typical macroporous calcium phosphate bone graft substitutes have cancellous bone-like foam architectures with 50%–90% total porosity and macropore sizes of 100–1000 µm, with a high level of interconnectivity between the pores (Seebach et al., 2010). Calcium phosphate particles form the struts or the "skeleton" of the material and to improve the scaffolds' resistance to crushing or damage they need to undergo densification/sintering, and the powder properties and sintering parameters can be optimized to achieve this.

Macroporous calcium phosphate bone graft substitutes and scaffolds are designed to have an interconnecting network of pores to encourage host bone ingrowth and formation. Characterization of this pore structure requires specific techniques (Jones et al., 2007). Scanning electron microscopy (SEM) is often used to study pore shape/structure, either on the material surface or from 2D sections cut through the material. Mercury intrusion porosimetry allows quantification of pore size distribution and an indication of interconnectivity/presence of trapped, isolated pores, and pore windows. An effective nondestructive alternative to these methods is using microcomputed tomography, which is effective at quantifying macroporosity but requires smaller pixel sizes to effectively quantify microporosity in the porous structures (Cengiz et al., 2017).

For bone regeneration, large pores are needed that allow for blood (carrying cells) flow into the scaffold and space for 3D growth of immature bone and, perhaps most importantly, population by blood vessels. The morphology and degree of interconnectivity of pores may be more critical than the pore size. Comparing 3D printed scaffolds with orthogonal pore channels with cancellous bone-like porous foams both in the form of synthetic HA, which has similar sizes of interconnections between the pores (Barba et al., 2017), it was found that bone ingrowth was more rapid in the foam scaffold than in the printed scaffold. This was attributed to bone progenitor cells preferring the concave niche of the pores in the foams.

As shown in Fig. 1.3.4.1, a large number of synthetic bone graft substitutes have been approved for clinical use and examples of some commercially available calcium phosphate-based bone graft substitutes are listed in Table 1.3.4.5, including the calcium phosphate phase(s) present in these materials and the form that the CaP takes in the product. This selection is chosen to represent the broad range of CaP compositions chosen for use in bone graft substitutes and does not represent a selection based on any clinical performance. Clinical data showing the efficacy of different synthetic bone graft substitutes are very limited, in terms of the number of studies, the size and design of published studies that do exist, and the broad range of fusion techniques/approaches studied. Some recent clinical studies compared clinical outcomes in spinal fusion of a synthetic

TABLE 1.3.4.5 A Selection of Commercially Available Calcium Phosphate-Based Bone Graft Substitutes, Selected to Show the Range of CaP Material Compositions Used

Product Name	Calcium Phosphate Phase	Product Form	References
NanoBone Granulate (Artoss)	Nanocrystalline HA and a silica gel matrix	Granules	Abshagen et al. (2009)
Chronos Granules (Synthes)	β-TCP	Macroporous granules	Seebach et al. (2010)
Actifuse ABX (Baxter)	(Silicated) HA	Macroporous granules in a poloxamer hydrogel carrier	Miramond et al. (2013)
In'Oss (Biomatlante)	BCP (60% HA:40% β-TCP)	Macroporous granules in a carboxymethyl cellulose hydrogel carrier	Miramond et al. (2013)
Attrax Putty (NuVasive)	BCP (4% HA:96% β-TCP)	Macroporous BCP granules in an AOC polymer carrier	Barbieri et al. (2017)
Mastergraft Strip (Medtronic)	BCP (85% HA:15% β-TCP)	Macroporous BCP granules in a bovine collagen scaffold	Qiu et al. (2015)
Vitoss BA (Stryker)	β-TCP and bioactive glass particles	Macroporous β-TCP granules in a bovine collagen scaffold, with BG particles	Barbieri et al. (2017)

bone graft substitute against autograft, which is the clinical gold standard (Parker and Malham, 2017; Lechner et al., 2017). This fact may suggest that there is a shift toward obtaining more clinical data on new bone graft substitutes that will enable comparisons to be made. The efficacy of synthetic bone graft substitutes in general was reviewed in comparison with allograft or autograft in spinal fusion surgery, and a lack of clinical data limiting strong conclusions to be made was highlighted (Buser et al., 2016).

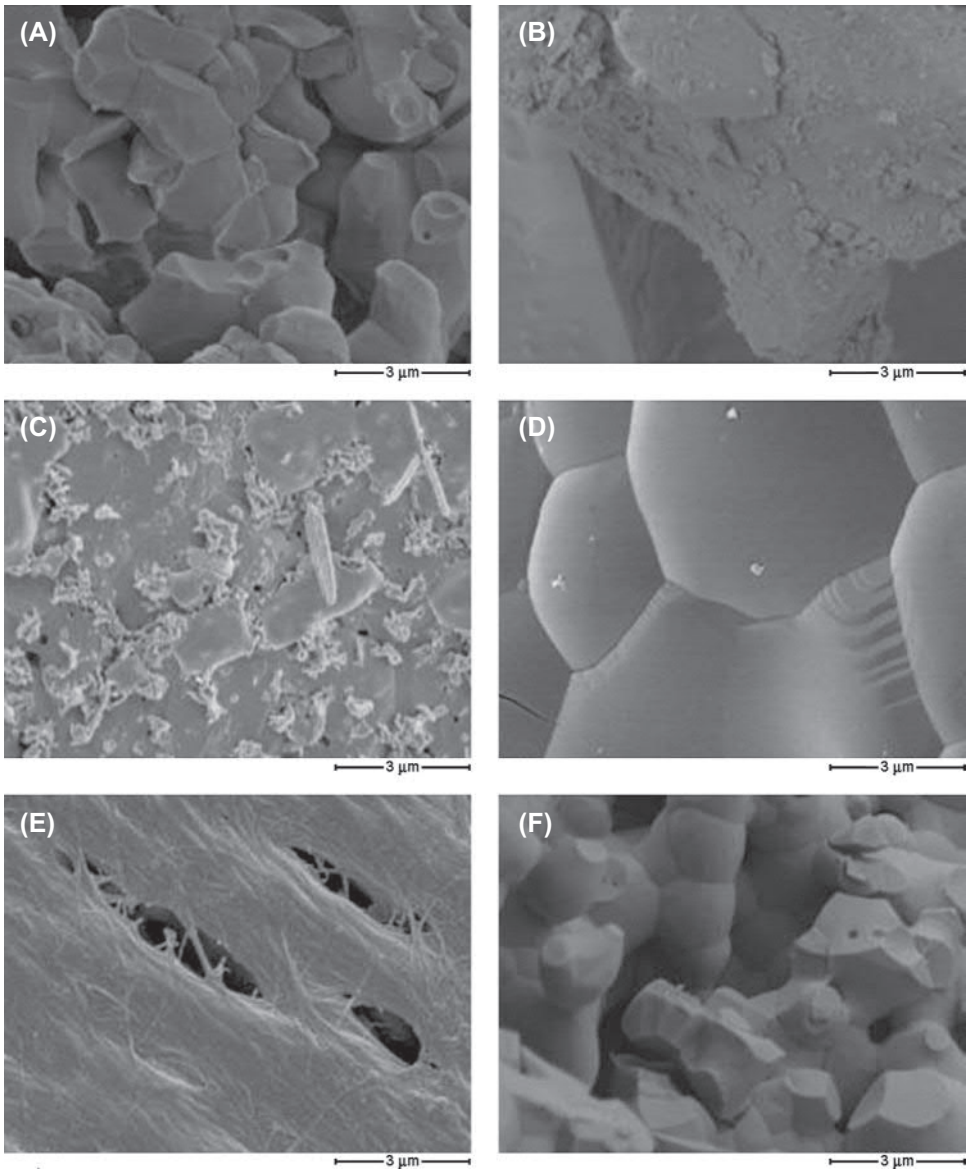
Calcium phosphate bone graft substitutes typically consist of macro- and/or microporous ceramics of HA, TCP, or BCP in a granular form, with typical sizes in the range of 0.4–2 mm. Some examples of synthetic calcium phosphate bone graft substitutes and of bone graft substitutes derived from human or bovine bones are presented in Fig. 1.3.4.2, highlighting the differences in sintered grain structures and microporosity (Seebach et al., 2010).

Granules are often mixed with saline, blood, or bone marrow aspirate (BMA) to improve their handling and to potentially introduce biological factors (from blood or BMA). Actifuse ABX (Baxter, UK) is a silicon-substituted synthetic HA available in the form of foamed granules (~3 mm dimensions). Microcomputed tomography imaging (Fig. 1.3.4.3) and subsequent image analysis showed how the pore network can be imaged and quantified and how its open pore architecture and modal interconnect size of 120 μm are important for its efficacy (Midha et al., 2013).

Most bone graft substitutes are designed to consist of granules in either a hydrogel carrier, anhydrous polymeric carrier, or collagen (or gelatin) scaffold (usually bovine or porcine collagen), with examples of these listed in Table 1.3.4.5. These formulations are designed to improve the intraoperative handling and placement of the synthetic bone graft substitute. They also allow surgeons to shape the graft material (if in the form of a putty) and/or combine with the patient's BMA, providing a cell population that might contribute toward bone repair. Some surgical procedures require delivery of a synthetic bone graft into a confined defect, possibly via a minimally invasive procedure, and/or a graft material that will set and harden in situ, which are cases where a cement has significant advantages.

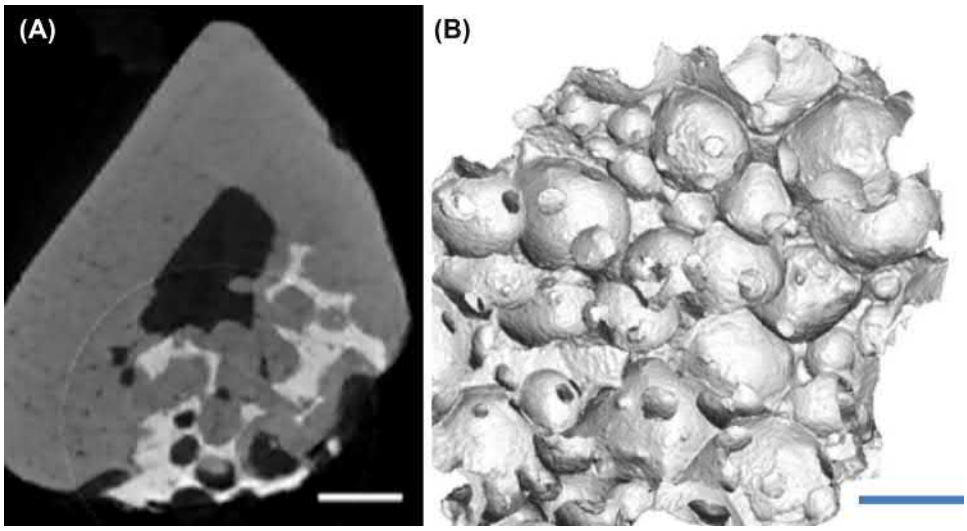
Calcium Phosphate Cements

A calcium phosphate bone cement involves mixing certain calcium phosphate phases with an aqueous solution to form a paste, which then undergoes a chemical dissolution and reprecipitation reaction analogous to calcium silicate construction cements, leading to interlocking/entanglement of new crystals of the product calcium phosphate phase and producing a set and hardened mass. This provides some unique advantages over typical ceramics for filling bone defects such as (1) being able to inject the paste into the defect, (2) creating a hardened mass that has a compressive strength similar to cancellous bone, and (3) incorporation of drugs or biomolecules into the aqueous phase, such as antibiotics. The final product of a calcium phosphate bone cement reaction is either brushite or an apatite phase (typically CDA), and which product phase is obtained will depend on the reactant phases chosen. The first calcium phosphate bone cement that led to a clinically used formulation was described in the early 1980s and consisted of mixtures of tetracalcium phosphate and dicalcium phosphate anhydrous or dihydrate (DCPA or



• **Figure 1.3.4.2** Scanning electron microscope images of a range of commercial synthetic and natural (derived from human or bovine bone) calcium phosphate bone graft substitutes: (A) synthetic silicate-substituted porous hydroxyapatite (Actifuse ABX); (B) synthetic α-TCP (Biobase); (C) processed bovine hydroxyapatite ceramic (Cerabone); (D) synthetic β-TCP (Chronos); (E) processed human cancellous allograft (Tutoplast); (F) synthetic β-TCP (Vitoss). *TCP*, Tricalcium phosphate. (Adapted from Seebach, C., Schultheiss, J., Wilhelm, K., Frank, J., Henrich, D., 2010. Comparison of six bone-graft substitutes regarding to cell seeding efficiency, metabolism and growth behaviour of human mesenchymal stem cells (MSC) in vitro. Injury 41, 731–738.)

DCPD), which formed an apatite as the product phase (Brown and Chow, 1983). An alternative cement formulation that produces an apatite product phase is a mixture of α-TCP and DCPA, with small amounts of precipitated HA (Fernández et al., 1996) or calcium carbonate (Fernández et al., 1998) added, and these formulations have led to clinically used cements. Many other mixtures of phases that result in an apatite product have been studied, but the TTCP/DCPA-DCPD and the α-TCP and DCPA systems provide optimum setting and handling characteristics. The effect of parameters such as particle size, surface area, liquid/powder ratio, and composition of aqueous solution used to form the cement on the properties of the paste/hardened cement has been studied extensively and reviewed elsewhere (Zhang et al., 2014). An example of the effect of the calcium phosphate used as a reactant in a cement is shown in Fig. 1.3.4.4, where the cement setting reaction of a cement composed of α-TCP is compared to a cement composed of β-TCP after immersion in water for 7 days (Montufar et al. 2013). The X-ray diffraction patterns show almost complete conversion of the α-TCP to a CDA product phase, with associated entanglement of apatite crystals observed by SEM, compared with minimal reaction in the β-TCP cement.



• **Figure 1.3.4.3** Microcomputed tomography images of Actifuse (porous silicon containing synthetic hydroxyapatite) bone graft: (A) 2D slice view (cross-section) of a rat tibia bone defect regenerating through the Actifuse granules 11 weeks after implantation, scale bar is 1 mm; (B) 3D image of an Actifuse granule, scale bar = 400 μm. The α-TCP cement reacts to form Ca-deficient apatite after 7 days, whereas the β-TCP cements exhibits minimal reactivity. *TCP*, Tricalcium phosphate. (Figure taken from Montufar, E.B., Maazouz, Y., Ginebra, M.P., 2013. Relevance of the setting reaction to the injectability of tricalcium phosphate pastes. Acta Biomater. 9, 6188–6198.)

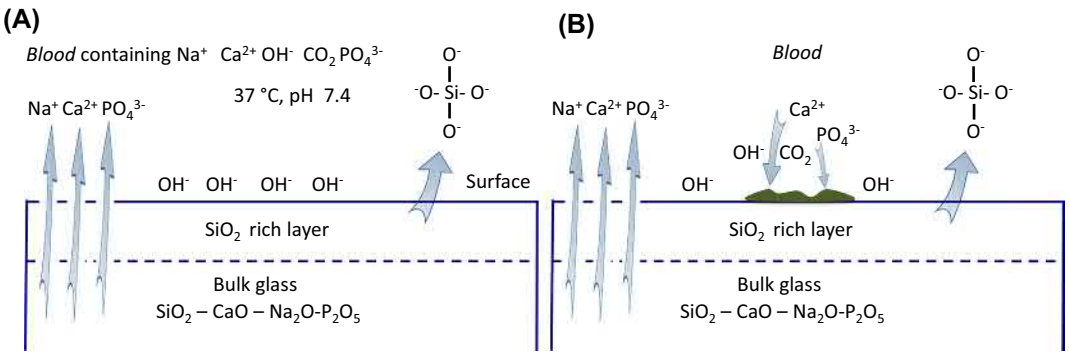
In the case of a cement with brushite as the product phase, a combination of β-TCP and monocalcium phosphate monohydrate with an aqueous phase led to the dissolution of the reactant phases and the precipitation of brushite crystals (Mirtchi et al., 1989). Although these cements are less common than the apatite-forming cement formulations, an interesting aspect of a brushite cement is that the product phase that forms is inherently unstable at physiological pH, and will undergo gradual dissolution during which it may be replaced by new bone. Brushite cements and their potential clinical applications have been reviewed in detail (Tamini et al., 2012).



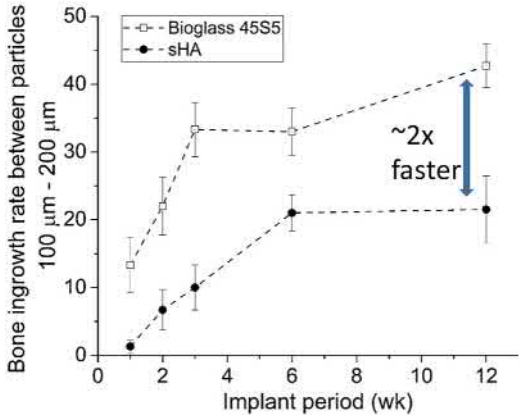
• **Figure 1.3.4.5** Schematic of the bone mineral-like hydroxycarbonate apatite (HCA) layer forming on the surface of a bioactive glass during solution-mediated dissolution: (A) cation exchange between the glass and protons in blood/solution; (B) deposition of amorphous calcium phosphate deposition, which crystallizes into HCA as glass dissolution continues.

Bioglass and Bioactive Glass

Bioglass was the first material to bond with bone, rather than be encapsulated by fibrous tissue, launching the field of bioactive ceramics (Hench, 2015). Bioglass degrades by dissolution in solution. Bioglass has two modes of bioactivity in terms of bone repair: (1) bone bonding is due to a hydroxycarbonate apatite (HCA) layer on the glass that forms following dissolution of the glass and precipitation of HCA on the glass surface (Hench et al., 1971), which is thought to integrate with collagen fibrils of the host bone, and (2) the osteogenic property of the bioactive glass due to the dissolution products of the glass, i.e., soluble silica and calcium ions, that stimulate bone cells to produce more bone (Hench and Polak, 2002; Silver et al., 2001). The first bioactive glass was discovered by Larry Hench (Hench, 2015) and was termed 45S5 Bioglass, having a composition of 46.1 mol% SiO_2, 24.4 mol% Na_2O, 26.9 mol% CaO, and 2.6 mol% P_2O_5 (Hench et al., 1971).

The mechanism for HCA layer formation on the surface of the glass is solution mediated. Cations in the glass, e.g., Na^+ and Ca^{2+}, exchange with protons (H^+) from the water in the blood/solution, leaving a silica-rich layer and Si–OH bonds on the glass surface. The low connectivity of the silica-rich layer means that some of the silica will also be lost and also enables continual ion transport out from the bulk of the glass. The blood already has high concentrations of calcium and phosphate and a further increase, plus a pH rise at the glass surface (due to the loss of H^+ from the solution), promotes calcium phosphate deposition on the glass surface, with Si–OH groups being suitable sites. The amorphous calcium phosphate then crystallizes as it incorporates OH and carbonate from the solution/blood, forming HCA (Fig. 1.3.4.5).

In vivo comparative studies between 45S5 and similar sized particles of synthetic HA showed that Bioglass produces more rapid and higher quality bone regeneration than HA (Oonishi et al., 1999) with 17 times more bone in defects filled with Bioglass after a week, and twice as much bone 24 weeks after implantation, compared to defects filled with sHA (Fig. 1.3.4.6) (Oonishi et al., 1997, 1999, 2000; Wheeler et al., 2000).



• **Figure 1.3.4.6** Percentage bone ingrowth into defects in rabbit femoral chondyle filled with particles of synthetic bone grafts of 45S5 Bioglass and synthetic hydroxyapatite (sHA). (Data replotted from Oonishi, H., Hench, L.L., Wilson, J., Sugihara, F., et al., 2000. Quantitative comparison of bone growth behavior in granules of Bioglass (R), A-W glass-ceramic, and hydroxyapatite. J. Biomed. Mater. Res. 51, 37–46.)

In vitro studies indicated that the reason for the improved bone growth was due to the dissolution products stimulating bone cells at the genetic level. The experiments involving human osteoblast cell media collected from the dissolution products of Bioglass, without the glass itself, showed that seven families of genes that support osteogenesis are upregulated within 48 h of exposure to the ion "soup" (Xynos et al., 2001). The dissolution media were prepared simply by soaking the glass in culture media, extracting the dissolution of the glass, before removing the glass. The dissolution products were then given to the cells that were cultured in conventional tissue culture well plates. Transcription of at least five extracellular matrix components was also induced. Extracellular matrix secretion increased, which mineralized without addition of osteogenic supplements or growth factors (Xynos et al., 2000a, b). The gene expression was dose dependent, with the highest observed at ~20 µg mL^{-1} of soluble silica, accompanied by 60–90 µg mL^{-1} of calcium ions (Hench, 2009).

The results enabled NovaBone Products LLC (Jacksonville, FL), the company that was producing the Bioglass

• **Figure 1.3.4.7** PerioGlas and NovaBone packaging with a scanning electron microscopy image of the Bioglass particulate grafts (scale bar is 200 μm) and BonAlive packaging with BonAlive granules in a delivery device.

particulate product at the time, to claim the term "Osteostimulation." Many research groups have since investigated incorporation of other cations with potential therapeutic benefits into bioactive glasses, but they are yet to reach clinical use (Hoppe et al., 2011).

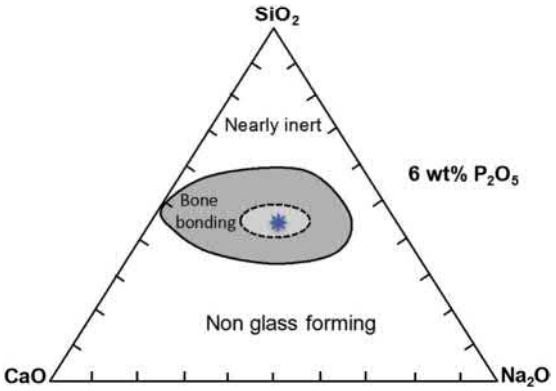
Bioglass Granules

The original Bioglass 45S5 has been used in more than 1.5 million patients (Pomrink, 2016) in the form of a particulate synthetic bone graft, marketed under the trade name NovaBone, to repair bone defects in orthopedics and maxillofacial reconstruction (Hench, 2011). However, NovaBone particulate did not reach the market until 2005. The first particulate Bioglass was PerioGlas, which was launched in 1993 as a synthetic bone graft for the repair of pockets in the jaw bone that resulted from periodontal disease. It is usually applied by mixing first with saline solution. Fig. 1.3.4.7 shows PerioGlas and NovaBone packaging and an SEM image of the particulate (90–710 μm). Clinical studies (Low et al., 1997; Lovelace et al., 1998; Rosenberg et al., 2004; Anderegg et al., 1999; Yukna et al., 2001; Park et al., 2001; Norton and Wilson, 2002; Sculean et al., 2002; Mengel et al., 2003; Froum et al., 1998; Shapoff et al., 1997; Zamet et al., 1997a, b) showed that bone pockets treated with PerioGlas were ~70% filled with new bone compared to ~35% for controls, which were often bovine bone mineral, which is slower to biodegrade/remodel. The product has also been used with polymeric membranes, which periodontists term guided tissue regeneration (Yadav et al., 2011).

For orthopedic applications, NovaBone is usually mixed with blood from the bone defect by the surgeon before being pressed into place. It was compared with autograft in posterior spinal fusion operations in clinical trials for the treatment of adolescent idiopathic scoliosis (curvature of the spine), wherein the grafts were compressed in place by the neighboring vertebrae via metal screws (Ilharreborde et al., 2008). NovaBone performed as well as autograft over the 4-year follow-up period, with the benefit that a donor site was not needed with NovaBone.

Biogran (Biomet 3i, Palm Beach Gardens, FL) is a 45S5 glass particulate graft with a narrow (300–350 μm) particle size range, and it is used in periodontal regeneration. In vivo studies showed that the HCA layer forms and then the particles hollow out within 4 weeks of implantation because of phagocytes entering the particles through cracks in the HCA shell to break down the glass core (Schepers and Ducheyne, 1997). Clinical trials showed that Biogran outperformed synthetic HA in bone pockets in the jaw (Schepers et al., 1993).

The 45S5 Bioglass composition is not the only glass composition that is considered bioactive. Fig. 1.3.4.8 shows a composition map, with the composition region marked that is predicted to be bioactive.



• **Figure 1.3.4.8** Composition map with a predicted area in which a glass composition will bond with bone; 4555 Bioglass composition is denoted with a star (phosphate content fixed at 6 wt%). The dashed region indicates a composition region that is likely to also bond with soft tissue (note: this is not a phase diagram).

The S53P4 composition (53.8 mol% SiO_2, 21.8 mol% CaO, 22.7 mol% Na_2O, 1.7 mol% P_2O_5) is another synthetic bone graft called BonAlive (BonAlive Biomaterials, Turku, Finland), which also has a larger particle size range (1–4 mm) (Andersson et al., 1990). In vitro studies indicated that the glass may have antimicrobial properties (Stoor et al., 1998) and clinical reports suggest that BonAlive can help treat chronic osteomyelitis (bone infection, usually caused by bacteria), even when antibiotics alone have been ineffective. In a clinical study, 11 patients with chronic osteomyelitis (*Staphylococcus aureus*) in the spine (Lindfors et al., 2010a) were treated with S53P4 with a 10–38-month follow-up. Nine patients healed without complications, while the other two had unrelated complications.

There are many more journal articles on clinical trials of S53P4 compared with those featuring the original 45S5 Bioglass. It is important in such trials to be able to compare with the clinical gold standard (autograft). BonAlive granules (1–4 mm, 14 patients) were compared with autograft (11 patients) for regeneration of defects created by the removal of benign bone tumors, with a 14-year follow-up (Lindfors et al., 2010b). Following treatment with BonAlive, the cortical bone thickness was twice as thick as it was after treatment with autograft. However, some of the glass remained in the bone, even after 14 years. NovaBone is thought to biodegrade in 1–2 years (Hupa et al., 2010). An 11-year follow-up on BonAlive in subchondral bone defects also showed some glass particles were still present, even at 11 years postoperation (Heikkila et al., 2011). The glass began to degrade between 12 and 36 months and stimulated remodeling of the bone (Lindfors et al., 2009) but remodeling was slower than in the case of autograft (at 12 months) (Lindfors et al., 2008). Slower resorption of S53P4 compared with 45S5 is due to glass composition, which has higher silica content and network connectivity than 45S5.

Network connectivity (Eq. 1.3.4.1) is a method of predicting the bioactivity of bioactive glasses based on their nominal composition (Hill and Brauer, 2011). It uses the glass composition (in mol%), where M_f is the molar fraction of the network oxide (e.g., SiO_2) and M^1_2O and $M^{II}O$ are molar fractions of the mono- and divalent modifier oxides, e.g., Na_2O and CaO. This calculation (NC′) assumes that phosphate forms its own orthophosphate network, charged balanced by divalent cations.

$$NC' = \frac{4\left(M_f\right) - 2\left(M^1_2O + M^{II}O\right) + 6\left(M_{P_2O_5}\right)}{M_f} \quad \textbf{(1.3.4.1)}$$

The relationship of network connectivity and bioactivity is limited by certain assumptions: that the glass is homogeneous; that once a bridging oxygen bond is broken, it will be replaced with a nonbridging oxygen; and that the user has to define what role a particular atom will play within the network. The last assumption may not be obvious, for example, magnesium in a silicate glass can act as a former (MgO_4) and/or a modifier (Mg^{2+}), with ~14% of the total magnesium acting as a network former (Watts et al., 2010).

The slow resorption rate of S53P4 becomes useful for dentists and maxillofacial surgeons who need to replace bone lost in the maxilla (upper jaw), for example, in patients with periodontitis. The treatment is termed a sinus floor lift, where bone grows partially into the sinus cavity. A mixture of S53P4 granules mixed with autograft showed more rapid bone repair compared to autograft alone (Turunen et al., 2004).

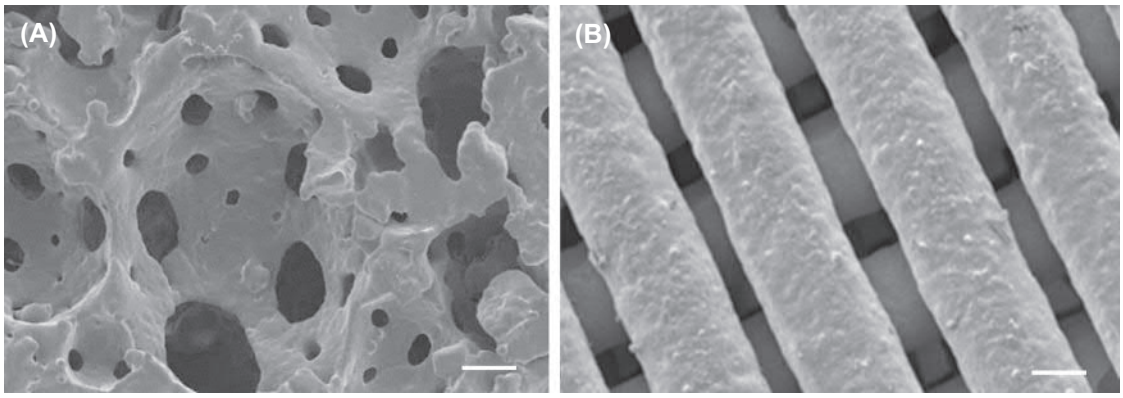
Bioactive Glass Composites and Putties for Bone Repair

NovaBone (45S5), GlassBone (45S5, Noraker, Lyon, France), and BonAlive (S53P4) are available in bioresorbable putty form (Schallenberger et al., 2014), which consists of a carrier matrix of PEG and glycerin containing the glass particles, with the aim of providing clinicians with easier delivery methods. Common bone graft devices combine bioactive glass with a natural polymeric matrix to partially mimic natural bone, e.g., Vitoss Bioactive Bone Graft (Stryker, NJ) and NanoFuse (Amend Surgical, Alachua, FL), which have been shown to improve bone over DBM alone (Kirk et al., 2013). The DBM-based devices are a mixture of components, with little mechanical integrity, rather than true composites.

Structural composites containing bioactive glasses can be made for sustaining cyclic loads. Noraker have developed a screw for anterior cruciate ligament reconstruction called LockActiv (CE marked in 2015), which is a poly(L-lactide)-*co*-poly(D,L)lactide polymer matrix containing 45S5 Bioglass particles. The screw must fix a detached ligament into a hole that the surgeon has drilled into the host bone. A problem with such a composite is that much of the bioactive glass particles will be embedded within the polymer, reducing its bioactivity.

Porous Bioactive Glasses

Porous synthetic hydroxyapatite (porous sHA) has been used successfully in the clinic but the 45S5 and S53P4 compositions cannot be made into porous constructs while



• **Figure 1.3.4.9** Scanning electron microscopy images of bioactive glass scaffolds: (A) gel-cast foam; (B) Robocast 3-D printed. Scale bars are 200 μm. (Courtesy of Dr. Amy Nommeots-Nomm.)

maintaining their amorphous glass structure. This is due to the small difference between their glass transition temperatures (T_g) and crystallization onset temperatures (T_{Conset}) (Wu et al., 2011). To enable sintering, glass particles must be heated above T_g to enable the viscous flow of the glass and fusion of the particles, but if the temperature reaches T_{Conset} the glass will crystallize, which reduces bioactivity and can cause instability, unless the glass is fully crystallized intentionally (a glass-ceramic) (Filho et al., 1996). New compositions have been designed with an increased sintering thermal processing window, allowing thermal processing postmelt quenching (Elgayar et al., 2005; O'Donnell and Hill, 2010).

Three processes are most commonly used for making porous glasses: the foam replica (reticulation) method, direct foaming (gel-cast foaming process), and additive manufacturing. Foam reticulation uses polyurethane foam as a sacrificial template. A glass particle slurry coats the foam and the foam is burned out during sintering, creating porous scaffolds (Chen and Boccaccini, 2006). However, the struts can remain hollow, reducing the compressive strength of the scaffold (Hoppe et al., 2014; Baino et al., 2013).

The additive manufacturing technique is termed robocasting, direct ink writing, or extrusion 3D printing (different names for the same technique). Robocasting prints glass particles dispersed within a polymer binder. The binder must exhibit shear thinning properties and burn out below the T_g of the glass. Typically, 3D grid-like structures with straight channels are printed (Fu et al., 2011a).

The glass composition 13-93 (54.6 mol% SiO_2, 22.4 mol% CaO, 6 mol% Na_2O, 1.7 mol% P_2O_5, 7.9 mol% K_2O, 7.7 mol% MgO) has an excellent processing window. 13-93 scaffolds have been produced by foam reticulation, with porosities of 85%, pore interconnect (windows between pores) diameters in the range 100–500 μm, and compressive strengths of 11 ± 2 MPa (Fu et al., 2008). Robocast scaffolds with interconnects of 500 μm in the *xy* direction and 100 μm in *z* direction, with a porosity of 60%, had a mean compressive strength of 136 ± 22 MPa (Fu et al., 2011b). While 13-93 sinters nicely without crystallizing, it has a much higher network connectivity (2.58) compared to 45S5 Bioglass (2.11). The ICIE16 composition (49.46 mol% SiO_2, 36.6 mol% CaO, 6.6 mol% Na_2O, 1.07 mol% P_2O_5, 6.6 mol% K_2O) was designed to enable glass scaffold production with a network connectivity as close to 2.11 as possible (2.13).

Gel-cast foaming involves direct foaming of a glass particle slurry with the aid of a surfactant (Wu et al., 2011). The surfactant stabilizes air bubbles and rapid gelation then solidifies the slurry so that bubbles remain and form the pores. Foam scaffolds produced from ICIE16 glass had porosities of 79%, with modal pore diameters of 379 μm and compressive strength of 1.9 MPa (Fig. 1.3.4.9) (Wu et al., 2011; Nommeots-Nomm et al., 2017).

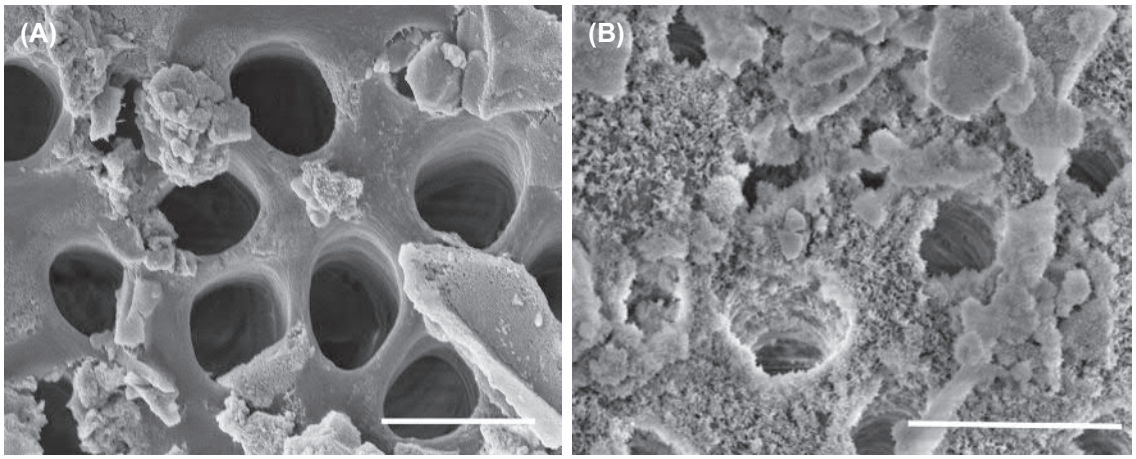
Wound Healing

Bioactive glass is thought to be useful in many applications aside from bone repair. One reason is that the amorphous glass can release many different ions with potentially therapeutic benefits as it biodegrades (Hoppe et al., 2011). The delivery of the ions is sustained and controlled by the degradation rate of the glass, which can be tailored more easily than drug release from conventional biodegradable polymers.

Another reason is the FDA approval of borate-based bioactive glasses for healing chronic wounds, e.g., diabetic venous ulcers (Rahaman et al., 2011). The cotton candy-like glass, named MIRRAGEN (ETS Woundcare, Rolla, MO), biodegrades rapidly in the wound bed (under a dressing) and encourages the wound-healing process in wounds that did not heal under conventional treatment (Jung et al., 2011).

Bioactive Glass in Toothpaste

Bioactive glass is not only used as a medical device or implant, it has also has an impact in consumer healthcare, with the largest commercial use of a bioactive material being in toothpaste. Enamel and dentine of the tooth are very similar to bone, in that they contain HCA mineral and collagen. The pain felt by 35% of the adult population



• **Figure 1.3.4.10** Scanning electron microscopy images of human dentin treated with Sensodyne Repair and Protect (UK formulation) toothpaste that contains NovaMin (45S5) particles: (A) immediately after application of NovaMin in artificial saliva; (B) 24 h after application. Scale = 5 μm. (Modified from Earl, J.S., Leary, R.K., Muller, K.H., Langford, R.M., Greenspan, D.C., 2011. Physical and chemical characterization of dentin surface, following treatment with NovaMin® technology. J. Clin. Dent. 22, 62–67.)

that suffer from hypersensitivity is due to exposure of the microtubules of the dentine (Fig. 1.3.4.10) that lead to the pulp cavity and nerves (Rees and Addy, 2002). A fine Bioglass 45S5 particulate (~18 μm), termed NovaMin, which has been owned by GlaxoSmithKline, UK, since 2010, has been used in toothpaste. NovaMin releases calcium and phosphate species during glass dissolution, which then form HCA on the dentine (Gillam et al., 2002). Fig. 1.3.4.10A shows exposed dentine tubules following a brief acid etch with the NovaMin immediately after it was brushed onto the dentine in artificial saliva. The particles attached and, within 24 h, the surface was almost completely covered by an HCA (Fig. 1.3.4.10B) mineralization.

The success of NovaMin has led to the development of more complex glass compositions, such as those designed to stimulate the formation of fluorapatite on the dentine, which is more resistant to acid attack than HCA, leading to a fluoride-releasing bioactive glass, BioMinF (BioMin Technologies Ltd., London, UK) for use in toothpaste (Hill et al., 2011).

Glasses for Cancer Therapy

Insoluble (nonbioactive) glass microspheres (TheraSphere, BTG, London, UK) are used as a microinjectable delivery system for in situ treatment of tumors. The glass microspheres contain ^{90}Y isotopes in the glass composition and are therefore radioactive and deliver a local dose of radiotherapy from inside the tissue. They travel to the site of a tumor through the blood and become lodged in the tissue, where they emit the radiation energy to kill the cancer cells with very little damage to surrounding tissues. This mode of action is currently considered the most effective in treating liver cancer, as the tumor blood supply comes almost entirely from the hepatic artery, making delivery of the spheres to the tumor possible.

Glass-Ceramics

The formation of a glass-ceramic material often starts as a glass and ends up as a polycrystalline ceramic. This is accomplished by first quenching a melt to form the glass object. A reason for doing this is that more complex compositions of a crystalline material can be made by first making a glass. The molten glass can also be poured into a mold to provide shape. The glass is transformed into a glass-ceramic in two steps. First, the glass is heated at a temperature range of 500–700°C to produce a large concentration of nuclei from which crystals can grow. When enough nuclei are present to ensure that a fine-grained structure will be obtained, the temperature of the object is raised to a range of 600–900°C to promote crystal growth. Crystals grow from the nuclei until they impinge with up to 100% crystallization achieved. The resulting microstructure contains fine-grained, randomly oriented crystals. When phase separation occurs, a microstructure can be produced that consists of glass phases suspended in a glass matrix. Crystallization of phase-separated glasses results in very complex glass-ceramic microstructures, as reviewed in Höland and Beall (2001). Glass-ceramics can also be made by pressing powders and a grain boundary glassy phase (Kokubo, 1991). Due to their high strength and the ability to closely mimic the color and aesthetics of natural teeth, glass-ceramics are used for dental restorations, including inlays, onlays, crowns, and multiunit bridges.

Summary

Bioceramics consist of ceramics, glasses, and glass-ceramics for biomedical applications. They can be nearly inert or bioactive/biodegradable. Nearly-inert bioceramics are used for their hardness and resistance to wear and degradation. Bioactive ceramics are good bone graft substitute materials. Bioactive glass was the first material found to bond to

bone. Bioactive glass can outperform sHA in terms of rate and quality of bone ingrowth. It is, however, challenging to produce it in a porous scaffold form. Porous sHA is widely used in orthopedic applications.

Chapter Questions

(a) Explain why "nearly bionert" bioceramics are not completely bionert.

[3 marks]

(b) Define the term "bioactive ceramic".

[2 marks]

(c) Explain how the general immune response to implants leads to the mechanism of bone bonding for a synthetic hydroxyapatite (sHA) bone graft.

[5 marks]

(d) Explain how biological apatite and stoichiometric sHA differ.

[3 marks]

(e) Discuss how the bioactivity mechanism of Bioglass differs from that of sHA.

[4 marks]

(f) Describe the synthesis chemistry and processing required to produce an sHA powder.

[4 marks]

(g) Describe the design criteria for bioactive ceramic scaffold for bone regeneration.

[6 marks]

(h) Explain why Actifuse contains some Si

[2 marks]

(i) Explain why it is challenging to produce porous 45S5 Bioglass.

[2 marks]

Questions with answers

Here are the answers

(a) Explain why "nearly bionert" bioceramics are not completely bionert.

[3 marks]

Answer: They do illicit a response from the body in that the body recognises them as foreign, triggering an inflammatory response

(b) Define the term "bioactive ceramic".

[2 marks]

Answer: Historically a hard crystalline material (ceramic) that can form bond with bone. Now modified to one that stimulates a positive biological response from the body.

(c) Explain how the general immune response to implants leads to the mechanism of bone bonding for a synthetic hydroxyapatite (sHA) bone graft.

[5 marks]

Answer: macrophages recruited: macrophages become osteoclasts; digestion of HA as it is similar to bone mineral; Ca and phosphate ion release; precipitation of Ca and phosphate as HCA; osteoblasts produce new bone

(d) Explain how biological apatite and stoichiometric sHA differ.

[3 marks]

Answer: biological apatite is calcium deficient and carbonate substituted (for phosphate) sHA has Ca/P ratio of 1.67

(e) Discuss how the bioactivity mechanism of Bioglass differs from that of sHA.

[4 marks]

Answer: Bioglass dissolution is Solution mediated via ion exchange, silica rich layer formation. Ions cause Osteostimulation– ions stimulate osteogenic cells to produce more bone

(f) Describe the synthesis chemistry and processing required to produce an sHA powder.

[4 marks]

Answer: solution precipitation by the equation

$$10\ Ca(OH)_2 + 6H_3PO_4 \rightarrow Ca10(PO_4)6(OH)_2 + 18H_2O$$

Once aged, the precipitate is thoroughly washed, filtered and dried.

(g) Describe the design criteria for bioactive ceramic scaffold for bone regeneration.

Answers [expected to be able to list at least 6 of]:

- Biocompatible
- Inflammation?
- No immuno-rejection
- No formation of fibrous capsules;
- Be easily and cheaply produced to ISO/FDA/CE standards (must be easily sterilised)
- Have mechanical properties similar to the host tissue
- Act as template for tissue growth in 3D;
- Have an interconnected macroporous network for vascularisation, tissue ingrowth and nutrient delivery;
- Bond to the host tissue without the formation of scar tissue;
- Resorb at the same rate as the tissue is repaired
- Provide signals to the cells

[6 marks]

(h) Explain why Actifuse contains some Si

[2 marks]

Answer: to increase dissolution rate by introducing some disorder in the crystal structure (particularly at grain boundaries); soluble silica dissolution (Si release) can stimulate osteogenesis

(i) Explain why it is challenging to produce porous 45S5 Bioglass.

[2 marks]

Answer: the original Bioglass composition will crystallise on sintering, losing its amorphous structure.

1.3.4A

Natural and Synthetic Hydroxyapatites

IAIN R. GIBSON

Institute of Medical Sciences, School of Medicine, Medical Sciences and Nutrition, University of Aberdeen, Aberdeen, United Kingdom

Introduction

Hydroxyapatite (HA, also described as hydroxyapatite, HAp) is a stoichiometric calcium phosphate phase with a composition $Ca_{10}(PO_4)_6(OH)_2$. This is a very specific composition that defines an absolute material but its chemistry allows a range of nonstoichiometric compositions to be described as apatite phases. The interest in HA in the biomedical field is due to its similarity to the calcium phosphate apatite phase in bone and tooth mineral. Bone mineral consists of nanoscale crystals of calcium phosphate but the chemical composition of this is not fixed and can vary with age, anatomical location, diet, disease, etc. Considering stoichiometric HA first, this is defined as having a calcium-to-phosphorus molar ratio of 10:6, or typically written 1.67. The structure has been commonly reported as having hexagonal crystal structure, with space group $P6_3/m$ (Kay et al., 1964) and typical unit cell parameters of $a = 9.422$ and $c = 6.883$ Å (Young and Elliott, 1966). It has also been reported as having a monoclinic crystal structure $P2_{1/b}$ (Elliott et al., 1973), with typical unit cell parameters $a = 9.426$, $b = 18.856$, and $c = 6.887$ Å, with $\gamma = 119.97$ degrees (Ikoma et al., 1999). This difference is ascribed to the hydroxyl groups existing in an ordered (monoclinic) or disordered (hexagonal) crystal lattice and is thought to be related to preparation conditions (Ikoma et al., 1999). Representations of the crystal structure of hydroxyapatite are provided in Fig. 1.3.4A.1 (Uskoković and Uskoković, 2011).

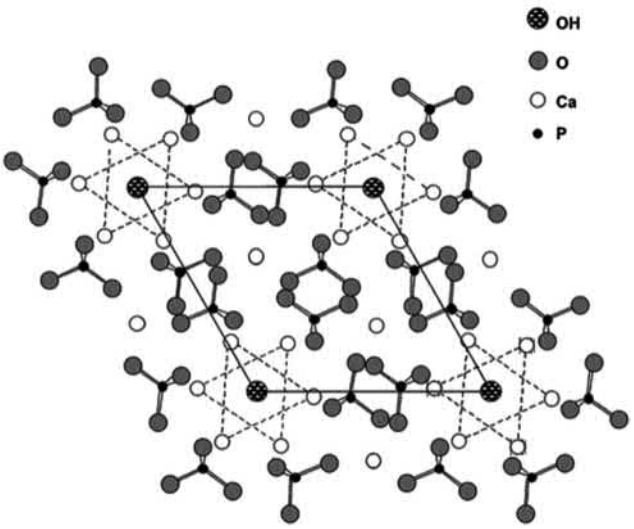
When HA is termed crystalline HA it can be considered analogous to naturally occurring mineral forms and it usually relates to an HA that has been heated to greater than ~800°C to form a ceramic. It should be noted that HA can be prepared using hydrothermal synthesis methods to produce large (up to 3 mm in dimension) crystals, which are clearly crystalline (Arends et al., 1979). Crystalline HA produces an X-ray diffraction pattern as shown in Fig. 1.3.4A.2A, with narrow diffraction peaks and a very high signal-to-noise ratio. X-ray (Kay et al., 1964) and neutron (Arcos et al., 2004) diffraction data have been used to describe the crystal structure of HA and several ICDD Powder Diffraction Files (PDFs) exist as "fingerprints" of HA with hexagonal symmetry, e.g., PDF no. 00-009-0432, and monoclinic symmetry, e.g., PDF no. 01-089-4405 (ICDD, 2013).

The X-ray diffraction pattern of crystalline HA differs from that of the calcium phosphate phase of bone mineral (Fig. 1.3.4A.2B) in that the diffraction peaks of the latter are very broad. This is due mostly to the very small crystallite size of the bone mineral apatite phase, but also due to crystal imperfections or lattice strain (Venkateswarlu et al., 2014). Indeed, the crystallites of bone mineral apatite can be described as nanoparticles, or nanocrystals, with a mean dimension in the *c*-axis of approximately 32 nm and a thickness of approximately 5 nm, as determined by dark-field transmission electron microscopy (Jackson et al., 1978). It should be noted that this phase is not amorphous because, although the diffraction peaks are broad, within a nanocrystal there is structural order. If bone mineral is heated to temperatures above ~800°C, analogous to sintering synthetic HA, then a diffraction pattern similar to that of crystalline HA is observed, although secondary phases may develop depending upon the absolute composition of the bone mineral apatite.

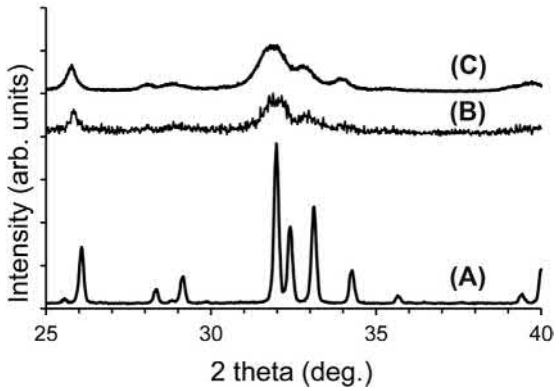
This brings us full circle to the synthesis of bone-like apatite phases. Using various aqueous-based synthesis methods we can prepare nanocrystals of apatite compositions, including stoichiometric HA, that have a similar size scale to bone mineral apatite and have a similar X-ray diffraction pattern (Fig. 1.3.4A.2C). As for bone mineral apatite, heating these synthetic nanocrystals to temperatures above ~800°C results in crystal growth and a diffraction pattern of "crystalline HA." A better description of the composition of HA and apatites produced by such methods is given in Eq. (1.3.4A.1), with $0 \leq x \leq 1$.

$$Ca_{10-x}(PO_4)_{6-x}(HPO_4)_x(OH)_{2-x} \qquad \textbf{(1.3.4A.1)}$$

For $x = 0$, this gives the composition of stoichiometric HA and when $0 < x \leq 1$ a calcium-deficient apatite phase is



• **Figure 1.3.4A.1** The crystal structure of hydroxyapatite. The unit cell is projected on the ab (001) plane showing the location of Ca, P, O, and H within the unit cell. (Reproduced and adapted from Uskoković, V., Uskoković, D.V., 2011. Nanosized hydroxyapatite and other calcium phosphates: chemistry of formation and application as drug and gene delivery agents. J. Biomed. Mater. Res. B. (Appl. Biomater.) 96, 152–191.)



• **Figure 1.3.4A.2** Representative X-ray diffraction patterns of (A) a crystalline synthetic hydroxyapatite prepared by an aqueous precipitation reaction then heated at 900°C in air, (B) bone mineral apatite, and (C) "poorly crystalline" synthetic hydroxyapatite prepared by an aqueous precipitation reaction and dried at 90°C.

obtained, which produces an X-ray diffraction pattern that is largely indistinguishable from that obtained when $x = 0$ (Fig. 1.3.4A.2C). Heating Ca-deficient apatite compositions to temperatures above ~800°C will result in the formation of HA and tricalcium phosphate (TCP, $Ca_3(PO_4)_2$) and the relative proportion of these phases will depend on the value of x; it should be noted that the value of $x = 1$ results in a Ca-deficient apatite that would produce only TCP upon heating to above ~740°C (Gibson et al., 2000).

Another major difference between bone mineral apatite and the crystalline or nanocrystal HA (or apatites) described so far is that bone mineral contains various other ions and also vacancies, partially substituting at the various Ca, PO_4, and OH sites in the structure. The types of ion substituted in bone mineral and tooth dentine and enamel have been

TABLE 1.3.4A.1 The Comparative Chemical Composition of Human Enamel, Dentine, and Bone Mineral

	Enamel (wt%)	Dentine (wt%)	Bone (wt%)
Calcium, Ca^{2+}	37.1	38.6	37.7
Phosphorus, PO_4^{3-} as P	18.2	18.6	16.1
Sodium, Na^+	0.5	0.5	1.1
Potassium, K^+	0.08	0.07	0.05
Magnesium, Mg^{2+}	0.45	1.6	0.85
Carbonate, CO_3^{2-}	2.4	6.4	8.9
Fluoride, F^-	0.01	0.07	0.03
Chloride, Cl^-	0.3	0.01	0.1
Calculated Ca/P molar ratio	1.57	1.60	1.80

Data taken from Legeros R.Z., 1981. Apatites in biological systems. Prog. Cryst. Growth Charact. 4, 1–45, and normalized to the reported total inorganic component.

reviewed extensively and are summarized in Table 1.3.4A.1 (Legeros, 1981). The composition of bone mineral apatite is not fixed, and the amount of different substitutions varies with age and most notably the carbonate content (LeGeros et al., 1987).

This observation led researchers to consider synthesis of HA compositions with various ion substitutions, partly to understand better various biological apatites, but more recently to test the hypothesis that including one or more of these ion substitutions in HA would result in improved biological responses (Shepherd et al., 2013). In terms of mimicking bone mineral, the main substitutions studied include sodium (Driessens et al., 1983), magnesium (Bigi et al., 1996), or strontium (O'Donnell et al., 2008) for calcium; carbonate (Nelson and Featherstone, 1982; Vignoles et al., 1988) for phosphate; carbonate (Ito et al., 1997), fluoride (Jha et al., 1997), or chloride (LeGeros, 1975) for hydroxyl ions; or carbonate for both phosphate and hydroxyl ions (Gibson and Bonfield, 2002).

This chapter will now discuss in more depth the various methods used to synthesize HA, the processing of HA to form medical devices, characterization of these materials as well as clinical use of HA. Reference will be made to the application of HA as a coating on biologically inert implant materials, but the focus will be on HA ceramics, principally as macroporous bone graft substitutes.

Synthesis of Hydroxyapatite Ceramics

Many synthesis methods have been used to prepare HA compositions and the suitability of each of these will depend on the final application but also the scale of product required. Some of the first HA ceramics were produced from natural

apatites or reactants. Coral-derived HA ceramics have been prepared by Roy and Linnehan (1974) and Sivakumar et al. (1996), where calcium carbonate coral acts not only as a template for the macroporous structure but also as a reactant in the hydrothermal reaction with a phosphate source to produce a macroporous HA product. HA ceramics have also been prepared by thermal and/or chemical conversion of bovine cancellous bone to form a macroporous HA ceramic that is then deproteinated. It is often described as inorganic bone (Spector, 1994). Such composition of inorganic bone should comply with ASTM F1581-08 (2016) that describes the standard specification for use as surgical implants. Many other natural sources of reactants and/or templates to synthesize HA include fish bones and shells, algae and egg shells and they have been reviewed elsewhere (Akram et al., 2014). The use of naturally occurring materials as templates/reactants may provide economically viable routes to manufacture HA, particularly when the process utilizes waste material (Inyang and Ibitoye, 2018).

Solid-state synthesis is a traditional method that is used to synthesize inorganic oxide materials as it allows excellent control of chemical stoichiometry. Challenges exits, however, when formation of the phase composition of the desired product is not compatible with the high temperatures and long thermal treatment times required to obtain complete solid-state reaction. This method is also not suitable when product with a high surface area is required, as the high thermal energy used in solid-state synthesis usually results in low surface area powders. HA can be synthesized by solid-state reaction of a mixture of reactant oxides, for example, between a mixture of calcium pyrophosphate and calcium carbonate at 1100°C in a vacuum, followed by further heating in 1.5 atm H_2O between 900 and 1100°C; after prolonged reaction times, including remixing of the product, a single-phase polycrystalline HA sample was obtained (Fowler, 1974).

The most widely used method to synthesize HA samples is an aqueous precipitation reaction, typically involving a calcium salt and a phosphate salt/acid mixed at alkaline pH. An example of an aqueous precipitation method to make dense HA ceramics used $Ca(NO_3)_2.4H_2O$ and $(NH_4)HPO_4$ as the reactants, and gradual mixing of these at an alkaline pH maintained with addition of NH_4OH produced a precipitate consisting of nanoscale crystals of HA (Jarcho et al., 1976). An alternative aqueous precipitation reaction uses a mixture of $Ca(OH)_2$ suspension and phosphoric acid solution, again mixed slowly at alkaline pH (Osaka et al., 1991). Calcium hydroxide has low solubility in water, but gradual dissolution is associated with a very high pH value; slow addition of phosphoric acid to a $Ca(OH)_2$ suspension results in a precipitation reaction to form nanocrystals of HA, and the pH can be maintained at high alkaline pH during the whole reaction by the addition of ammonia. These methodologies of producing a precipitate of nanoscale crystals of HA, which is then dewatered by, e.g., filtering and drying the filter cake, have been used extensively in the synthesis of HA powders and ceramics. A distinct advantage of aqueous precipitation methods as a route to synthesize HA is the ability to scale up the process to the large-scale manufacture of a product that has a high surface.

A number of other synthesis methods have been reported, including: sol-gel synthesis (Deptula et al., 1992); biomimetic synthesis using supersaturated solutions (Tas, 2000a); hydrolysis of a calcium phosphate precursor, for example, brushite (Monma and Kamiya, 1987); microwave solid-state sintering (Cao et al., 2005); mechanochemical synthesis (Yeong et al., 2001); sonochemical synthesis (Fang et al., 1992); emulsion techniques (Lim et al., 1997); hydrothermal synthesis (Yoshimura et al., 1994); combustion synthesis (Tas, 2000b); and pyrolysis methods (Itatani et al., 1994). These methods have been optimized and/or adapted to control chemical and phase composition, morphology, and other specific properties of the synthesized HA, with recent reviews describing in detail the current status of HA synthesis (Zakaria et al., 2013; Haider et al., 2017). An HA or Ca-deficient HA composition can also be produced as the product phase of calcium phosphate cement-setting reactions, whereby reactant phases (typically one or more calcium phosphate phases) is mixed with water and the paste undergoes a dissolution/reprecipitation reaction forming interlocking apatite crystals producing a hardened mass (Fukase et al., 1990; TenHuisen and Brown, 1998).

A feature of a number of these synthesis methods is that the primary (smallest) crystallite size has nanoscale dimensions and these nanoparticles can have a wide variety of morphologies, depending on the method but also specific parameters within the chosen synthesis method. The range of morphologies has been reviewed by Lin et al. (2014), ranging from very small spherical (Nathanael et al., 2011) nanoparticles to nanoneedles (Kobayashi et al., 2012), nanorods (Manafi and Rahimipour, 2011), nanowires (Lin et al., 2011), nanowhiskers (Teshima et al., 2012), nanosheets (Xiao et al., 2010), hollow nanospheres (Cai et al., 2007), nanotubes (Lester et al., 2013), nanobelts (Ma et al., 2018), and whiskers (Zhang and Darvell, 2011). Although synthetic HA has conventionally been utilized as a ceramic or as a coating, these nanoscale morphologies open up new possibilities for potential applications of HA in medicine, including drug delivery (Li et al., 2016), gene delivery (Curtin et al., 2015), delivery of cells in tissue engineering/regenerative medicine (Zannettino et al., 2010), hyperthermia therapy of cancer (Hou et al., 2009), and in vivo imaging (Altınoglu et al., 2008; Ashokan et al., 2010).

In addition to the various synthesis methods just described, which can alter the morphology of the formed HA crystals, many studies have focused on modifying the chemical composition of HA to incorporate ions that exist in bone mineral or may have a biological function. As mentioned previously, studies have reported the substitution of sodium, magnesium, strontium, carbonate, fluoride, and chloride ions, but other ions, including potassium (Nordström and Karlsson, 1992), lithium (Wang et al., 2016), barium (Bigi et al., 1984), silicate

(Gibson et al., 1999), copper (Gomes et al., 2018), cobalt (Ignjatović et al., 2013), silver (Shi et al., 2016), and zinc (Thian et al., 2013), have been described. Some of these ions have been shown to have osteogenic (e.g., Li et al., 2018), angiogenic (e.g., Birgani et al., 2016), or antibacterial (Shi et al., 2016) properties in vitro and their potential mechanisms by which ions may enhance osteogenesis and angiogenesis have been reviewed comprehensively (Bose et al., 2013).

Another approach to alter the properties of HA ceramics is the synthesis of compositions that are a mixture of HA and β-TCP, termed biphasic calcium phosphate (BCP) ceramics (reviewed in Bouler et al., 2017). BCPs are described in detail in Chapter 1.3.4.

HA has been utilized as a bioactive coating on the surfaces of implant materials that are considered biologically nearly inert, such as some metals (Sun et al., 2001) and polymers (Barkarmo et al., 2013). This changes the mode of fixation of these implants to the host bone and may improve integration of joint replacements (Goosen et al., 2009), dental tooth root implants (Zhou et al., 2011), and spinal cages (Daentzer et al., 2005). The most widely applied HA coating method in the area of medical devices is plasma spraying, where HA powder is fed into a high-temperature plasma torch that then sprays semimolten HA powder particles onto the substrate to be coated (de Groot et al., 1987). A number of spraying parameters and powder properties can be modified to control the properties of the final coating. ASTM 1609-2014 (Standard Specification for Calcium Phosphate Coatings for Implantable Materials) describes the requirements of HA coatings on surgical implants; a number of other coating methods in addition to plasma spraying are described within this ASTM. An ISO standard also exists that describes the requirements of an HA coating that is specifically applied by thermal spraying: ISO 13779-2:2018 (Implants for surgery—Hydroxyapatite—Part 2: Thermally sprayed coatings of hydroxyapatite).

Examples of other coating methods used to coat HA include sol-gel (Weng and Baptista, 1998), electrophoretic deposition (Shirkhanzadeh, 1995), biomimetic coating (Habibovic et al., 2002), and various sputter-coating methods (Yang et al., 2005). Although most of the published literature focuses on HA-coated metallic implants there has been a recent growth in studies that aim to apply HA coatings to polymeric implants such as polyether ether ketone spinal cages (Hahn et al., 2013), with the purpose of improving implant fixation and integration.

A major application of HA, along with other BCPs and β-TCP, is as synthetic bone graft substitutes. These require both the densification of the calcium phosphate and the introduction of micro- and macroporosity during sintering. These somewhat conflicting processes require optimization of the powder properties and also of the method of introducing the macroporosity. These processes are described in detail in Chapter 1.3.4.

TABLE 1.3.4A.2 The Key Chemical and Physical Variables Used to Describe a Synthetic Hydroxyapatite Bone Graft Substitute (BGS)

Possible Variable	Description/Examples
Chemical composition	Ca/P molar ratio, presence of substituted ions, e.g., carbonate, sodium, strontium, magnesium, silicate ions
Phase composition	100% hydroxyapatite, or the presence of additional phases, e.g., β-tricalcium phosphate, CaO, $CaCO_3$
Density/porosity	Density (often expressed as a percentage of theoretical density), porosity (often expressed as a percentage of theoretical density)
Pore size and size range	Diameter and range, including distinguishing between macropores (e.g., 100–200 μm) and micropores (e.g., 2–5 μm)
Pore interconnectivity	Trapped pores or fully interconnected pore structures
Grain size	Submicron or micron size range of grains, e.g., 1 μm
Physical form of BGS	Granule, block, putty, foam, paste, etc.
Granule size and size range	Diameter and range, e.g., 200–300 μm or 1–2 mm
Additive (putty, foam, paste)	Description of organic additives, e.g., collagen, gelatin, carboxy-methyl cellulose, hyaluronic acid, saline, etc.

Characterization of Hydroxyapatite Ceramics

Physicochemical Characterization

HA ceramics can be characterized using a number of different methods that establish key parameters, including phase composition and chemical composition, including Ca/P molar ratio and trace metal content. HA materials intended for use in medical devices can be characterized as guided by ASTM F1185-03 (2014)—Standard Specification for Composition of Hydroxyapatite for Surgical Implants. A standard reference material of HA is also available from the National Institute of Standards and Technology (Markovic et al., 2004). Some of the key chemical and physical characteristics of HA and products composed of HA are summarized in Table 1.3.4A.2. These characteristics are all parameters that can be varied to modify or optimize the properties of the product.

X-ray diffraction analysis of HA was described earlier in terms of comparing the diffraction patterns of biological apatite and synthetic HA (nanoscale and sintered HA). Extensive

information can be derived from diffraction data, including determination of crystallite size (Venkateswarlu et al., 2014), unit cell parameters, and the effect of composition on these structural parameters (Legeros, 1981), as well as phase composition, namely the presence and quantification of any additional crystalline phases (Keller, 1995). Estimations of the relative amount of amorphous phase to crystalline phase have also been reported, which are particularly relevant to HA coatings produced by high-temperature methods (Wang et al., 1995).

Infrared spectroscopy, most typically Fourier transform infrared spectroscopy (FTIR) and Raman spectroscopy, also provide significant information on synthetic and biological apatites (Koutsopoulos, 2002). The phosphate and hydroxyl groups in stoichiometric HA produce various vibrations in the FTIR spectra of HA samples and the presence of other ions can also be identified, notably carbonate ions, in substituted HA and biological apatites. The specific infrared (IR) vibration peaks for PO_4^{3-}, OH^-, and CO_3^{2-} groups in synthetic and biological apatites are summarized in Table 1.3.4A.3 (Koutsopoulos, 2002). These vibration peaks can provide significant information on the effect of synthesis or processing conditions on synthetic HA, and they can also help distinguish other calcium phosphate phases. IR data can also be used to identify and characterize the substitution site of carbonate in HA, on the phosphate site (B-type) and/or hydroxyl site (A-type) (Fleet, 2009), and the crystallinity of apatites can be assessed from analysis of the phosphate vibrations at 550–600 cm^{-1} (Termine and Posner, 1966). Example FTIR spectra of synthetic HA (nanocrystals and sintered) are presented in Fig. 1.3.4A.3. Raman spectroscopy provides complementary data to IR data (Khan et al., 2013), with some advantages of minimal sample preparation and high spatial resolution using a Raman microscope.

The chemical composition of HA can be determined by a number of analytical techniques, but the most common method for determining the Ca/P molar ratio and the elemental content of a number of different trace elements such as sodium, magnesium, potassium, strontium, and silicon that may be present in the reactants used is X-ray fluorescence spectroscopy. Trace elements that may be present at ppm levels (such as As, Hg, Pb, and Cd) are more effectively measured using, e.g., ion-coupled plasma optical emission spectroscopy. Solid-state nuclear magnetic resonance (NMR) spectroscopy also provides additional information about local structure in HA compositions, with ^{43}Ca, ^{31}P, ^{1}H solid-state NMR all providing insights into the structure of synthetic HA and natural apatites (Ben-Nissan et al., 2001; Laurencin et al., 2008; Kaflak and Kolodziejski, 2007). Additionally, ion substitutions in HA can also be probed by solid-state NMR, such as carbonate using ^{13}C and silicate using ^{29}Si solid-state NMR (Beshah et al., 1990; Gillespie et al., 2010). X-ray photoelectron spectroscopy and time-of-flight secondary ion mass spectrometry provide the ability to study phase composition on very small samples and the very surface layers of a material, which has aided the understanding of correlations of the bulk composition with surface composition of HA (Chusuei and Goodman, 1999; Lu et al., 2000). These techniques have also been used extensively to characterize the chemical and physical properties of bone mineral and tooth enamel apatite crystals dating back to the 1950s, and these have been reviewed in detail elsewhere (Rey et al., 2009).

TABLE 1.3.4A.3 The Specific Infrared Vibrations for PO_4^{3-}, OH^-, and CO_3^{2-} Groups in Synthetic Hydroxyapatites

	Peak (cm^{-1})
Hydroxyl group, stretching mode, ν_s	3572
Hydroxyl group, librational mode, ν_L	631
Phosphate group, triply degenerated asymmetric stretching mode, ν_{3a}	1087
Phosphate group, triply degenerated asymmetric stretching mode, ν_{3b}	1046
Phosphate group, triply degenerated asymmetric stretching mode, ν_{3c}	1032
Phosphate group, nondegenerated symmetric stretching mode, ν_1	962
Phosphate group, triply degenerated bending mode, ν_{4a}	602
Phosphate group, triply degenerated bending mode, ν_{4b}	574
Phosphate group, triply degenerated bending mode, ν_{4c}	561
Phosphate group, doubly degenerated bending mode, ν_{2a}	472
Phosphate group, doubly degenerated bending mode, ν_{2b}	462
Carbonate group, bending mode in A-type CHA, ν_4	1550
Carbonate group, stretching mode in CHA, ν_3	1500
Carbonate group, stretching mode in A-type CHA, ν_1	1465
Carbonate group, bending mode in A- and B-type CHA, ν_4 or ν_3	1452–1455
Carbonate group, stretching mode in B-type CHA, ν_1	1430
Carbonate group, bending mode in A-type CHA, ν_2	883
Carbonate group, bending mode in B-type CHA, ν_2	875

CHA, Carbonate hydroxyapatite.

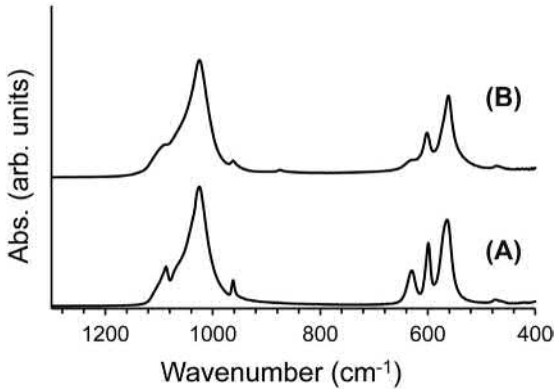
In Vitro and In Vivo Characterization

HA ceramics are long established as being biocompatible, osteoconductive, and bioactive, typically evaluated by cell



• **Figure 1.3.4A.3** Fourier transform infrared spectroscopy spectra of (A) a crystalline synthetic hydroxyapatite prepared by an aqueous precipitation reaction then heated at 900°C in air and (B) "poorly crystalline" synthetic hydroxyapatite prepared by an aqueous precipitation reaction and dried at 90°C.

culture studies (Seebach et al., 2010), in vivo bone healing response (Peric et al., 2015), and surface apatite layer formation when immersed in a physiological salt solution, such as simulated body fluid (Kim et al., 2004). These responses can be evaluated following established ISO protocols, including ISO 10993-5, ISO 10993-6, and ISO 23317, and ASTM standards, including ASTM F2721-09 (2014) and ASTM F3207-17 (2017). In addition to the osteogenic response of mesenchymal stem cells, preosteoblasts or osteoblasts to HA surfaces (Samavedi et al., 2013), the response of osteoclasts (Yamada et al., 1997; Nakamura et al., 2016), endothelial cells (Pezzatini et al., 2007), and macrophages (Linares et al., 2016) have also been studied. Moreover, aside from being very dependent on culture model and cell source, the surface physical properties of the HA, such as the surface roughness (Yang et al., 2016), will also have a significant effect on any cell response and this should be considered in addition to the HA chemistry.

The shift in application of HA from coatings and monolithic dense ceramics toward use as macroporous bone graft substitutes or scaffolds for bone tissue engineering/repair has led to an increase in the in vivo evaluation of these materials in models for repair of critical size bone defects (Kon et al., 2000), spinal fusion (Walsh et al., 2009), and osteoinductivity (Ripamonti, 1996; Duan et al., 2018). The development of specific macroporous structures, HA chemistry, and microstructures has led to HA-based bone graft substitutes that exhibit osteoinductive properties, whereby bone is formed within the porous structure when the material is implanted into an intramuscular or subcutaneous defect (LeGeros, 2008; Barradas et al., 2011; García-Gareta et al., 2015; Bohner and Miron, 2019). The mechanisms for this response are not yet clear and a single pathway may not describe osteoinductive response in all these different materials. Proposed mechanisms have included an influence on the inflammatory/wound-healing response, localized changes in Ca and PO_4 concentrations, or localized adhesion/capture of exogenous osteoinductive growth factors such as BMP-2 (Bohner and Miron, 2019).

TABLE 1.3.4A.4 Different Forms That Hydroxyapatite has Been Utilized in as, or as Part of, a Medical Device

Granules (porous or dense)—typically between 200 μm and 5 mm
Granules within a putty (polymeric carrier)
Granules within a collagen matrix
Coating on metallic or polymeric device
Injectable paste or slurry (small particles dispersed in a carrier)
Cement
Porous blocks or wedges
Filler phase of a composite
Nanoparticles

With the increased development of HA nanomaterials there has been a renewed interest in the specific in vitro and in vivo response that these materials may produce. As with most materials that consist of nanoparticles, these nanoparticles typically agglomerate to form a larger secondary particle or a cluster. In applications where the use of HA nanoparticles is reliant on the size of the primary particle, such as cell transfection (Tenkumo et al., 2016), which requires the nanoparticles to cross the cell membrane, methods to functionalize the HA nanoparticles to improve dispersion can be utilized (Xu et al., 2015).

The in vitro and in vivo inflammatory responses to nanoparticles of HA in different morphologies, including dots, sheets, long rods, and fibers, were shown to have the highest acute inflammation in vivo (Pujari-Palmer et al., 2016). Studying a broader range of particle sizes and particle shapes, a similar result was observed, with small needle-shaped particles producing a strong inflammatory response compared with spherical nanoparticles (Lebre et al., 2017). A recent review noted "the risk associated with an exposition to nanoparticulate calcium phosphate in doses that are usually applied in biomedicine, health care products, and cosmetics is very low and most likely not present at all" (Epple, 2018).

Clinical Use of Hydroxyapatite Ceramics

The use of HA for medical applications has been largely as a ceramic, where a solid mass can be obtained by sintering a compacted powder at temperatures greater than 1100°C, or as a coating on biologically inert materials, traditionally on metals (Sun et al., 2001) but more recently on polymers (Barkarmo et al., 2013). As noted, however, the ability to synthesize HA as a nanocrystal has created applications in drug delivery (Li et al., 2016) and gene delivery (Curtin et al., 2015). HA can be used in a variety of forms and these are listed in Table 1.3.4A.4.

The use of HA as a coating on medical devices has been most closely associated with orthopedic hip and knee implants and with dental tooth root implants, hence a significant body of data on their clinical use is available now. The coating of metallic hip or knee implants provides an alternative method of fixation to the use of polymeric bone cements. A challenge for understanding the clinical outcome of using HA-coated implants is that there are a considerable number of variables in the plasma-spraying process and also in the HA powder used.

A systematic review of randomized clinical trials attempted to identify if there was a difference in clinical outcome when an HA coating was applied to uncemented porous titanium-coated femoral hip prostheses (Goosen et al., 2009). Exclusion criteria meant that only a small percentage of the initial publications were identified in their search, but data pooled from the five studies that met the strict criteria showed that there was no significant difference in Harris hip score and that there was no clear benefit of an HA coating in radiographic or clinical success. In a metaanalysis from a systematic review of randomized clinical trials of HA-coated uncemented knee implants versus cemented implants (Nakama et al., 2012), the authors showed that the HA-coated implants had a much lower risk of future failure by aseptic loosening compared with the cemented implants, but again only five studies met the strict exclusion criteria for this study. Clinical studies using HA-coated dental implants have shown good early fixation of the implants, but the survivorship of the implants is inferior after longer periods. For instance, the 8-year survivorship of titanium plasma-sprayed dental implants was at 92.7% compared with that at 77.8% for HA-coated implants (Wheeler, 1996).

The main use of hydroxyapatite and other calcium phosphate ceramics (TCP or BCP) is as synthetic bone graft substitutes, where they can be used as an alternative to autograft bone to fill bone defects (Campana et al., 2014; de Grado et al., 2018). They are typically in the form of porous granules or blocks, sometimes within a polymeric carrier or dispersed within a collagen foam strip. The porous structure encourages bone ingrowth and integration and the granules or blocks can act as a carrier for growth factors, antibiotics, bone marrow aspirate, or platelet-rich plasma. More than 2 million bone-grafting procedures have been performed globally (Campana et al., 2014). A large number of synthetic bone graft substitutes that contain HA have been approved for clinical use but clinical trial data are still very limited to support specific products. These products (some are listed in Chapter 1.3.4) have different permutations of the features described in Table 1.3.4A.2, so understanding which of these parameters affects clinical outcomes is challenging. The use of various ceramic bone graft substitutes in spinal surgery was described in a systematic review (Fischer et al., 2013). The authors noted that a lack of good clinical data limited the grading of these materials in comparison with bone graft alternatives, restricting their recommendation on the efficacy of calcium phosphate bone graft substitutes. They further noted that the situation would likely improve as more studies showing stronger evidence became available. This lack of high-level clinical efficacy data is also observed in other clinical studies reporting the use of bone graft substitutes (Buser et al., 2016). Although many clinical studies reporting the efficacy of specific synthetic bone graft substitute products have been reported in the last 5 years, these are typically observational studies or open label interventional trials, thereby lacking high-quality clinical evidence. This is one area in general that needs to be addressed to help translate the development of the science of biomaterials into improved clinical treatments, and it is not exclusive to synthetic bone graft substitutes.

Structural Ceramic Oxides

GARY FISCHMAN, PhD.

Future Strategy Solutions, LLC, Gambrills, MD, United States

Introduction

Structural ceramics are materials of significant importance in medical applications. They are strong and hard, desirable for load-bearing and structural support applications in many biomedical devices. Within medical devices, known examples of structural ceramics include articulating surfaces for hip and knee joints, including femoral heads, acetabular cups, and femoral condyles, as well as dental implants. They have also been used as electrical feedthroughs, internal support structures, and enclosures for devices such as cochlear implants. The advantages of these materials include high strength and hardness, good electrical insulation, low solubility, good biocompatibility, and radiofrequency (RF) transparency, and they can be machined to achieve extremely high degrees of surface smoothness, which is ideal for many articulating applications. One tradeoff aspect of these advantages is that their very high Young's modulus as compared with bones makes these materials prone to problems such as stress shielding, which is detrimental to bone healing and repair.

In orthopedics, structural ceramics are used most often in wear surface applications such as femoral hip (ball) and acetabular (cup) structures; they are also used the same way for other joints. In spinal applications, they are used for wear purposes in cervical implants as well as spacers for intervertebral systems. In dentistry, structural ceramics have been used for dental implants as well as articulation restoratives such as crowns. Other products that are less obvious include protective housings for implanted electronics such as pacemakers and cochlear implants; structural internal parts for the electronics for implants; as well as electronic feedthroughs for products like pacemakers and electrosurgical units. Structural ceramics have also been used as bone spacers, for ear, nose, and throat applications, and in maxillofacial surgeries. Implants from these materials have been used in neurosurgical operations such as cranioplasties. Alumina, which can be made transparent, has been used in keratoprostheses (corneal replacement). Porous alumina has been used for controlled delivery of hormones, vaccines, and drugs for dose rates needed over long periods of time. Interestingly, zirconia has been used as an oxygen filter and generator due to the high diffusion rate of oxygen within the material.

This chapter provides an overview of structural oxide ceramics with a focus on biomedical applications with load-bearing and/or load-transferring requirements. Of the ceramics being used for biomedical applications, the oxide materials are more common, though to a lesser extent nonoxide ceramic materials such as carbides (silicon carbide) and nitrides (e.g., silicon nitride) are also used for these purposes. An example of oxide ceramics for such applications is the BIOLOX delta, a zirconia-toughened alumina (ZTA) composite used as an arthroplasty material. Overall, devices made of nonoxide structural ceramics represent only a small share of the market, and they therefore will not be discussed further here. For a broader perspective on structural ceramics, readers are encouraged to consult specific texts on the subjects, including Carter and Norton (2007), Callister (2009), or Morrell (2011).

Structural Ceramic Oxides

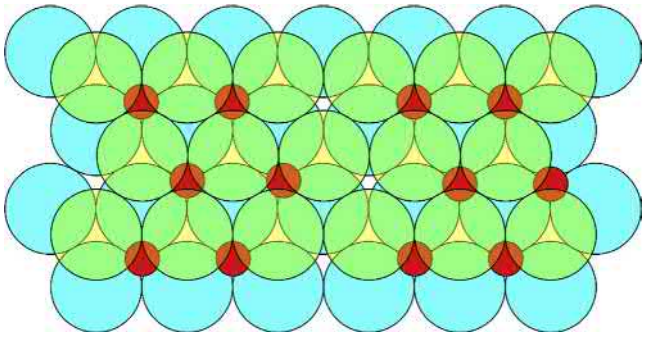
Ceramics are materials that are physically nonmetallic and chemically inorganic. They are generally derived from commonly mined materials such as silica sand (silicon dioxide or silica), bauxite (aluminum hydroxide mineral), zircon sands (zirconium sulfate minerals), and others. Like metals, they are mined from sands and ores, but their commonality ends there: ceramics tend to have ionocovalent bond structures. Moreover, ceramics tend to form three-dimensional amorphous (glassy) as well as lattice (crystalline) structures. Structural ceramic oxides like alumina and zirconia are formed based on an oxygen anion lattice structure with metal cations (such as aluminum, zirconium, and silicon) in interstitial locations within the oxygen anion structure. The properties of structural ceramics can vary depending upon the full chemical makeup of the materials and the thermal processing (the heating profile) that is used to coalesce them in a process known as sintering.

The three most commonly used materials in structural ceramics for medical devices are alumina, zirconia, and a composite of alumina in which zirconia is added to make a material called ZTA. We will discuss all three of these materials here.

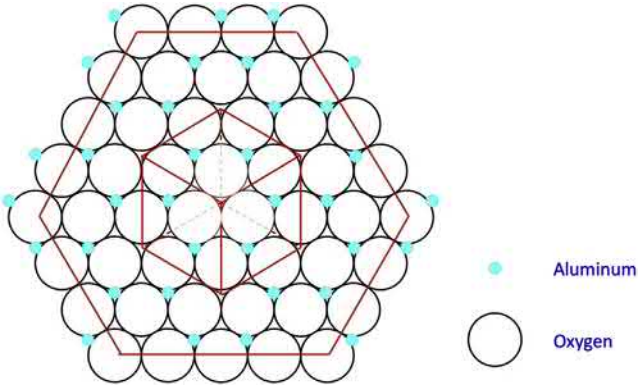
Aluminum Oxide (Alumina)

Aluminum oxide, Al_2O_3, corundum sapphire, and alumina are all the same material. Gemological specimens of aluminum oxide, sapphire, abound from clear to red to blue depending on the impurities that are found in the material. Chrome-doped alumina, which is also used in medical-grade ceramics (see the Section "Zirconia-Toughened Alumina") is known gemologically as ruby and has a red color. Both sapphire and ruby are types of alumina and are extremely hard, brittle materials.

Alumina was the first ceramic used in a major way for medical applications. Crystallographically, alumina is classified as rhombohedral. It is based upon a hexagonal close-packed structure of oxygen anions. This structure has aluminum cations sitting in two-thirds of the octahedral interstitial sites (Fig. 1.3.4B.1). The aluminum sits between the first (A) layer and the second (B) layer creating an AaB structure. For electroneutrality, the alumina in each layer moves over by one interstitial site, meaning that it takes three layers to come back to the original layer positions. This means that it takes six oxygen layers ([AaBbAcBaAbBc]Aa) to create the repeat unit for the alumina structure and it is within this thickness of layers that the rhombohedral unit cell for alumina exists (Fig. 1.3.4B.2).



• **Figure 1.3.4B.1** Alumina structure with two layers of oxygen atoms (blue below, yellow above) and aluminum in two-thirds of the octahedral interstitial sites.



• **Figure 1.3.4B.2** Adaptation of the alpha alumina crystal structure (see Krönberg, 1958).

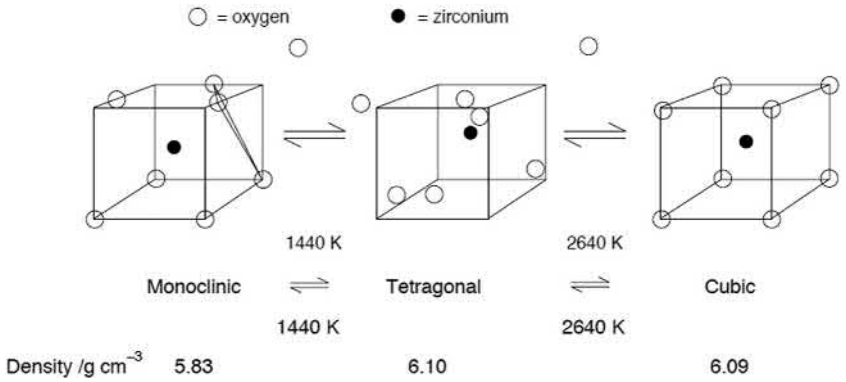
Zirconia

Zirconia is a material that also has been around for decades. It is made up of oxygen anions that are not set in a hexagonally structured close-packed arrangement but, more or less, in a square pattern. Zirconia was known for decades for its use in highly reactive glass furnaces. It had limited use until the last quarter of the 20th century because of the destructive nature of the reversible phase transformation to and from tetragonal to monoclinic. Zirconia has also become a synthetic gem quality replacement for diamond in its cubic form.

There are three polymorphs of zirconia as shown in Fig. 1.3.4B.3. Starting by cooling a zirconia liquid, the cooling liquid solidifies to the cubic phase of zirconia at approximately 2750°C. Upon further cooling, the cubic phase then transforms at 2370°C to the tetragonal phase. At 1170°C the tetragonal phase transforms to the monoclinic phase. If we look at the changes in volume of the phases as they transform we see that the phase transformation from cubic to tetragonal is accompanied by a 0.18% decrease (based on the higher temperature material in the denominator) in volume, whereas the transformation of tetragonal to monoclinic is accompanied by a relatively large (4.4%) increase in volume. Because of the very large change in volume, the microcrystalline structure of a material cannot maintain its integrity during the tetragonal-to-monoclinic transformation.

Yttria and Magnesia-Stabilized Zirconias

Yttria tetragonal zirconia polycrystalline (YTZP) ceramic and magnesia partially stabilized zirconia (MgPSZ) are both types of zirconia. As discussed earlier, zirconia goes through



• **Figure 1.3.4B.3** Unit cells for the three polymorphs of pure zirconia and their transition temperatures.

a set of phase transformations when it is heated and cooled (Fig. 1.3.4B.3). Though they do so differently, yttria and magnesia promote toughness in zirconia through control of the transformation from tetragonal to monoclinic zirconia within the material.

Like other chemically forced phase change manipulations (like the freezing point depression of water), zirconias can be chemically or morphologically stabilized so that a particular polymorph of zirconia such as cubic, tetragonal, or monoclinic is stable beyond the temperature ranges defined by the pure form. For instance, cubic zirconia (which looks similar to diamond) can be designed to be stable with the appropriate dopants (elements) at room temperature. Appropriate dopants and thermal processing can create a metastable tetragonal phase in the material. This tetragonal phase can be transformed to the monoclinic phase through a diffusionless martensitic transformation. Because of the martensitic nature of the change, stress can cause the material within a stress region to transform to monoclinic. Because of the major volume increase that the transformation from tetragonal to monoclinic zirconia causes, a designed transformation can create a high compressive stress when the transformation occurs. This is the basic idea behind the zirconias that are used in medical devices.

Depending on the dopant used to create the metastable tetragonal phase (in medical ceramics this is usually yttrium or magnesium) the phases and microstructures that form (and therefore the risks) are different.

In YTZP, the whole zirconia microstructure is designed to be made up of small tetragonal zirconia crystals. If a crack forms, there is a stress region emanating from the crack front that leads the crack as it moves through a solid. When the crack front moves through a region of YTZP, it causes the tetragonal zirconia within the crack front zone to martensitically transform to the monoclinic phase. This change is accompanied by an increase in volume and so causes a compression in front of the crack tip. This compressive stress is similar to pushing the crack together so that the stress is used to slow down or stop the crack.

One of the problems that had to be overcome in YTZP was its sensitivity to transformation when in water (US FDA, 1997). Water can replace some of the bonds in the structure and cause the material to spontaneously transform from tetragonal to monoclinic. This issue was mitigated through the optimization of YTZP both by further chemical additives and by grain size adjustments.

Different to YTZP, the MgPSZ microstructure is made up mostly of large cubic zirconia crystals. In this particular type of zirconia, the large, stabilized cubic grains of zirconia have transformable tetragonal seeds embedded within the larger crystal. When a crack front approaches, the seeds inside the grain transform creating a compressive stress to the material.

Zirconia-Toughened Alumina

Another currently commonly used structural ceramic is a ceramic matrix composite called ZTA. ZTA is a composite of alumina in which zirconia is added. The zirconia modifies the alumina by utilizing zirconia's ability to create a compressive stress region (through transformation) if a crack moves through the region. This material maintains much of the hardness of alumina and adds much of the toughness of zirconia into an optimized material.

Current ZTAs are toughened with YTZP. The ZTAs used in orthopedics are currently further toughened by the addition of strontium, which causes the alumina to grow disproportionately in a platelet configuration. Many ZTAs are also pink because of the addition of chromium, which was originally added to improve the hardness that was lowered due to the addition of the softer zirconia to the alumina matrix.

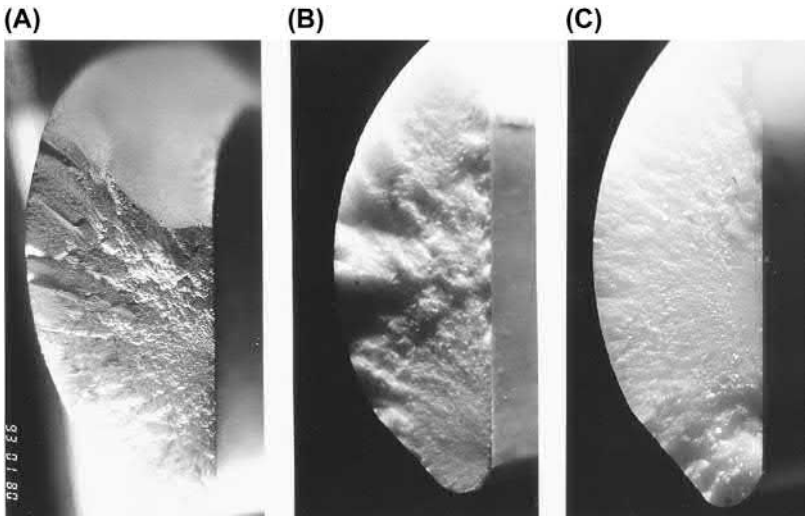
A History of These Structural Materials in Medical Devices

These three materials, namely alumina, zirconia, and ZTA, are the basic materials that are used in biomedical applications. Dentistry and orthopedic surgery have led the introduction of these materials into the medical device industry. Alumina was an obvious place to start, zirconia matured appropriately at an ideal time in history, and ZTAs were in exactly in the right place at the right time.

Alumina was the first biomedically important structural ceramic. It is one of the earliest and most heavily researched ceramics available. It has been used commercially at least since the 1930s as an insulator for spark plugs. It has been studied heavily to model and better understand the science of sintering and structure–property relationships in ceramics. When Boutin considered ceramics for hip implants in the early 1970s, alumina became a material for the manufacture of components for prostheses and surgical devices. Before this, metal was the femoral end (ball) that was used. Unfortunately, the metal system usually failed because of wear based on CoCr grinding away at the polyethylene cup. Much of this was because the metal could only be polished to a certain level of smoothness. The failure was accompanied by a large amount of wear debris in the joint space. The result of this wear debris was characterized as particle disease.

To mitigate the wear–failure–particle problem, implant manufacturers turned to a very highly polished alumina. Alumina is extremely hard. On a Mohs hardness scale (the geological scratch test) alumina tests at 9, just under diamond, which tests at 10. From this perspective, alumina can scratch metal, glass, and most natural minerals. If manufactured properly, alumina can be polished to be very smooth. It also is resistant to corrosion in an in vivo environment, elicits minimal response from biological tissues, and remains stable for many years of service.

In testing, a polished alumina femoral end (head) replacing the metal femoral end basically doubled the life of the total hip replacement (THR) implant based on wear rates. The abrasion rate on ultrahigh molecular weight polyethylene (UHMWPE) in switching from metal to alumina improved from 0.2 mm/year (loss of thickness of UHMWPE) to less than 0.1 mm/year (Willmann, 2000).



• **Figure 1.3.4B.4** Fracture surfaces of alumina hips: (A) fractured in testing as per ISO 7206-5; (B) head fractured in vivo; (C) head fractured via proof test. (From Richter, H., 1998. Application of Proof-Testing to Ceramic Hip Joint Heads, 3rd Ceramtec Symposium, Stuttgart.)

The major problem with alumina has always been its brittleness. When a crack forms, there is very little that can be done to stop the crack from worsening and so a device (such as a femoral head) fractures catastrophically (Fig. 1.3.4B.4). Failure of ceramic heads for hip replacements due to brittleness then became a problem. In the 1990s the failure rate of alumina heads varied greatly and in some cases it could be as high as 0.5% (1 out of every 200 heads could fail) (Richter, 1998). This failure rate was a barrier to the acceptance of alumina as a material for high-load THR and was mitigated through the use of a proof-testing tool. Improvements in manufacturing along with the proof-testing tool brought the failure rate in alumina down to a very acceptable 0.01%. In the 1980s, alumina was the up and coming material for hip joint replacement.

Attempting to further reduce wear caused primarily by the loss of UHMWPE from the cup, alumina was considered for the acetabular cup as well using a "hard-on-hard" alumina system. The hard-on-hard Mittelmeier system failed by wearing at a phenomenally high rate. This was due to a combination of placement and the unforgivingly high rigidity of the alumina. Today, designs have dealt well with this issue, further reducing wear without creating a high failure risk.

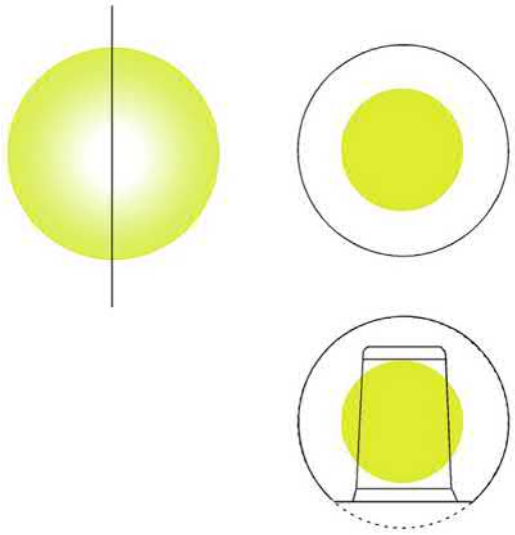
The proneness to fracture of alumina created an opportunity for another ceramic described as "ceramic steel[1]" (Garvie, 1975). Zirconium oxide, or zirconia, which is derived from zircon (mostly in sands), is a much more complicated material. For many years it was not an easy material to use because of a high-volume phase change occurring in the material. The "pure" material has three basic crystal phases and it can undergo transformation from one phase to another. At 2400°C, it is in the cubic crystal form. As it cools, it transforms at 2370°C to the tetragonal crystal form and then at 1173°C it transforms yet again to the monoclinic crystal form, which is its natural stable state at room temperature. This in itself does not pose a serious problem, but the phase transformation from a tetragonal to a monoclinic crystal results in a martensitic phase transformation which causes a diffusionless volume change of about 5 vol%, which can totally destroy the structure. If pure zirconia powder is pressed, machined, formed, and then sintered by placing it in an oven, heating it up to its sintering temperature and then cooling it down, the result would likely result in a broken or defective part.

It was known that additives like magnesium oxide (MgO) could stabilize the cubic phase, creating a hard, brittle ceramic. However, in the 1960s, people started realizing they could delay the monoclinic-to-tetragonal transformation and thereby create a metastable phase. The partially stabilized material is much more flaw tolerant than alumina or its stabilized counterpart because when a crack starts propagating, the metastable material transforms martensitically and the volume change from the transformation creates a compressive layer that slows the crack down. This is the basic idea behind zirconia toughening in ceramics. There are basically two ways that the metastable tetragonal zirconia structure is formed, namely partially stabilized zirconia and tetragonal zirconia polycrystalline materials, which we will go into more depth later.

In medical devices, there are basically two different zirconia-based materials that have been cleared for use by the Food and Drug Administration (FDA) as of 2018: (1) YTZP ceramic, and (2) MgPSZ. The highest market share in the 1990s was by far YTZP, which became the "go-to" material for arthroplasty instead of alumina. Although not as hard as alumina, its toughness (see the high Weibull modulus in Table 1.3.4B.2) suggested that it was not expected to have the same problems with catastrophic failure. In the late 1990s, the desire for YTZP heads outpaced the manufacturers' capabilities.

It is more nuanced to properly manufacture partially stabilized zirconias than it is to manufacture an alumina.

[1] R.C. Garvie, R.H. Hannink, R.T. Pascoe, "Ceramic steel?", Nature 258, 703–704 (1975).

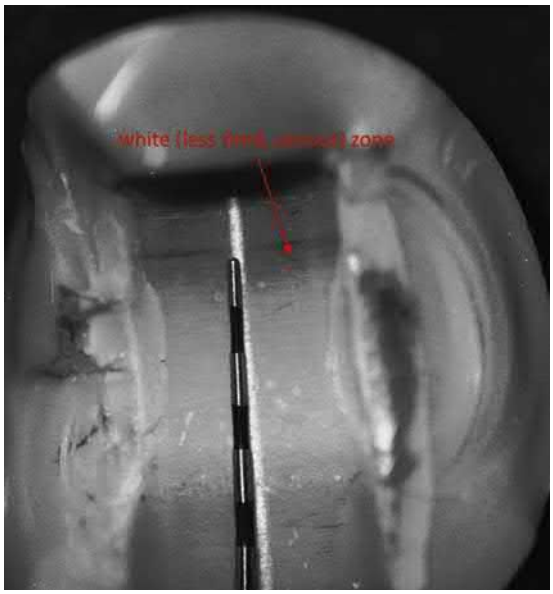


• **Figure 1.3.4B.5** St. Gobain Prozyr fast transformation region based on discussions with St. Gobain following the 2001 recall.

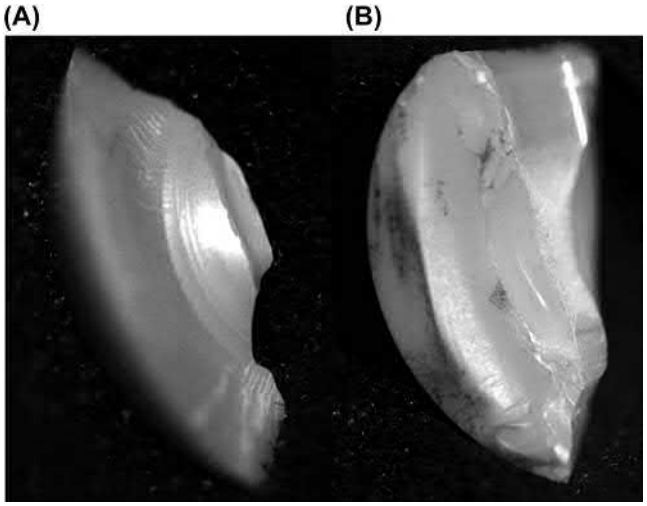
Depending on whether it is a YTZP or MgPSZ, there are different issues to resolve and different things that must be done to make sure the material is and remains appropriately stable. As an example, YTZP has a problem with water-initiated degradation. Water replaces the oxygen in the material and destabilizes it. This prompted the FDA to issue a "do not steam resterilize" warning to medical facilities (US FDA Dear Dr Letter, 1997). Beyond requirements against steam sterilization, the issue was controlled by adjustments in chemistry as well as the grain size of the structure. Thus the YTZPs that were used for medical implants were highly optimized materials. This created a very good material, but the optimization also made this material more challenging to manufacture.

In the late 1990s, due to a high demand for the material, the major manufacturer of YTZP upgraded its manufacturing process. One of the changes was switching from a batch furnace (kitchen oven) to a belt furnace (pizza oven), which changed the temperature profile of the process, which was followed by another change in temperature variable (i.e., weather). These changes led to serious quality issues. Of a series of seven lots from this new process there were known failure rates well above the 0.001% anticipated. For example, of the seven lots in question, the failure rates were 36%, 13%, 0.42%, 0.17%, 0.56%, 0.14%, and 0.68%, respectively. These failures were devastating to the zirconia medical implant industry.

Because the forming process of zirconia was so highly optimized, it was extremely sensitive to manufacturing changes. The change in thermal processing profile left very little room for error. When ambient conditions changed, the center of the material was not properly fired. The company made the heads by forming a sphere, firing the sphere, and then machining the bore in the finished sphere. Machining the bore in the sphere cut into the improperly fired region and opened material that could easily transform to an environment that included a water-intense body fluid environment. These materials failed dramatically, often revealing an internal, spherical transformation core (Fig. 1.3.4B.5).



• **Figure 1.3.4B.6** Failed head from the recalled material with the fast transformation region showing up as a white band. (From author's private collection.)



• **Figure 1.3.4B.7** Other views of a failed head. (A) shows a crack emanating from the spherical fast transformation region and (B) shows the crushed bore surface where the metal stem articulated against the bore in the head. (From the author's private collections.)

The resulting failures were usually a crushed region that presented itself as a band (Fig. 1.3.4B.6) in the fast transformation region where cracks emanated and moved outward toward the surface, creating orange slice-like pieces of ceramics (Fig. 1.3.4B.7). The failed materials were recalled globally by the company and zirconia became an uncomfortable term in the industry. Because there was no other material besides alumina and zirconia on the market, the ceramic hip replacement industry was in peril. As the industry was considering returning to alumina, another ceramic was already in the later stages of development.

The dwindling in market share for alumina caused by the success of zirconia pushed CeramTec, the major alumina head manufacturer, to become innovative. A material that

TABLE 1.3.4B.1 Properties of Various Grades of Alumina Offered by Kyocera and CoorsTek

Property and Unit	Kyocera	CoorsTek	Kyocera	Kyocera	Kyocera	CoorsTek	CoorsTek	Kyocera
Alumina content (wt%)	99	99.5	99.5	99.5	99.7	99.8	99.9	99.9

Thermal conductivity (w/(m*K))	29	30	32	32	32	31	33	34

was used for other purposes (such as machine tools) was already available. It was an alumina that was toughened with a little bit of zirconia, hardened with the addition of chromium, and further toughened by adding strontium, which enabled the alumina to grow in hexagonal platelets. This material became the new Biolox delta material in the early 2000s. Its introduction at about the time of the zirconia failure was fortuitous because it was not alumina, which zirconia replaced due to better toughness, and not zirconia, which just had a major failure, but rather a mixture of both, which made it both harder and tougher. These materials are by and large the materials still used today.

Properties in General

Structural ceramics are used in medical devices because they are very hard, very strong, not soluble, and can be made with an extremely smooth surface. Because of this, they gained a great deal of popularity in orthopedic implants, mostly hips, and they have been a major factor in the reduction of failure of these devices due to wear of the articulating surfaces.

Another property that has made them important structurally is their use as electrical insulators, which have made them ideal materials for electrical feedthroughs in electrical packages for devices. Moreover, because they are relatively transparent to RF frequencies, they can be used for containers for electronics and batteries allowing communication and battery charging of an implanted device.

It is simple reality that materials, including ceramics, are not absolutely pure. Elements that are different from the material but found naturally in it are generally called impurities. If an element is desired or added to the material to modify its properties, that element is called a dopant. One should be aware that material properties will be affected by the impurities and dopants that are found in that material. Determining the level of impurities that exist and what those impurities are is important in both the manufacturing and final properties of the material itself. As an example of the comparable[2] final property difference, Table 1.3.4B.1 lists a number of different aluminas from Kyocera[3] and CoorsTek[4] (both companies make ceramics for medical devices) between 99 and 100 wt% alumina.

The properties of these materials will vary depending on their manufacturing processes, phase content, and impurities. For other applications beyond medical devices, readers are encouraged to refer to specific ceramic topic books (e.g., Carter and Norton, 2007). Commercially, medical-grade aluminas, zirconias, and ZTAs adhere to international specifications that have been developed for these materials by the industry and regulatory bodies through the standards development agencies of ASTM and ISO. A comparison of these materials with respect to specified properties considered significant for medical device manufacture in general is given in Table 1.3.4B.2. These properties are based on standard specifications from both ISO and ASTM, which means that these properties are minimum allowable values. The Biolox data are actual data for the product used here as an example and therefore should be higher than the values for ZTA Type X, which is the specification for that material.

One significant aspect of Table 1.3.4B.2 is that both alumina and ZTA have two different types of materials. There is a high strength (Type A alumina, Type X ZTA) and a low strength (Type B alumina, Type S ZTA) material found in the specifications. When the specifications were first developed, it was important to make clear that an alumina (or later a ZTA) used for a feedthrough does not need to have the same property as an alumina (or later a ZTA) used for a hip replacement.

While any of the three materials (alumina, zirconia, and ZTA) would make a good, strong, inert electrically insulative material that would be transparent, there are nuances as to why one would choose alumina over zirconia or ZTA. For instance, alumina is quite hard and very strong, but it is very flaw sensitive. Once a crack propagates in alumina, it is very difficult to stop. This makes alumina highly sensitive to flaws such as scratches externally and voids internally in the structure. One might choose not to use zirconia over alumina because the former is quite dense (~6 vs. ~3 g/mL), hence in terms of minimizing the weight of the material, alumina would be the preferred material. When X-ray translucency is important, alumina would be preferable over zirconia or ZTA. When toughness is important zirconia or ZTA would be preferable over alumina.

[2] Tests are done the same way.

Introduction

The recognition of the biocompatibility of carbon dates back to ancient times, where manmade permanent tattoos using pulverized charcoal could be placed under the skin without apparent adverse effects. However, it was only in the late 1960s that a pyrolytic form of carbon was found to have remarkable blood compatibility and the structural properties needed for application in long-term artificial heart valves (Haubold et al., 2016). Since then, several forms of carbon have sparked investigation for application as medical devices. This chapter outlines the existing forms of carbon biomaterials and their main biomedical applications to date. The main properties and production techniques of all existing carbon biomaterials are firstly presented. Following, the biomedical applications of carbon biomaterials are described taking into consideration their use as colloids, free-standing materials, coatings or composites. Focus was given to commercially available and under research uses in drug delivery, phototherapy and imaging, biosensors, antimicrobial therapy, cardiovascular, orthopedic, dental, neurological and ophthalmological applications, catheters and guidewires among others. Short considerations are presented at the end of the chapter to raise awareness about safety of carbon biomaterials.

Carbon Biomaterials

Carbon atoms consist of six electrons, which are arranged in the $1s^2 2s^2 2p^2$ electronic configuration. Their unique properties and high plasticity allow them to form covalent bonds with other carbon atoms or elements, which empower their presence from small organic molecules to complex structures such as carbon materials (Fig. 1.3.5.1) with distinct and remarkable properties.

SIDEBAR #1

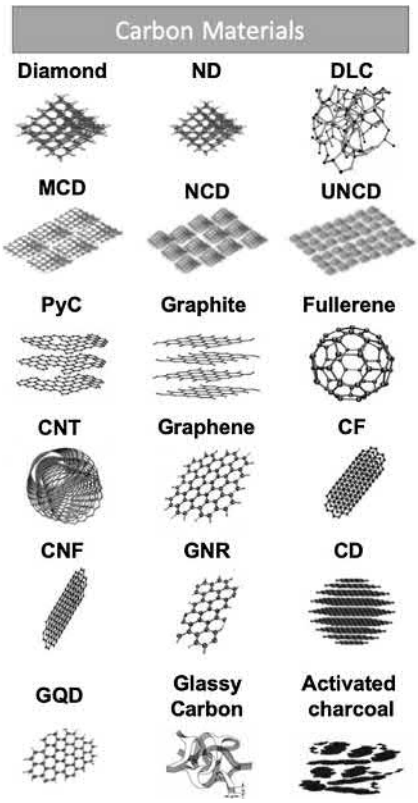
Carbon biomaterials can be characterized regarding: (1) dimension, ranging from 0D materials, which have all the dimensions in nanometric size, such as nanodiamonds, fullerene, graphene quantum dots, and carbon dots, to 3D materials, which have 3 dimensions out of the nanometric size range, such as diamond, pyrolytic carbon, diamond-like carbon, carbon fibers, and graphite; (2) crystallinity, ranging from entirely crystalline allotropic materials, such as diamond and graphite, to entirely amorphous, like pyrolytic carbon, diamond-like carbon, and carbon dots; and (3) carbon atoms hybridization state, ranging from materials that display only sp^2 hybridized carbons, such as graphite, to materials which mainly contain sp^3 hybridized carbons, as diamond.

Fig. 1.3.5.2 displays the organization of the most common carbon biomaterials regarding their dimension, crystallinity, and carbon atoms hybridization state.

Diamond and Diamond-Like Carbon

Diamond

Diamond is a 3D material with a fully crystalline form of carbon, containing sp^3 hybridized atoms. It presents a cubic structure in which each carbon atom is linked to four other carbon atoms arranged tetrahedrally around it. Its crystalline structure and the strength of its chemical bonds score diamond as the hardest known material. Diamond-based materials comprise microcrystalline, nanocrystalline, and ultrananocrystalline diamond films or coatings, mostly



• **Figure 1.3.5.1** Carbon biomaterials structure. *CD*, Carbon dots; *CF*, Carbon fibers; *CNF*, Carbon nanofibers; *CNT*, Carbon nanotubes; *DLC*, Diamond-like carbon; *GNR*, Graphene nanoribbons; *GQD*, Graphene quantum dots; *MCD*, Microcrystalline diamond; *NCD*, Nanocrystalline diamond; *ND*, Nanodiamonds; *PyC,* Pyrolitic carbon; *UNCD*, Ultrananocrystalline diamond.

produced by chemical vapor deposition (CVD), or nanodiamond (ND) particles produced by top-down methods such as detonation or grinding (Fig. 1.3.5.3). Diamond and diamond-like carbon (DLC) materials exhibit excellent features for applications that require high wear resistance such as hip, knee, and other joint prostheses.

Microcrystalline Diamond. Microcrystalline diamond (MCD) is a material with a crystalline form of carbon containing a high fraction of sp^3 hybridized atoms. MCD grows as a film, having grain sizes larger than 0.1 µm, therefore being considered 3D. Sp^2 hybridized atoms as well as amorphous carbon are commonly observed at the grain boundaries.

Nanocrystalline Diamond. Nanocrystalline diamond (NCD) is a material with a crystalline form of carbon containing sp^3 hybridized atoms. NCD grows as a film, having grain sizes below 100 nm, therefore being considered 0D. As grain size decreases, more sp^2 hybridized atoms and amorphous carbon are present at diamond grain boundaries, consequently, the degree of sp^3 bonding also decreases with the grain size.

Ultrananocrystalline Diamond. Ultrananocrystalline diamond (UNCD) is a material with a crystalline form of carbon containing sp^3 hybridized atoms. UNCD grows as a film, having grain sizes below 10 nm, therefore being considered 0D. Among MCD, NCD and UNCD, UNCD has the lowest fraction of sp^3 hybridized atoms.

Nanodiamonds. Nanodiamonds (ND) are 0D materials with a crystalline form of carbon containing sp^3 hybridized atoms. These nanoparticles have a diameter range from 1 to 20 nm. Nanostructures with higher sizes (> 20 nm) are similar to bulk diamonds and the ones with lower sizes (<1 nm), called diamondoids, appear naturally in petroleum deposits. ND production techniques have high influence on their size, shape, and quality.

Detonation nanodiamonds (DND) are produced by the detonation of an explosive mixture of certain carbon-containing compounds (such as trinitrotoluene). Particles of 5 nm are usually produced with narrow size distribution and in large scale. The main disadvantage of this procedure is the formation of aggregates coated with a graphitic layer, which are not dispersible in organic or aqueous solvents. However, DND's large surface area and small size, which allow the attachment of large amounts of drugs, and the reproducibility of their particle size are major assets as drug delivery systems. DND are not suitable for labeling or sensing applications due to their small size and high amount of impurities. However, nitrogen vacancy (NV) centers can be introduced in deep locations, conferring fluorescence even after surface modification, unlike in other carbon materials such as quantum dots (QD).

ND from grinding are particles with different features obtained by grinding larger diamonds (typically high-pressure high-temperature diamonds). These ND have a flake-like shape and different sizes that can be selected by centrifugation. They are purer and contain fewer defects than DND.

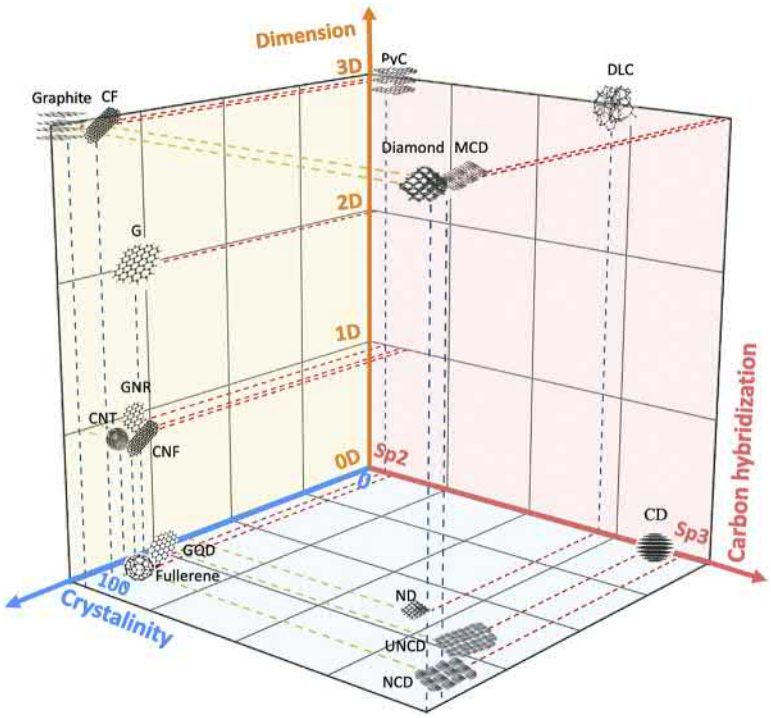
Besides these, other techniques have been developed to produce ND. One possibility is to use a predefined adamantine (small molecule with a diamond-like position of molecules), which already has the atoms required for defects, and then grow a diamond around it. ND can also be produced by microfabricating bulk diamond, resulting in very pure materials with controlled shape. Despite the promising features for sensing or labeling, the low yields of these methods are a disadvantage.

Diamond-Like Carbon

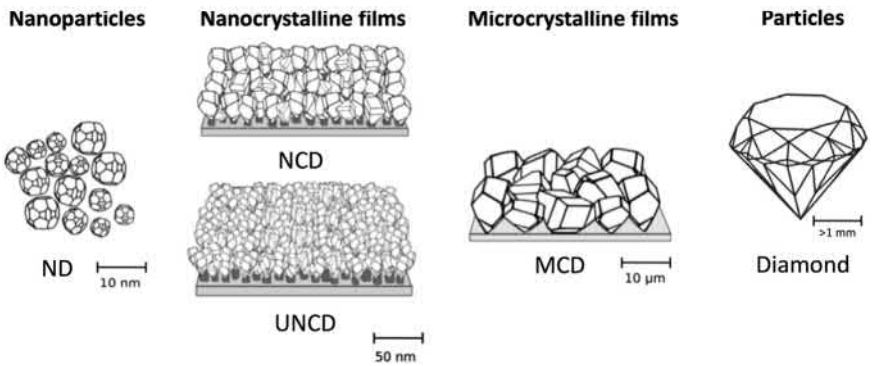
Diamond-like carbon (DLC), a 3D material, is a variety of amorphous carbon material film containing significant amounts of sp^3 hybridized atoms and varying amounts of hydrogen.

DLC is characterized into four categories by their predominant bonding type (either trigonal sp^2 bonding or tetrahedral sp^3 bonding) and hydrogen content. The forms that contain low levels of hydrogen (around 1%) may have low amounts of sp^3 bonds, being referred to as amorphous carbon (a-C), or high amounts of sp^3 bonds (up to 85%), being referred to as tetrahedral amorphous carbon (ta-C). The forms that contain high levels of hydrogen (up to 50%) may have low amounts of sp^3 bonds, being referred to as hydrogenated amorphous carbon (a-C:H), or high amounts of sp^3 bonds (up to 85%), being referred to as hydrogenated tetrahedral amorphous carbon (ta-C:H).

The mechanical, electronic, and optical properties of DLC are closely related to the sp^3/sp^2 ratio, which in turn



• **Figure 1.3.5.2** Organization of carbon biomaterials regarding dimension, crystallinity, and carbon hybridization. Dimension was classified taking into account their size/grain size (0D: all dimensions < 100 nm; 1D: 1 dimension > 100 nm; 2D: 2 dimensions > 100 nm; 3D: all dimensions > 100 nm). Crystallinity was classified taking into account their 3D structure, therefore considering graphite and diamond as fully crystalline, since besides having a crystalline form of C, they have well-organized 3D structures. *CD*, Carbon dot; *CF*, Carbon fiber; *CNF*, Carbon nanofiber; *CNT*, Carbon nanotube; *DLC*, Diamond-like carbon; *G,* Graphene; *GNR*, Graphene nanoribbon; *GQD*, Graphene quantum dot; *MCD*, Microcrystalline diamond; *NCD*, Nanocrystalline diamond; *ND*, Nanodiamond; *PyC*, Pyrolitic carbon; *UNCD*, Ultrananocrystalline diamond.

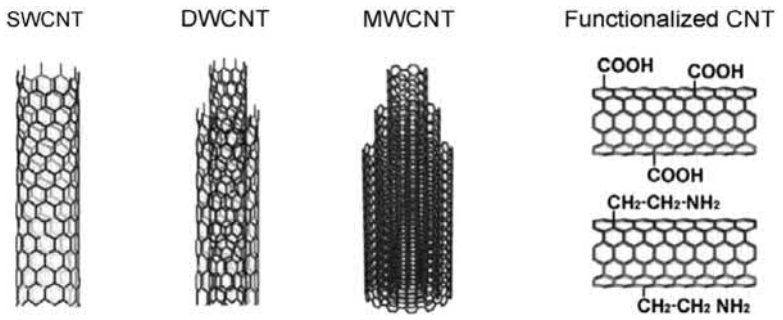


• **Figure 1.3.5.3** Diamond-based materials. *MCD*, Microcrystalline diamond; *NCD*, Nanocrystalline diamond; *ND*, nanodiamond; *UNCD*, Ultrananocrystalline diamond. Adapted from (Pennisi et al., 2014).

is dependent on the substrate material, growth method, and growth parameters (*e.g.,* growth temperature and ion energy) (Ducheyne, 2011). DLC films' high hardness, wear resistance, chemical inertness, and biological properties make them attractive coatings for biomedical devices.

Pyrolytic Carbon

Pyrolytic carbon (PyC) is a 3D turbostratic form of carbon with an amorphous structure containing sp^2 hybridized atoms. This material is produced by pyrolysis (thermal decomposition) of hydrocarbon precursors and consists of randomly layered, kinked or curved "graphene-like sheets" (turbostratic), generating large gaps between layers. PyC is one of the best thermal conductors available and exhibits high wear resistance and low thrombogenicity, being mostly applied as coatings in commercially available mechanical heart valves, vascular stents, and orthopedic implants.



• **Figure 1.3.5.4** Carbon nanotubes (CNT): single-walled carbon nanotubes (SWCNT), double-walled carbon nanotubes (DWCNT), and multiwalled carbon nanotubes (MWCNT), and possible surface modification by adding functional groups to the CNT surface (functionalization) (Jackson et al., 2013).

Hexagonally Bonded Carbon

Graphite

Graphite (Gt) is a 3D material with a crystalline form of carbon containing sp^2 hybridized atoms. This material consists of hexagonally bonded carbon atom-stacked sheets connected to each other through van der Waals interaction that allows slipping of graphene (G) sheets past one another; it is consequently a soft material but an excellent lubricant.

Fullerenes

Fullerenes are 0D materials with a crystalline form of carbon containing sp^2 hybridized atoms. These materials are closed hollow cages made of 12 pentagons and a number of hexagons dependent on the total number of carbon atoms ($20 + 2n$, where n is the number of hexagons). C_{60} is the most abundant and studied fullerene and the smallest carbon nanostructure, with a size of 0.71 nm. Fullerenes show a high reactivity, which is associated with the pyramidalization of the carbon atoms in a spherical shape and small size, allowing their use in several biomedical applications, mainly as imaging contrast agents and drug delivery systems.

Carbon Nanotubes

Carbon nanotubes (CNT) are 1D materials with a hexagonal lattice crystalline form of carbon mostly constituted by sp^2 hybridized atoms. CNT can be single-walled (SWCNT), having a single G layer in the wall and a diameter ranging from 0.2 to 2 nm, double-walled (DWCNT), or multiwalled (MWCNT), with two layers or more, respectively, and several micrometers long (Fig. 1.3.5.4).

CNT can be produced by laser ablation, electric arc discharge, catalytic CVD, catalytic plasma-enhanced CVD, or template-based CVD. They present high aspect ratio (more than 10,000 length/diameter ratio), are mechanically robust, electrical and thermal conductors, and have unique optical properties. These features are highly dependent on aspect ratio, chirality of carbon tubes, and also on the number of walls. Despite being chemically inert, they can be modified to obtain chemically reactive groups (Fig. 1.3.5.4). CNT can be potentially applied in the design of tissue-engineered scaffolds, providing electrical conductivity and mechanical reinforcement, as biosensors, in drug delivery systems, and in phototherapy.

Graphene-Based Materials

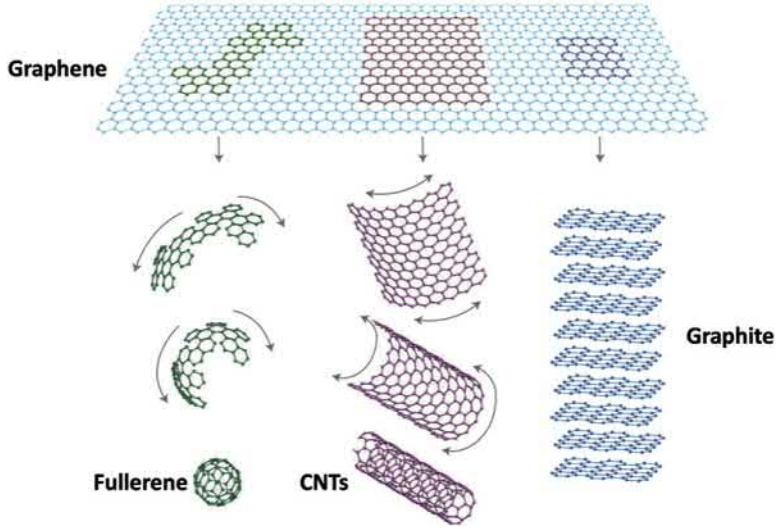
Graphene (G) is a 2D material with a crystalline form of carbon containing sp^2 hybridized atoms. It is the basic building block of hexagonally bonded carbon materials and consists of a 6-ring honeycomb lattice structure where each carbon atom is bonded to three neighboring carbon atoms (Fig. 1.3.5.5).

SIDEBAR #2

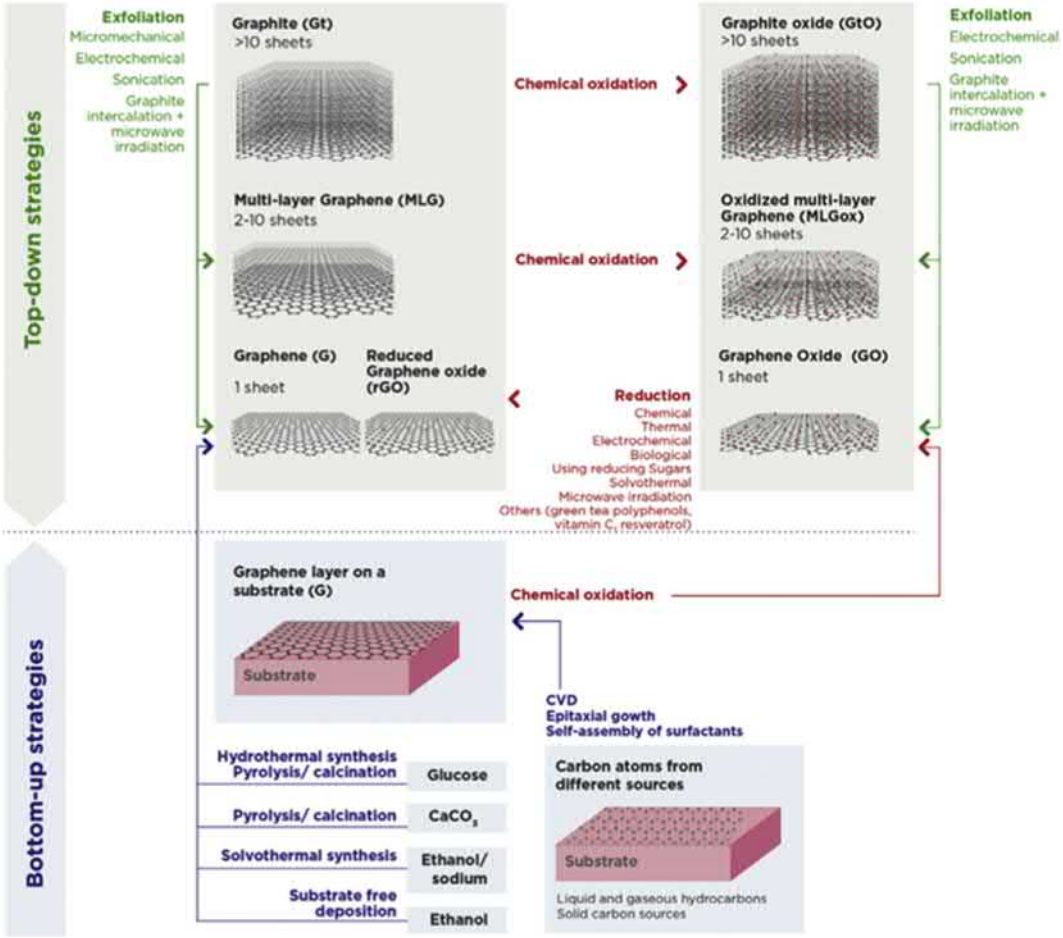
Despite many of us not always being aware of it, carbon materials are part of our daily routines, being present in things like coal, jewelry, pencils, biomaterials, graphite lubricants, etc., but two of these materials have even reached higher stages … the Nobel Prize ceremony! In 1996, Professor Robert Curl Jr. and Richard Smalley from Rice University, Houston (USA), and Professor Sir Harold Kroto from the University of Sussex, Brighton (UK), won the Nobel Prize in Chemistry due to the discovery of fullerene. These three scientists wanted to evaluate the formation of carbon chains in interstellar space and circumstellar shells, and when they laser irradiated graphite, it was vaporized, producing C_{60}, which was believed impossible to build. This discovery opened the door for a wide range of applications such as the creation of tiny carbon-based and superfast computers. Later on, in 2010, Professors Andre Geim and Konstantin Novoselov from the University of Manchester (UK) won the Nobel Prize in Physics due to groundbreaking experiments in graphene. By peeling off graphite using regular tape, these two scientists isolated graphene for the first time, obtaining a single layer of the carbon atom, which was believed impossible to obtain due to its instability. Graphene is considered a breakthrough material with potential to revolutionize the world of materials science.

G was first isolated in 2004, and since then, along with its derived graphene-based materials (GBM), has been remarkably studied. G can be produced by top-down approaches, using Gt as raw material, and/or bottom-up approaches, using alternative carbon sources as raw material (Henriques et al., 2018).

GBM are a broad class of materials that involve single-layer G, few-layer G (FLG, 2–5 G layers packed together), and multilayer G (MLG) also called G nanoplatelets (GNP)



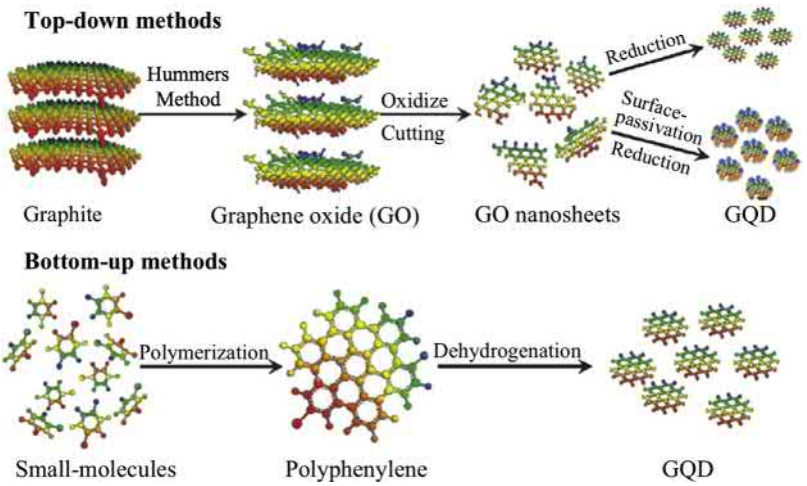
•**Figure 1.3.5.5** Graphene is the 2D building block of hexagonally bonded carbon materials, being wrapped up to form fullerene, rolled to generate carbon nanotubes (CNT), or stacked to create 3D graphite. Adapted from (Geim et al., 2007).



• **Figure 1.3.5.6** Graphene-based materials family and their production methods (Henriques et al., 2018).

(2–10 layers), while materials with more than 10 layers are considered Gt. Each of this class of materials can be oxidized (usually by the modified Hummers method), being referred as G oxide (GO), oxidized FLG, oxidized MLG, and Gt oxide (Fig. 1.3.5.6).

In addition to its unique thermal and electrical conductivity, G is the strongest, thinnest, and one of the lightest materials in the world. However, with the increase in G layers a decrease in electric conductivity is observed. GBM oxidation disrupts the aromatic system, introducing oxygen



• **Figure 1.3.5.7** Schematic diagram of the top-down and bottom-up methods for synthesizing graphene quantum dots (GQD). Adapted from (Shen et al., 2012).

in the form of hydroxyl and ether groups at the bulk surface and carboxyl and carbonyl at the edges of the sheets. This also leads to a decrease in conductivity, which can be partially reestablished by reduction, resulting in reduced GO (rGO) when GO is used.

Other Hexagonally Bonded Carbons

Graphene Quantum Dots. Graphene quantum dots (GQD) are 0D materials (2–20 nm) with a crystalline form of carbon containing sp^2 hybridized atoms. These materials can be produced by top-down techniques, applying a cutting process to Gt, carbon black, GO, and CNT, or by bottom-up techniques, which are associated with the assembling of large aromatic molecules (reviewed by Chen et al., 2018) (Fig. 1.3.5.7). Their optoelectronic and electronic properties are highly dependent on their lateral size, with smaller particles having nonzero band gaps, which exhibit outstanding properties. GQD can be potentially applied in bioimaging and phototherapy as discussed later in this chapter.

Carbon Fibers. Carbon fibers (CF) are a 3D material (diameter: 5–10 μm) with a crystalline form of carbon containing sp^2 hybridized atoms. These materials are produced by drawing a precursor polymer, commonly polyacrylonitrile, into long strands or fibers followed by heating in vacuum to a very high temperature, causing a violent vibration in the molecules and expelling most of the noncarbon atoms (carbonization). CF exhibit high mechanical resistance and thermal conductivity and have been explored as biomaterials for the past 30 years, mainly incorporated as composites in commercially available orthopedic implants (Saito et al., 2011). More recently, a nanosized CF was developed, named carbon nanofiber (CNF).

Carbon Nanofibers. Carbon nanofibers (CNF) are noncontinuous 1D materials with a crystalline form of carbon containing sp^2 hybridized atoms. CNF consist of stacked and curved G with a cylindrical or conical shape. The main differences between CNF and CNT is the absence or presence of a hollow cavity, respectively. CNF are produced in a similar way to CF, through the carbonization of electrospun nanofibers using polymeric precursors (Georgakilas et al., 2015).

Graphene Nanoribbons. Graphene nanoribbons (GNR) are 1D materials with a crystalline form of carbon containing sp^2 hybridized atoms. GNR are commonly produced by the chemical unzipping of MWCNT under strong oxidizing conditions, which causes the graphitic layers of the tube to unfold one by one, releasing them as GNR rich in oxygen-containing groups. Similarly to the oxidized forms of GBM, the electrical conductivity of these GNR is poor, despite it being substantially increased by reduction using hydrazine or annealing under H_2.

Other Carbon Biomaterials

Carbon Dots

Carbon dots (CD) are quasispherical 0D materials (2–10 nm in diameter) with an amorphous form of carbon, mostly containing sp^3 hybridized atoms. These materials consist of combinations of turbostratic and graphitic carbon with a high oxygen content. CD can be produced by laser ablation followed by oxidation and surface passivation, which results in the production of nanoparticles with a mean diameter of about 5 nm, by thermal decomposition or carbonization of organic compounds in high-boiling solvents, by pyrolysis of polymer–silica nanocomposites, by ultrasonic carbonization, or by microwave hydrothermal or solvothermal treatment of organic compounds, organosilanes, polymers, or natural products such as carbohydrates. CD present a very high photoluminescence (PL) capacity, which depends on the excitation wavelength, size, and surface functionalization.

Glassy Carbon

Glassy carbon (GC) is a 3D material with an amorphous form of carbon containing sp^2 hybridized atoms. This bulk solid has a turbostratic structure with strongly curved and poorly

organized bonded G sheets being arranged in ribbons, as in polymers. GC can be produced by pyrolysis of organic polymers. It combines glassy and ceramic properties with those of Gt. GC is unsuitable for applications that are mechanically demanding, but its biological properties are similar to that of PyC, being suitable for blood contact applications.

Activated Charcoal

Activated charcoal is a 3D material with an amorphous form of carbon. These solid particles have very high porosity and a very large internal surface area. It can be produced from organic natural carbon-based materials by heating at high temperatures in the presence of oxidizing gases or impregnation with chemicals and heating. Activated charcoal can be processed into powder, granular, and pellet forms. It can adsorb molecules from both the liquid and gas phases and is therefore used in purification and cleaning processes, including the biomedical field (Hasirci and Hasirci, 2018).

Biomedical Applications of Carbon Biomaterials

The existing wide variety of carbon biomaterials and their inherent unique properties have instilled their investigation and/or commercialization in a wide range of biomedical applications. Depending on the application, carbon biomaterials are currently used as colloids, free-standing materials, coatings, or composites (Table 1.3.5.1).

Colloids in the form of carbon micro- and nanoparticles, mostly ND, fullerenes, CNT, GBM, and CD, have been mainly explored for drug and gene delivery, phototherapy, imaging (diagnostics), and as antimicrobial agents (Table 1.3.5.1). Despite no products being commercially available, their efficacy has been shown both *in vitro* and *in vivo*.

Free-standing materials comprise free-standing films that can be quickly and cheaply produced through vacuum filtration or direct evaporation methods (Kong, 2013; Gong et al., 2018), and carbon aerogels, generally produced by critical point drying, 3D printing, or freeze-drying methods (Duong et al., 2016). CNT, GBM, and CF free-standing materials have been mainly explored for the development of biosensors, cardiac, orthopedic, and neurological tissue engineering applications, skin wound healing, and antibacterial surfaces (Table 1.3.5.1).

Carbon-based coatings have been used for decades to enhance biomaterial performance. Coatings can be performed by diverse methods, being the most common, CVD, electrophoretic deposition, and dip, drop, spin or spray coating. Table 1.3.5.1 shows examples of commercially available carbon-coated implants and the most relevant potential applications under investigation of carbon-based material coatings. DLC and PyC coatings are commercialized in ventricular-assisted devices, vascular stents, urethral stents, mechanical heart valves (MHV), or orthopedic implants. NCD, UNCD, DLC, fullerenes, CNT, GBM, and CD are being investigated for cardiovascular, orthopedic, dental, neurological, and ophthalmological applications and as biosensors, antimicrobial materials, catheters, and guidewires.

As for carbon composites, these presuppose that carbon materials are combined with polymers, ceramics, or metals. Carbon composites can be produced using different techniques, such as *in situ* polymerization, melt blending, and solvent mixing (followed by casting, doctor blading, electrospinning, 3D printing, etc.) (Henriques et al., 2018). The final features of the produced materials are highly dependent on the used carbon material, production technique, and base polymer. Thus, playing with all these features allows the production of a wide range of biomaterials. CF and ND containing composites are commercialized for orthopedic and dental applications, respectively. ND, Gt, CNT, GBM, or CQD composites are widely explored for the development of drug and gene delivery systems, biosensors, antibacterial materials, and medical implants, including both permanent prosthesis and regenerative medicine approaches, as summarized in Table 1.3.5.1.

The following subsections highlight the most common biomedical applications in which the different carbon materials are being applied or investigated.

Drug Delivery

Most of the drug delivery systems containing carbon materials can load the drug directly at their surface. Nevertheless, carbon materials can also be functionalized to improve biocompatibility or drug interaction, as reviewed in Kumar et al. (2017), Mohajeri et al. (2018), and Swetha et al. (2018).

DND with a primary particle size of 4–5 nm are of particular interest for biomedical applications due to their small dimensions, inertness, generally good biocompatibility, and higher purity compared to other carbon nanomaterials such as CNT. Drugs, biological molecules, or imaging agents can be loaded at ND surface through chemical functionalization or by physical interaction. Because ND possess the ability to penetrate through tissues and cell membranes, they have been explored for the delivery of drugs (cisplatin, purvalanol A, 4-hydroxytamoxifen), proteins (insulin, bone morphogenetic proteins), and genetic material (DNA) (Fig. 1.3.5.8) (van der Laan et al., 2018; Passeri et al., 2015; Kaur and Badea, 2013; Zhang et al., 2016).

Pristine fullerenes are highly hydrophobic and form colloidal aggregates in aqueous biological solutions, which have hindered their study for biomedical applications for several years. However, strategies have been developed to increase their water solubility, such as solvent exchange stabilization, external chemical functionalization of their cage (e.g., hydroxylation, carboxylation, amination, quaternary ammonium salts), and stabilization/encapsulation with macromolecules (e.g., surfactants, saccharides, proteins, lipids, polymers). Modifications are often performed with bioactive compounds that have affinity to target nucleic acids, cell receptors, or proteins (Bakry et al., 2007; Rasovic, 2017; Torres and Srdjenovic, 2011;

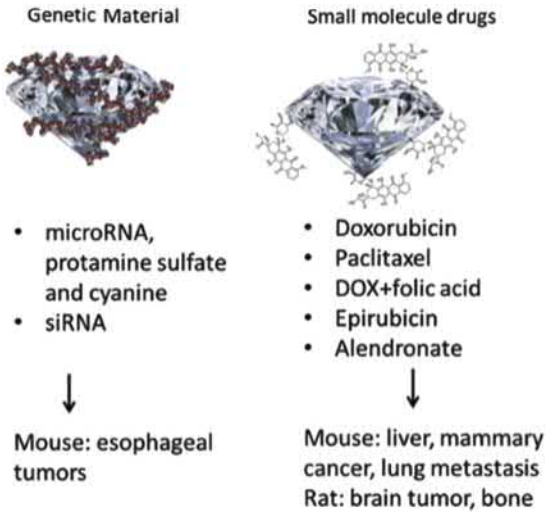
Dellinger et al., 2013; Castro et al., 2017). Due to their small size (≈0.7 nm), fullerenes can easily penetrate mammalian cell membranes and are therefore used for gene and drug delivery, presenting comparable or better efficiency than some commercial lipid vectors. Moreover, they can protect DNA during delivery, increasing its lifetime in liposomes, leading to more effective chromosomal incorporation. Taking advantage of its amphiphilicity, functionalized fullerenes have also been used for delivery of hydrophobic drugs, such as anticancer chemotherapeutics (Bakry et al., 2007; Dellinger et al., 2013). Fullerenes have also improved the bioavailability of erythropoietin upon small intestinal administration in rats (Venkatesan et al., 2005). Finally, the ability of fullerenes to penetrate through skin makes them an ideal carrier for transdermal delivery of pharmaceutical formulations (Bakry et al., 2007; Dellinger et al., 2013).

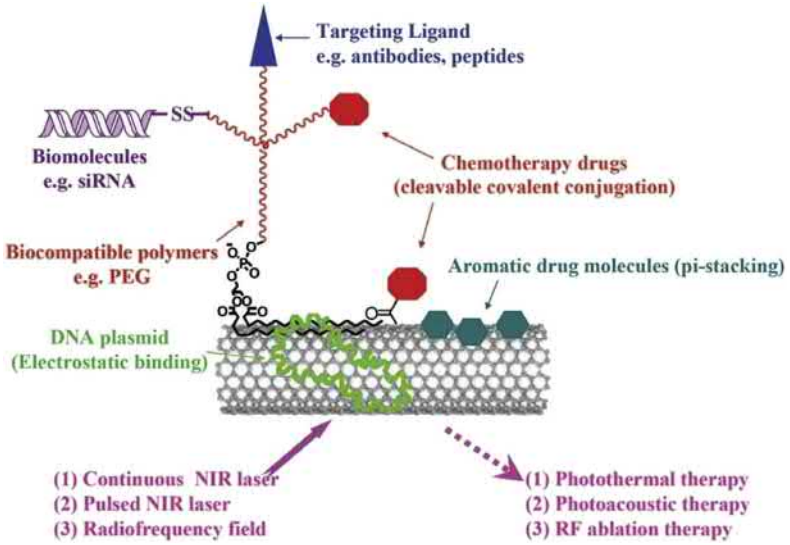


• **Figure 1.3.5.8** Examples of nanodiamond (ND)-based drug and gene delivery approaches tested in *in vivo* models. Adapted from (van der Laan et al., 2018).

CNT in their different unfunctionalized forms, from single to multiwalled, are water insoluble. Several covalent and noncovalent functionalization strategies have been employed to improve their solubility and stability in physiological medium, which can also be used for biological properties enhancement. Due to their high surface area and aspect ratio, CNT can be attached with suitable delivery vectors (e.g., antibodies, peptides), permeate cell membranes, and accumulate intracellularly, with enhanced permeability and retention effect being reported. Also, their hollow interior facilitates the loading of molecules through noncovalent interactions (π–π stacking, hydrophobic) as aromatic drugs, proteins, DNA, siRNA, and antisense oligodeoxynucleotides. Covalent bonding can be performed with some small drugs and biomacromolecules. Some of these modifications are represented in the following section (Fig. 1.3.5.9). Several anticancer drugs (e.g., paclitaxel, cisplatin, epirubicin, doxorubicin, methotrexate) have been conjugated with CNT and successfully delivered *in vitro* and *in vivo* (Liu et al., 2011b; Saito et al., 2014; Sharma et al., 2016; Grumezescu, 2018; Alshehri et al., 2016; Sajid et al., 2016).

GBM edges and large surface, allow chemical modification by oxidation or functionalization with groups of interest, to improve dispersibility in water or interaction with molecules to be loaded. The large delocalized π-conjugated network allows effective loading of aromatic drugs. GO can be used for delivery and targeting of small drug molecules, and when functionalized with cationic polymers, it has been used for delivery of biomacromolecules, such as plasmid DNA and siRNA (Zhang et al., 2016; Grumezescu, 2018; Liu et al., 2011b; Pinto et al., 2013).

CD and GQD have sizes bellow 10 nm, possessing oxygen-containing surface groups that confer them good water solubility and biocompatibility. Chemical surface modifications with several polymeric, inorganic, organic, or biological entities have been tried to tune their drug/gene delivery and targeting ability, as well as their performance for



• **Figure 1.3.5.9** Illustration of carbon nanotube possible modifications for theranostic uses. *NIR*, Near-infrared; *PEG*, Poly(ethylene glycol); *RF*, Radiofrequency (Liu et al., 2011b).

phototherapeutic and bioimaging applications. Cell uptake of CD can occur passively due to their small size and surface charge, by active delivery (e.g., reversible membrane permeabilization, nanochannel electroporation, microfluidic cell squeezing), or through facilitated delivery, using peptides, polymers, or small molecules (Grumezescu, 2018; Namdari et al., 2017; Venkatesan et al., 2005; Nurunnabi et al., 2014).

Some GBM-containing composites with good biocompatibility have also been described, such as $CaCO_3$/tetraethylenepentamine-rGO, which shows pH-sensitive delivery of doxorubicin (Li et al., 2016) and G-oleate-poly(amidoamine) dendrimer hybrids used as gene delivery vectors with gene transfection capacity (Liu et al., 2014). Moreover, drug delivery systems based on GO/polyethylenimine allow an effective loading of DNA and RNA, preventing their degradation, which is promising for nonviral gene delivery and stem cell differentiation (Choi et al., 2016).

Phototherapy and Imaging

Phototherapy is a minimally invasive treatment that can be used for several complications, from skin diseases to cancer. Photosensitizers (PS) or photothermal agents are often used to improve its effectiveness. Carbon materials have been generally reported to have strong light absorption while maintaining their stability, therefore being a promising new class of agents for phototherapy. Moreover, they can also be used as platforms for imaging and/or diagnostics. Table 1.3.5.2 summarizes the main properties of the carbon biomaterials that are currently under investigation for use in phototherapy and imaging.

While ND with ideal crystalline structure are not fluorescent or optically absorptive in near-infrared (NIR) radiation, they can be implanted with color centers, mainly nitrogen-vacancies, or covalently conjugated with specific molecules, such as octadecylamine, to provide them with photoproperties. Fluorescent ND are highly photostable and do not photobleach or blink on relatively long time scales. For those reasons, they have been used as contrast agents to visualize internalization pathways and cellular uptake of several molecules. ND exhibit a sharp Raman peak ($\approx 1330\,cm^{-1}$), which facilitates distinction from tissue signals, allowing mapping up to small space resolutions ($\approx 100\,nm$). ND have also been used for bioimaging with several other techniques, such as tip-enhanced Raman spectroscopy, electron spin resonance, photoacoustic imaging, or magnetic resonance imaging (MRI). Examples of ND *in vivo* applications can be found in Fig. 1.3.5.10 (van der Laan et al., 2018; Passeri et al., 2015; Kaur and Badea, 2013; Zhang et al., 2016).

Functionalized fullerenes have been widely studied as PS for the photodynamic therapy (PDT) of tumors. Fullerenes present weak absorbance at wavelengths above the ultraviolet (UV) region, which limits radiation penetration depth in tissues. However, functionalization with donor chromophore antennae are performed to improve absorbance, resulting in compounds that produce a substantial amount of reactive oxygen species (ROS) in aqueous biomedical solutions, especially superoxide anion, which leads to cell apoptosis. Photothermal therapy (PTT) of tumors has also been successfully performed in mice using fullerenes irradiated in the NIR region (Chen et al., 2012; Krishna et al., 2010; Torres and Srdjenovic, 2011; Huang et al., 2014). A poly(ethylene glycol)-conjugated fullerene containing Gd^{3+} ions was shown to be effective for both PDT and MRI in tumor-bearing mice (Liu et al., 2007). Also, other works have reported metallofullerenes being used as contrast agents or in the development of novel platforms for theranostics (Zhang et al., 2016; Castro et al., 2017; Rasovic, 2017).

TABLE 1.3.5.2 Absorption Wavelengths for Phototherapy and Current Imaging Techniques of the Most Commonly Used Pristine Carbon Biomaterials for Theranostics

Carbon Colloids	 ND	 Fullerene	 CNT	 GBM	 CD

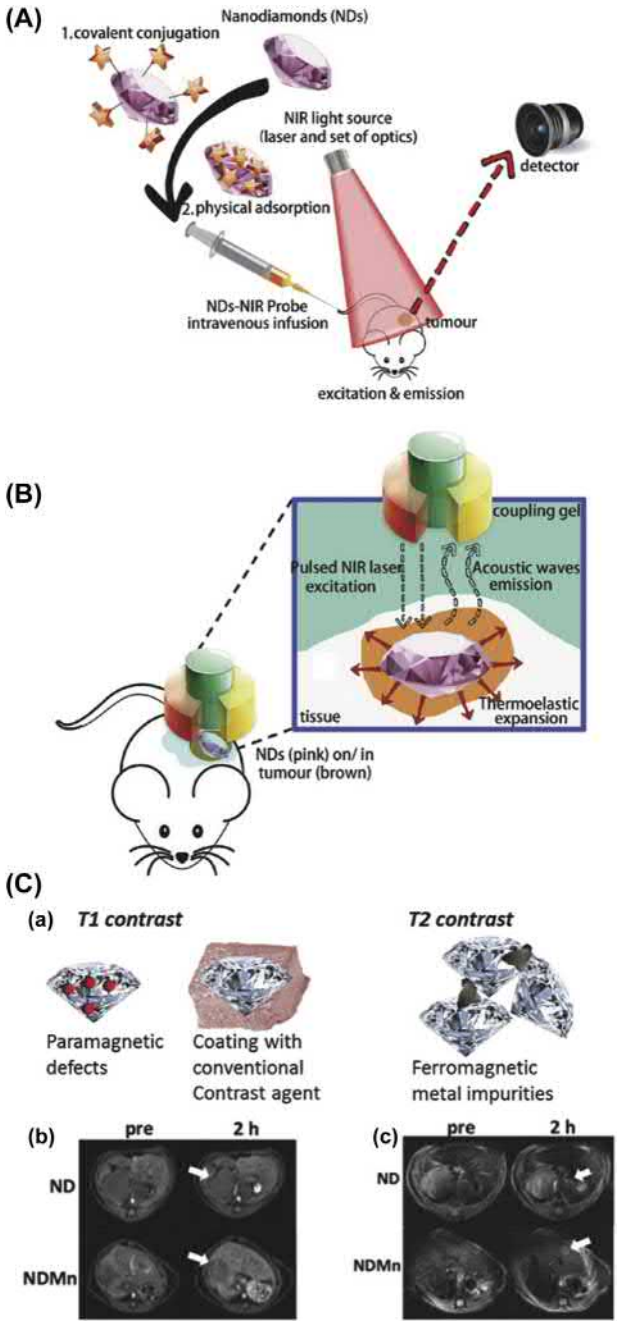
CD, Carbon dots; *CNT*, Carbon nanotubes; *ESR*, Electron spin resonance; *GBM*, Graphene-based materials; *MRI*, Magnetic resonance imaging; *ND*, Nanodiamonds; *NIR*, Near-infrared radiation; *Tip-Raman*, tip-enhanced Raman spectroscopy; *UV*, Ultraviolet radiation.



• **Figure 1.3.5.10** The mechanics of nanodiamond (ND)-based near-infrared (NIR) fluorescence imaging. (A) NIR emitting dyes (indicated by an orange star) are linked to the diamond covalently (1) or adsorbed nonspecifically (2). The conjugate is intravenously injected into mice. Excitation is performed with a laser or LED in the NIR range and is read out optically. The mechanics of ND-based photoacoustic imaging (B). ND absorb energy of nonionizing laser pulses and convert it into heat, resulting in thermoelastic expansion and ultrasonic waves. Meanwhile, the ultrasound signal is monitored via ultrasonic transducers. Blue color indicates medical ultrasound gel, which distributes between the skin and the detector for ultrasonic signal conduction (van der Laan et al., 2018). (C) ND for conventional MRI imaging: (a) different ways how ND can create a contrast in MRI. T1 signal contrast can be achieved by using the paramagnetic defects in the diamond itself or by coating with conventional contrast agents. T2 signal contrast has been achieved via metallic impurities in the diamond material. (b) A T1 signal-weighted image, which was taken from mice liver; *arrow* indicates a tumor. The images were taken using ND or ND conjugated with a manganese contrast agent (NDMn). (c) The same in T2 contrast mode. Adapted from (Hou et al., 2017).

CNT present strong absorption and fluorescence in the NIR region, and strong Raman signals. This makes them ideal platforms for cancer phototherapy (through ablation or increasing tumor permeability) and bioimaging, more specifically by lowering autofluorescence during imaging, as Raman probes for specific detection and multiplexed imaging, and for photoacoustic imaging with high sensitivity and resolution (Fig. 1.3.5.9). Also, CNT have been proven to be effective for other techniques, such as MRI and radioimaging (Liu et al., 2011b; Saito et al., 2014; Sharma et al., 2016; Grumezescu, 2018; Alshehri et al., 2016; Sajid et al., 2016).

GBM have been shown to improve the stability, bioavailability, tumor accumulation, and photodynamic efficiency of PS. They have also been reported to behave as electron sinks for UV-based PDT. GBM also absorb in the NIR region, allowing a combination of both PDT and/or PTT. A study using tumor-bearing mice has demonstrated that the intravenous injection of reduced nanographene oxide-polyethylene glycol (average diameter of 27 nm) together with NIR irradiation induced complete tumor ablation. The laser (808 nm) power density (0.15 W/cm^2) was lower than usually applied when using other nanomaterials, with irradiation time being 5 min (Yang et al., 2010). Moreover, combined platforms with other carbon biomaterials can be developed to obtain synergistical phototherapeutic effects (Li et al., 2015a; Yang et al., 2010; Hu et al., 2015).

GBM have lower quantum yields than other carbon materials, which limits their use for *in vivo* imaging. For that reason, they have been conjugated with fluorescent dyes and PS. However, because of the strong π–π stacking interaction between dye/sensitizer porphyrin rings with the GBM plane, fluorescence quenching was observed. Thus other luminescent inorganic materials (e.g., QD, metal clusters, upconversion nanoparticles) have been used to achieve efficient fluorescent imaging and even MRI (Grumezescu, 2018; Chen and Wang, 2016).

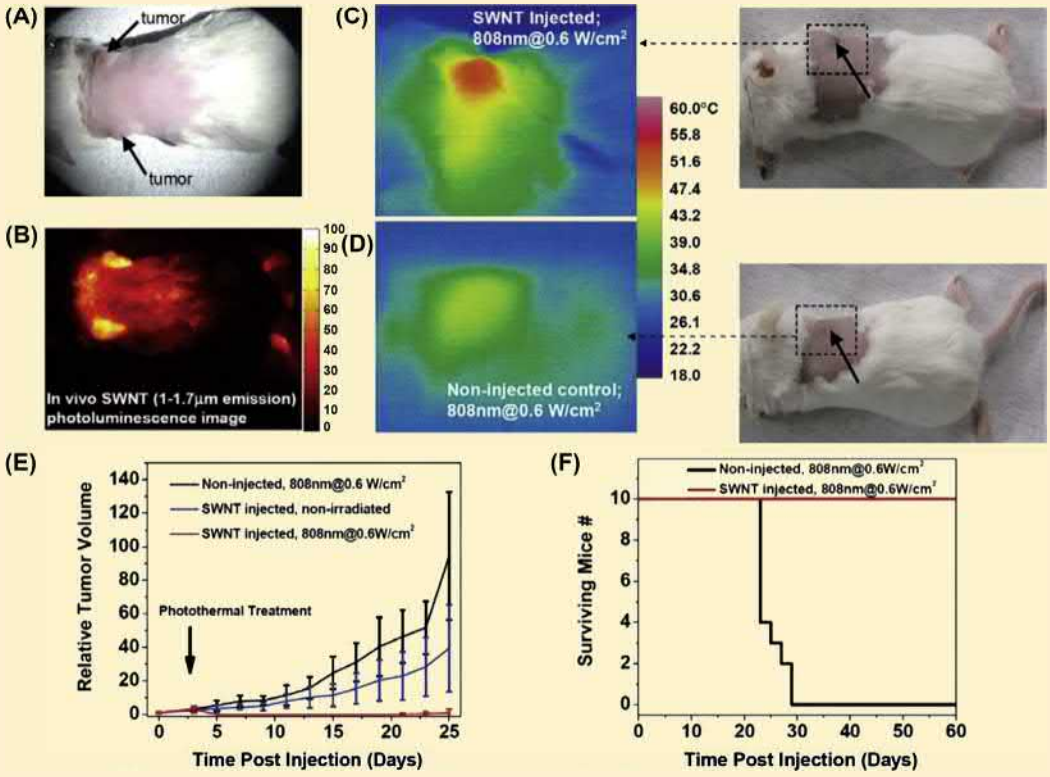
CD present nonblinking photoluminescence and excellent photostability, in contrast to organic fluorophores. The nonblinking PL ability enables single-molecule tracking, while the photostability allows long-term real-time imaging. PL can be tuned by size, edge configuration, shape, attached chemical functionalities, heteroatom doping, and defects. Usually, CD present strong fluorescence in the visible region upon excitation with UV light; however, particles with excitation and emission in visible to NIR regions can be obtained (Chen and Wang, 2016; Namdari et al., 2017; Nurunnabi et al., 2014). As an example, GQD (average diameter ≈ 5 nm) were able to destroy both cancer cells *in vitro* and tumor cells in mice, while allowing real-time imaging. GQD acted as a PS generating singlet oxygen, and also led to temperature increase resulting in tumor ablation (Fig. 1.3.5.11) (Nurunnabi et al., 2014).

Biosensors

Disease diagnostics play an important role in the clinical treatment and outcomes of several diseases. During disease,

SIDEBAR #3

Short single-walled carbon nanotubes functionalized with PEGylated phospholipids (SWNT) are biologically nontoxic nanomaterials with intrinsic near infrared (NIR) photoluminescence and strong optical absorbance in the NIR. It has been shown that after intravenous injection in tumor bearing mice (A), SWNT migrate to the tumor and serve as photoluminescent agents for *in vivo* tumor imaging in the 1.0-1.4 μm emission region (B) and as NIR absorbers and heaters at 808 nm for photothermal tumor elimination, reaching temperatures around 52 °C (C, D), decreasing the tumor volume (E) and increasing mice survival (F) (Robinson et al., 2010). The performance of these materials was also compared to gold nanorods (AuNR), being verified that higher tumor elimination was achieved with SWNT at 10x lower injected doses and lower irradiation powers than for AuNR. These results highlight the potential of the intrinsic properties of SWNT for combined cancer imaging and therapy.



the profile of some biomolecules is altered in body fluids allowing their use as biomarkers of such illnesses. These molecules could be identified using an analytical tool such as a biosensor. Conventionally, a biosensor consists of three parts: a receptor that detects the molecule, a signaling transducer that converts the physical/chemical signal, and a signal processor. Biosensors can be electrochemical (physical/chemical signal is transduced to an electrical signal), piezoelectric (mass bound to the piezoelectric crystal surface sensor promotes a change in oscillation), optical (recognition of a target changes light emission), and electrochemiluminescent (electrochemical reactions produce a luminescence signal). Carbon nanomaterials have shown excellent performance in biosensor development due to their unique mechanical, electronic, and optical properties, high specific surface area, and biocompatibility, as reviewed by Pasinszki et al. (2017), Liu et al. (2017), and Teradal and Jelinek (2017). Among all carbon materials, CNT, GBM, and CD are the most applied materials in the development of biosensors, despite fullerenes also being used. These materials can be used for the recognition of target molecules, for target molecule labeling, and in the transducer component, by either adsorbing molecules at their surface or being functionalized, despite the latter potentially compromising their conductivity properties.

Fullerene-C60 has been used to improve the sensitivity of electrochemical biosensors, due to its high conductivity. It provides a suitable immobilization platform for DNA and antibodies and has the ability to induce the proper orientation of redox-active proteins, which results in better electron transfer properties (Pilehvar and Wael 2015).

CNT-based biosensors have been assembled for the detection of several molecules such as dopamine, uric acid, glucose, prostate-specific antigen (PSA), osteopontin, miRNA, DNA, K-ras, carcinoma antigen-125, alpha-fetoprotein, and amyloid-β (Pasinszki et al., 2017). In most of these cases, biosensors have a low limit of detection and high linear range, showing suitable sensor performance (Pasinszki et al., 2017). A piezoelectric biosensor that recognizes carbohydrate antigen 19–9, which is a marker for colorectal,

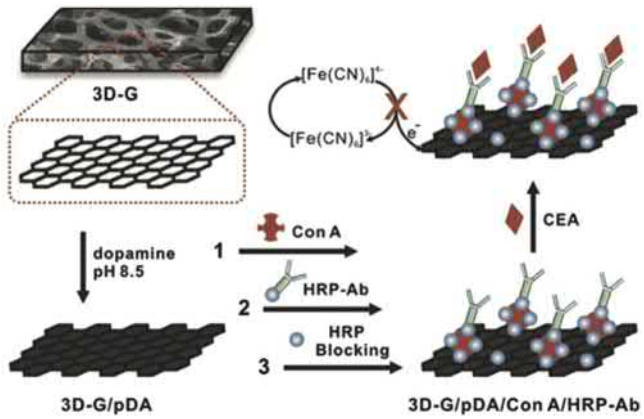
pancreatic, and hepatic cancer, was developed using a quartz crystal microbalance probe modified with poly-L-lysine/hydroxyapatite/CNT nanocomposite functionalized with antibody. This biosensor exhibits a high marker-binding activity (Ding et al., 2008). In a uric acid electrochemical biosensor, SWCNT are used as a matrix for enzyme immobilization (uricase) and as a mediator (Chen et al., 2010). Signal transduction is based on electrocatalytic reduction of H_2O_2 produced upon uricase activity. This biosensor has a low detection limit, high sensitivity, a wide linear range, and good stability (Chen et al., 2010).

Similarly to CNT, GBM have been incorporated in several biosensors for the detection of glucose, dopamine, uric acid, PSA, and carcinoembryonic antibody (CEA). A 3D-G foam was modified with concanavalin using polydopamine as adhesive, and the antibody (anti-CEA) labeled with horseradish peroxidase added to concanavalin (Fig. 1.3.5.12) (Liu et al., 2015). This biosensor shows a low detection limit, a linear range, and decreased incubation time (Liu et al., 2015).



• **Figure 1.3.5.12** Schematic illustration of the fabrication and carcinoembryonic antibody (CEA) detection process of the immunosensor (Liu et al., 2015). Concanavalin A (Con A) was immobilized in 3D graphene foam using polydopamine (pDA) as adhesive. Anti-CEA contains a sugar protein conjugated (HRP) that links to Con A allowing its immobilization. Upon recognition of CEA by anti-CEA, there is a change in solution-phase redox probes ($[Fe(CN)_6]^{4-/3-}$), which is measured by differential pulse voltammetry.

A glassy carbon electrode coated with gold nanoparticles hybridized with hydrazine-modified GQD showed strong electrochemiluminescence activity in the presence of H_2O_2 after CEA binding to the surface. This biosensor could be used for the rapid, sensitive detection of CEA (Dong et al., 2015).

Antimicrobial Therapy

The antimicrobial properties of carbon materials have been mostly explored using ND, fullerenes, CNT, GBM, and CD as colloids (Table 1.3.5.3). However, much interest has arisen regarding their incorporation in surfaces, with research using CNT and GBM films, DLC coatings, and CNT-, GBM-, and CD-containing composites also being described.

ND antibacterial effect depends on size, surface chemistry, and composition of biological medium. ND with a size of 5 nm have more effective antibacterial activity against *Escherichia coli*, while ND with sizes between 18 and 50 nm are more effective against *Bacillus subtilis*. Both ND types were found interacting with bacterial surfaces, which might have affected bacterial cell wall and/or membrane permeability (Beranova et al., 2014). It has also been observed that fully carboxylated ND do not show antibacterial activity, while partially oxidized ND show similar potency to silver nanoparticles toward both Gram-positive (*B. subtilis*) and Gram-negative (*E. coli*) bacteria at concentrations of 50 mg/L. This might be explained based on reactive oxygen-containing surface groups fostering interactions with cellular components, while the anisotropic distribution of charges on ND surfaces facilitates alterations in bacterial surfaces. However, the bactericidal potential is gradually inhibited as protein concentration in culture media increases (Wehling et al., 2014). Several antiadhesive nanoparticles displaying activity against *Staphylococcus aureus* and *E. coli* biofilms have been developed using glycan-modified ND, revealing themselves to be of great promise for combating microbial infections

TABLE 1.3.5.3 Mechanisms of Action and Photoactivation Wavelengths of Antibacterial Carbon Colloids

Carbon Colloids	ND	Fullerene	CNT	GBM	CD
Membrane action	Destabilization	Oxidation (functionalized forms)	Piercing Oxidation Destabilization Wrapping	Piercing Oxidation Destabilization Wrapping	Destabilization
Oxidative stress	–	Yes (hydrophobic forms)	Yes (reduced impact)	Yes	Yes
Photo activation	–	UV (ROS production)	NIR (thermal effect)	UV NIR	Visible light (ROS production)

CD, Carbon dots; *CNT*, Carbon nanotubes; *GBM*, Graphene-based materials; *ND*, Nanodiamonds; *NIR*, Near-infrared radiation; *ROS*, Reactive oxygen species; *UV*, Ultraviolet radiation.

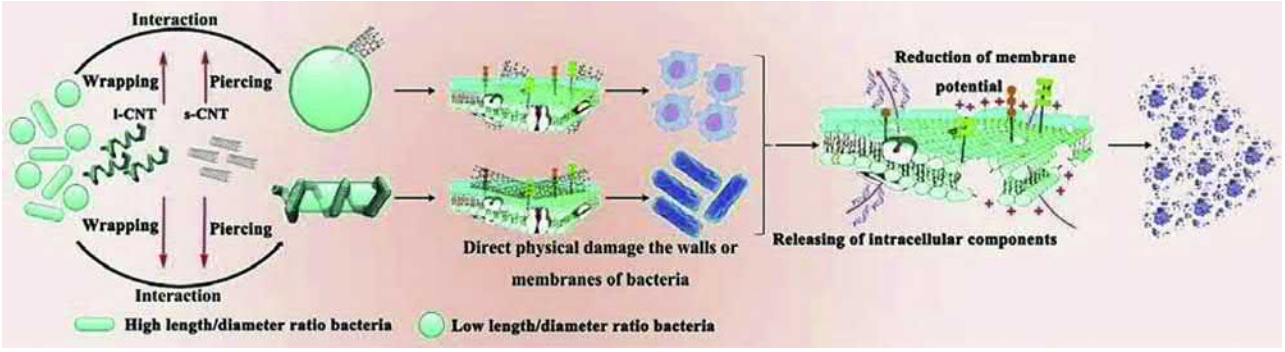
(Szunerits et al., 2016). Also, menthol-modified ND were shown to decrease surface adhesion of these two bacteria (Maas, 2016).

Hydrophobic fullerenes do not cause membrane damage to bacteria, instead they adsorb onto it and cause ROS-independent oxidative stress. In contrast, functionalized fullerenes were reported to insert and damage bacterial cell walls, much like GBM or CNT as described later. Fullerene derivatives have been reported to be effective against different bacterial types (e.g., *S. aureus*, *B. subtilis*, *E. coli*), and even fungus (*Candida albicans*). Upon photoirradiation, functionalized fullerenes are able to produce superoxide anion, which is generally more toxic toward bacterial than mammalian cells. (Al-Jumaili et al., 2017; Dizaj et al., 2015; Maas, 2016). Functionalized fullerene-mediated UV phototherapy was shown to be effective to treat skin wounds in mice infected with different Gram-positive and Gram-negative bacteria. This perspective is applied in infection treatment where antibiotics are ineffective, such as in many infected burn wounds (Huang et al., 2014). Fullerenes have been extensively studied for HIV treatment, because they specifically bind to the HIV-1 protease active site, inhibiting virus replication (Chen and Wang, 2016; Castro et al., 2017). Fullerenes also present activity against several other viruses, such as influenza and hepatitis (Bakry et al., 2007; Torres and Srdjenovic, 2011).

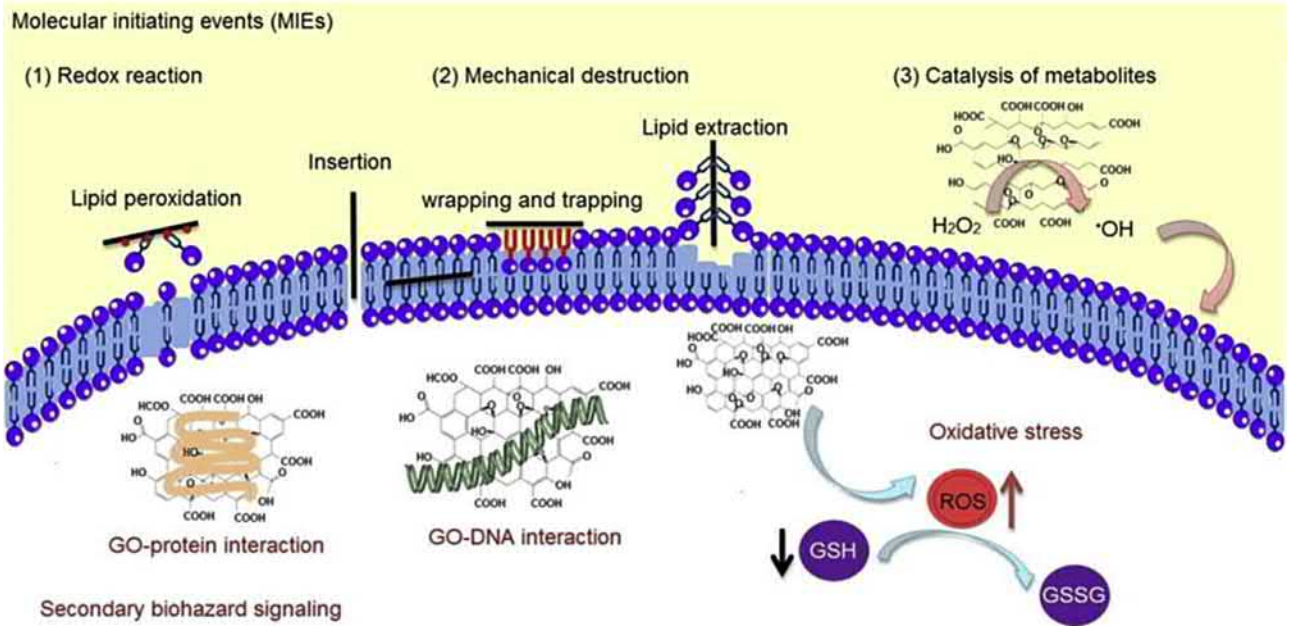
CNT have been found to selectively lyse the walls and membranes of pathogenic and nonpathogenic, Gram-positive and Gram-negative, spherical and rod-shaped bacterial strains, depending not only on the length and surface functional groups of CNT, but also on the bacteria features. Thin and rigid SWCNT show more effective wall/membrane piercing on spherical bacteria than MWCNT. Long MWCNT may wrap around bacteria, increasing the area contacting the bacterial wall (Fig. 1.3.5.13). Generally, short MWCNT and functionalized MWCNT are more toxic to bacteria than long MWCNT (Chen et al., 2013b). Membrane disruption can be caused by powerful electrostatic forces between the microbial outer surface and CNT, leading to membrane oxidation. Oxidative stress contributes to the CNT antibacterial effect; however, it has been described as less relevant than direct membrane damage. Since impurities remaining from CNT production (metallic nanoparticles, catalysts) can present an antibacterial effect, suitable cleaning of the materials is essential prior to biological testing (Al-Jumaili et al., 2017; Maas, 2016). Photothermal ablation of *E. coli* has been demonstrated using SWCNT and MWCNT upon NIR irradiation. Additionally, anti-*Streptococcus* group A antibody-functionalized MWCNT were employed to demonstrate effective targeted photothermal ablation (NIR) of planktonic bacteria and bacteria living within a biofilm using an *ex vivo* full-thickness porcine skin model (Mocan et al., 2017).

The antibacterial activity of GBM is described to be higher for GO than for rGO (Liu et al., 2011a; Gurunathan et al., 2012). Differences are explained by the different states of dispersion and amounts of oxygen-containing functional groups, which impact on both membrane and oxidative stress. Large GO nanosheets, which can cover bacteria preventing proliferation, have been pointed out as having a stronger antibacterial effect. By contrast, some results indicate that small GO sheets have higher oxidative and antibacterial capacity (Shi et al., 2016; Zheng et al., 2018). There are three different molecular initiating events caused by GBM that lead to the antibacterial effect: redox reaction with biomolecules, mechanical destruction of membranes, and catalysis of extracellular metabolites (Fig. 1.3.5.14). UV radiation has been described as possibly activating GO basal and edge radicals, leading to a superior antibacterial effect than that of nonirradiated GO, and even the standard antibiotic kanamycin (Veerapandian et al., 2013). Potential for *in vivo* antibacterial and antifungal PTT leading to wound healing has already been demonstrated, as GO absorbs NIR radiation increasing local temperature, which acts synergistically with its intrinsic antimicrobial mechanisms (Khan et al., 2015).

CD show a strong broad-spectrum antibacterial and antifungal activity. Due to their small size, they can enter microorganisms by diffusion, destroy the cell wall, bind



• **Figure 1.3.5.13** Carbon nanotubes (CNT) antibacterial mechanisms of action. Short CNT (s-CNT) are more prone to pierce spherical bacteria walls/membranes than long CNT (l-CNT), which wrap around and interact with the cell surface. Induced release of intracellular components (DNA, RNA) and loss of membrane potential lead to bacterial cell integrity loss (Chen et al., 2013b).



• **Figure 1.3.5.14** Graphene-based material (GBM) antibacterial mechanisms of action. Three different molecular initiating events (MIEs) have been described for GBM: (1) redox reaction with biomolecules; (2) mechanical destruction of membranes; and (3) catalysis of extracellular metabolites. The downstream signaling pathways may include reactive oxygen species (ROS) generation and glutathione (GSH) depletion, protein and DNA damage. *GO*, Graphene oxide; *GSSG*, Glutathione disulfide (Zheng et al., 2018).

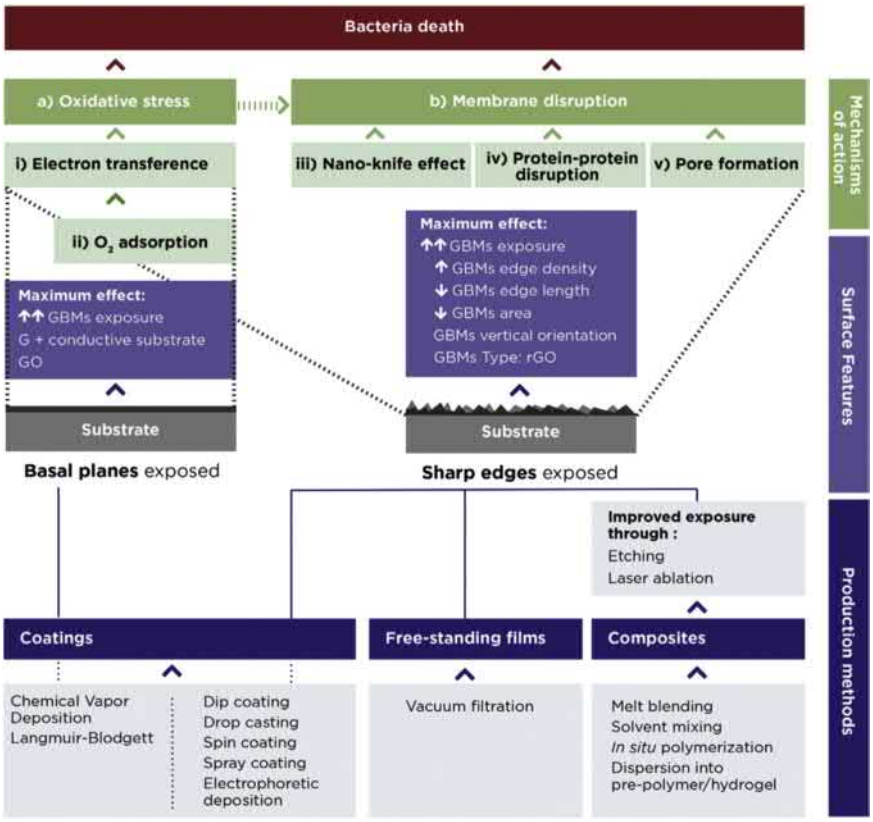
to DNA and RNA, inhibit gene expression, and lead to apoptosis even at low concentrations. Moreover, they are easily biodegradable and eliminated from the body (Li et al., 2018; Jhonsi et al., 2018; Bing et al., 2016). CD bactericidal activity depends on their surface chemistry. Nitrogen-doped CD have higher antibacterial effect than sulfur-doped ones. This is explained by electrostatic interactions between CD-protonated forms and bacterial cell membrane lipids (Travlou et al., 2018). CD can be photoactivated under visible light for antibacterial effect enhancement through ROS production (Al Awak et al., 2017; Bing et al., 2016; Meziani et al., 2016; Ristic et al., 2014). They are also fluorescent allowing real-time bacterial imaging and selective staining (Gram-positive over Gram-negative) (Yang et al., 2016). GQD-based band-aids for wound disinfection have been successfully tested in mice (Sun et al., 2014).

The carbon biomaterials previously mentioned in the form of micro/nanoparticles also have potential to be used as antibacterial films, coatings, or composites, retaining most of their properties when incorporated in a biomaterial. New factors must be taken into account, for example the exposure angle of sharp particles should be maximized to obtain effective mechanical damage at the bacterial membrane, and stability of the coatings assured.

The antimicrobial activity of GBM free-standing 2D films has been assessed in a review (Henriques et al., 2018). Despite the controversy, since some authors defend that GBM free-standing 2D films could indeed support bacterial growth (Park et al., 2010; Ruiz et al., 2011; Aryal et al., 2017), the particles' lateral size and oxidation degree seem to have a crucial impact on antimicrobial activity (Fig. 1.3.5.15). Films containing smaller GO particles have a stronger antimicrobial effect than films containing large particles and/or rGO (Henriques et al., 2018; Perreault et al., 2015; Singh et al., 2017), and these smaller GO particles seem to induce higher oxidative stress in bacteria. Besides surface chemistry, the roughness of GBM free-standing 2D films also influences their antimicrobial properties. When using G, rough surfaces that expose the sharp edges promote bacteria killing while smooth surfaces promote bacterial adhesion (Henriques et al., 2018; Pham et al., 2015). Possible piercing of the bacterial cell wall and membrane by exposure of sharp edges has been pointed out as the main mechanism for this phenomenon, although some authors defend a low probability of it occurring (Pham et al., 2015; Romero-Vargas Castrillón, 2015).

The application of UNCD, DLC, CNT, and GBM coatings in the development of antimicrobial surfaces has also been suggested.

UNCD and DLC coatings have been used to improve the surface properties of biomedical implants (Al-Jumaili et al., 2017). DLC films are highly hydrophobic, which leads to variations in bacterial cell membrane, and prevents bacterial adhesion. However, differences in antibacterial



• **Figure 1.3.5.15** Relation between graphene-based materials (GBM)-containing surface production methods, surface features, and antibacterial mechanisms of action. *G,* Graphene; *GO*, graphene oxide; *rGO*, reduced graphene oxide (Henriques et al, 2018).

effects have been found according to fabrication conditions, which lack reproducibility. A widely observed factor is that decreasing the sp^3/sp^2 ratio has a positive effect on surface antibacterial properties.

Paper coated with functionalized SWCNT that contain amine, phosphate, and carboxylic groups at their surface exhibits an antimicrobial action against *S. aureus* and *E. coli*. This effect is higher in Gram-positive *S. aureus*, being correlated with CNT direct contact that promotes the piercing of bacterial membrane leading to the loss of cell shape integrity (Deokar et al., 2013). CNT films on silicon substrate also inhibit the growth of *S. aureus* (Narayan et al., 2005).

Depending on the coating production technique, it is possible to obtain surfaces with different features that can promote a wide range of effects in bacteria. GBM-containing surfaces produced by CVD and Langmuir–Blodgett techniques have a high exposition of G and GO basal planes at the surface, promoting oxidative stress, which culminates in bacterial death. In the case of G, the presence of conductive substrate seems to be a necessary condition to exhibit an antimicrobial effect (Li et al., 2014; Henriques et al., 2018). Surfaces produced by dip, spray, or spin coating, drop casting, and electrophoretic deposition expose GBM in a random orientation. As such, besides basal planes, they also expose sharp edges, which promote bacterial cell membrane disruption by piercing (nanoknife effect), protein–protein interaction, or pore formation (Fig. 1.3.5.15).

Regarding the incorporation of carbon biomaterials as composites, the antimicrobial effect of composites containing CNT is highly dependent on CNT type, length, and amount in the polymeric matrix. As observed for CNT powders, when incorporated in polymeric matrices, SWCNT with shorter lengths are the most effective in killing bacteria, forming a poly(lactic-*co*-glycolic acid) (PLGA) composite with antimicrobial activity of 98% (Mocan et al., 2017; Aslan et al., 2010). Incorporation of CNT in ZnO (Akhavan et al., 2011), poly(vinyl acetate) (Youssef et al., 2019), Ag–TiO_2 (Hossain et al., 2018), and gelatin-fluoroquinolones (Spizzirri et al., 2015) leads to a general increase of their antimicrobial activity. Electrospun polysulfone-SWCNT mats reveal an antibacterial effect of 76%, even in the presence of very low amounts of SWCNT and after a short contact time of 15 min or less (Schiffman and Elimelech, 2011).

The antimicrobial performance of GBM-containing composites depends not only on the incorporated GBM and its amount but also on the adopted composite production technique. Production techniques that promote GBM

exposure at composite surfaces generate materials with higher antimicrobial properties (Henriques et al., 2018). Due to the poor characterization of incorporated GBM and resulting composites, comparisons between different studies are difficult. However, incorporation of GO to create polymeric composites such as chitosan (CS)/GO (Mazaheri et al., 2014), CS/polyvinylpyrrolidone/GO (Mahmoudi et al., 2016), polylactic acid/polyurethane (PU)/GO (An et al., 2013), PCL/GO fibrous scaffolds (Melo et al. 2020) and agar/GO (Papi et al., 2016) hydrogel promoted an antimicrobial effect between 50% and 100% in different bacteria species.

Upon excitation with visible light, a CD-decorated $Na_2W_4O_{13}$ composite with WO_3 photocatalyst (CD/$Na_2W_4O_{13}$/WO_3) exhibited excellent antimicrobial activity against *E. coli* without promoting cytotoxicity. Similarly to what happens in CD colloids, ROS production during light activation plays a critical role in composites' bactericidal effect (Zhang et al., 2018a). Also, an epoxide-functionalized CD/organomontmorillonite composite exhibits great antimicrobial properties inhibiting biofilm formation (De et al., 2015).

Cardiovascular Applications

According to the World Health Organization, cardiovascular diseases are the number one cause of death globally. Biomaterials have long been used in cardiovascular applications, with carbon-based materials playing an important role mostly as coatings of long-term implants, where devices are already commercially available, despite also being investigated for tissue-engineering approaches.

Long-Term Implants

Mechanical Heart Valves

Mechanical heart valves (MHV) are composed of man-made materials (e.g., stainless steel, ceramic, carbon materials) and have been developed into different shapes (e.g., caged ball, monoleaflet, bileaflet).

CASE STUDY: MECHANICAL HEART VALVES

In the past, MHV design and materials were optimized to reduce wear and thromboembolism, which were much more severe, until a drastic improvement was found when carbon materials were tested (Musumeci et al., 2018; Nachlas et al., 2017). The Gott–Daggett bileaflet valve was first produced in 1963 with a Gt-benzalkonium-heparin coating, upon Dr. Vincent Gott's findings of its high potential to reduce blood clotting on rings implanted in canine vena cava. Later, in 1965, Dr. Jack Bokros proposed a collaboration to try to bind heparin to a highly polished PyC, which he had developed at General Atomic, and which proved not to be suitable to bind heparin, but to have outstanding thromboresistance performance on canine *in vivo* assays. Following these finds, Bokros developed the ball puppet for the DeBakey-Surgitool valve, also discs and leaflets for most of the MHV produced thereafter. Since then, PyC has been used in more than 25 different MHV designs, and nowadays 95% of all MHV have at least one structural component made of this carbon biomaterial. The balance between blood compatibility, physical and mechanical properties, and durability made PyC the best material option available in MHV. This allowed MHV anticoagulation therapy dose reduction, despite it not being suppressed. It is still uncertain if hemocompatibility issues arise from the biointeractions with the PyC itself or from hemodynamic interaction of the devices in which it is integrated. However, it has been observed that PyC first adsorbs and denatures albumin over other proteins, forming a surface passivant layer. Also, adsorbed fibrinogen is rapidly conversed to a nonelutable form, which is less reactive to platelets (Robert et al., 2013; Gott et al., 2003).

Nowadays, MHV are composed of two hemidiscs in a housing, both made of pyrolytic carbon, being commercialized by several companies (Fig. 1.3.5.16). A 17-year follow-up study in 500 patients implanted with Sorin mechanical valves revealed that only five reoperations were necessary, and that there was a total of 15 valve-related deaths (Kheradvar et al., 2015). A study comparing contemporary bileaflet valves revealed that On-X MHV presented the lowest incidence of thrombosis, stenosis, and hemolysis in the aortic position (Chaudhary et al., 2017). However, strategies to further decrease thrombogenicity are still being pursued, in the search for an MHV that does not require lifelong anticoagulation therapy.

In 2018 the Food and Drug Administration (FDA) approved the world's smallest MHV, which was produced with PyC, and commercialized by Abbott. This new valve can be used to treat babies and toddlers in need of a mitral or aortic valve replacement, who until now could not be submitted for treatment due to the small size of their hearts. More than 50 years after started being used in MHV, PyC is still integrated on those devices, even for the most demanding procedures.

• **Figure 1.3.5.16** Images of mechanical heart valves from the major manufacturers (Kheradvar et al., 2015).

As described in this chapter's case study, MHV made of PyC present a satisfactory performance. Despite being commercialized, further improvement is desired and therefore research on this topic is still ongoing. The potential use of UNCD (Zeng et al., 2016) and DLC (Tran et al., 1999) coatings on MHVs have been proposed. These types of coatings have desirable chemical inertness, mechanical durability, and biocompatibility (Dearnaley and Arps, 2005; Roy and Lee, 2007; Ma et al., 2009).

Materials used in the production of heart valves, such as poly(tetrafluoroethylene), polyvinyl chloride, segmented PU, silicon rubber, and poly(ether urethane urea), have a low cycle fatigue strength, which impacts their durability. As previously mentioned, incorporation of carbon materials in polymeric matrices improves their mechanical performance significantly (Vellayappan et al., 2015). Thus, some carbon biomaterial-containing composites have been developed for application as cardiac prostheses.

The incorporation of low amounts of CNT in PU induces higher mechanical performance, but high amounts of CNT decrease material fatigue strength (Vellayappan et al., 2015; Rozeik et al., 2017). Besides the mechanical improvement, incorporation of MWCNTs with oxygen-containing functional groups in a PU matrix promotes anticoagulant activity at the polymer surface.

Incorporation of 2-(methacryloyloxy) ethyl phosphorylcholine functionalized GO in PU improves its hemocompatibility, even when a small amount of GBM is used Vellayappan et al., 2015; Rozeik et al., 2017 Incorporation of 2-(methacryloyloxy) ethyl phosphorylcholine functionalized GO in PU improves its hemocompatibility, even when a small amount of GBM is used (Vellayappan et al., 2015).

Vascular Stents

Stent development has focused on the mitigation of in-stent thrombosis, flexibility, and ease of implantation. Carbon material coatings can be used to encapsulate metallic stents, preventing toxic ion release and providing a low friction, bioinert surface for biointeraction. This leads to better cell adhesion and proliferation, suppression of immune response, increased albumin adsorption, and low platelet activation, decreasing thrombogenicity and preventing restenosis.

Vascular stents coated with DLC or PyC are currently available on the market (Table 1.3.5.1).

Carbostent (Sorin, Italy) has a coating of a turbostratic structure equivalent to that of PyC, produced by physical vapor deposition, which has been used both in stents and MHV.

a-C:H DLC coatings are used in Diamond Flex (Phytis, Germany), BioDiamond (Plasma Chem, Germany) (Fig. 1.3.5.17), and DLN or Dylyn (Bekaert, Belgium). ta-C coatings have been reported to adhere less to platelets than PyC, and to be less inflammatory toward macrophages than uncoated stainless steel. Thus this might be a coating material for future consideration for biocompatibility improvement of medical devices (Dearnaley and Arps, 2005; Roy and Lee, 2007; Ma et al., 2009).

A study on nitinol coated with CVD-transferred G has revealed no significant *in vitro* toxicity to endothelial and smooth muscle cell lines. Coatings were chemically inert, durable, and impermeable, revealing low fibrinogen/albumin ratio, which might result in good hemocompatibility (Podila et al., 2013). This promotes G as a new candidate coating material for stents, with patents already registered for this use.

Ventricular Assist Devices

Ventricular assist device (VAD) is an alternative to patients with severe heart failure with secondary pulmonary hypertension, for whom transplant may be contraindicated. Its rotary blood pumps are commonly made of titanium alloy (Ti 6Al4V), but strategies to reduce its thrombogenicity are needed.

A DLC coating was tested in a centrifugal VAD (Sun-Medical Technology, Japan), maintaining a stable performance without any adverse effect over 6 months in calves under postoperative anticoagulation protocol. Blood-contacting surfaces of the DLC coating were entirely free from thrombus formation and there were no major organ infarcts except a few small-sized ones at the kidneys. The wear rate of the seal face was 10 µm after 200 days of continuous operation and there was no measurable wear at the hydrodynamic journal bearing (Yamazaki et al., 1998). An FDA-approved DLC-coated centrifugal VAD, VentrAssist (Ventracor, Australia), is already on the market.

Tissue-Engineering Approaches

Cardiovascular diseases comprise problems in blood vessels and/or the heart, and usually culminate in the occurrence of heart attacks and strokes. In the heart, myocardial infarction leads to large-scale loss of cardiomyocytes that exceeds the limited regenerative capacity of the myocardium leading to a collagen-based scar and loss of function (Prabhu and Frangogiannis, 2016). Tissue engineering is one promising strategy to allow cardiac repair but has revealed to be challenging, since cardiac scaffolds must merge exactly the mechanical and electrical features of the natural tissue. Most of the biocompatible polymers such as alginate, collagen, polycaprolactone (PCL), CS, gelatin methacrylate

(GelMA), polyglycerol sebacate, and PLGA have weak mechanical properties and are insulators, which impair the electrical signal propagation compromising the contractile behavior of cardiac cells (Pok et al., 2014). The mechanical properties and electricconductive capacity of some carbon materials such as CNT and GBM prompted their investigation as materials for cardiac regeneration, mostly as free-standing materials or as composites.

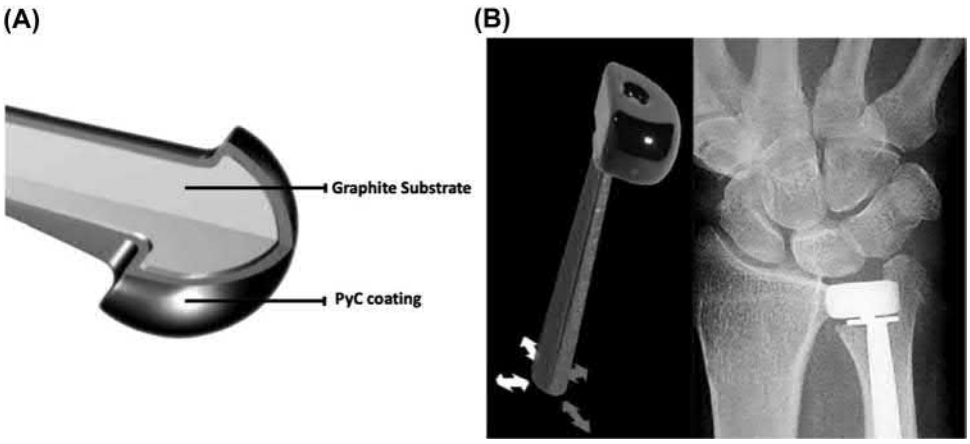
The potential application of CNT in cardiac tissue engineering has been validated by several studies as reviewed by Gorian *et al.* (Gorain et al., 2018). CNT films stimulate the expression of genes involved in growth and in the differentiation process of neonatal cardiomyocytes (Martinelli et al., 2013). Additionally, these cardiomyocytes have an upregulation of the genes involved in the formation of intercalated discs (Fig. 1.3.5.18), which establish a network between cardiomyocytes, enabling the rapid transmission of electrical impulses and coordinated contraction of the myocardium (Sun et al., 2015). Superaligned CNT sheets present improved conductivity along the alignment and promote growth of cardiomyocytes with regular and synchronized contractions, exhibiting an elongated morphology with alignment similar to the natural myocardium (Ren et al., 2017). The incorporation of CNT as composites improves electrical conductivity and/or mechanical performance of the base polymers (Gorain et al., 2018; Vellayappan et al., 2015), promoting the adhesion of cardiomyocytes and supporting their function, growth, and maturation (Gorain et al., 2018) without inducing toxicity and/or apoptosis (Kroustalli et al., 2013). Early differentiation of human mesenchymal stem cells into cardiomyocytes has also been described using CNT-containing 3D poly(ε-caprolactone) scaffolds, due to the high similarity to the native tissue regarding conductivity and mechanical strength (Crowder et al., 2013a). Likewise, increased cardiac differentiation of embryoid bodies was reported for gelatin methacryloyl hydrogels containing aligned CNT (Ahadian et al., 2016).

GBM have also been applied in the design of scaffolds for cardiac regeneration. Overall, all GBM exhibit the capacity to improve cardiomyocyte adhesion and proliferation. The chemical features and conductive capacity of GBM play a critical role in the beating capacity of cardiomyocytes. G films produced by CVD showed stable cardiac cell attachment and excellent biocompatibility (Kim et al., 2013b). Despite the conductive capacity of GO being lower than G, GO incorporation in polymeric matrices such as CS (Jing et al., 2017), tropoelastin (Annabi et al., 2016), and collagen (Norahan et al., 2019) still promotes cell adhesion, proliferation, electrical signal propagation, and expression of specific cardiac markers. rGO reestablishes its conductivity, and its incorporation in GelMA hydrogel induces a faster spontaneous beating rate and stronger contractibility of cardiomyocytes compared to GO-GelMA (Shin et al., 2016). Multilayer cardiac constructs have been attempted using layer-by-layer assembly of poly-l-lysine-functionalized GO and cardiac and endothelial cells, revealing that these engineering 3D tissue structures present improved cell organization, electrophysiological function, and mechanical integrity (Shin et al., 2014). GO incorporation in thermoplastic PU, besides improving the mechanical properties of electrospun fibers, increases human umbilical vein endothelial cell adhesion and proliferation, revealing to be promising for the development of tissue-engineered vascular grafts (Jing et al., 2015).

Orthopedic Applications

Aging of the world population leads to an increase in musculoskeletal and cartilage-associated diseases. The traditional materials conventionally used in orthopedic applications, namely polymers, ceramics, and metals, commonly induce wear, debris, inflammation, mechanical loosening, implant fracture, and bone resorption caused by foreign body reaction.

The mechanical properties of available polymers are not suitable for load-bearing orthopedic applications. Thus they need a mechanical reinforcement to be applied in such a field. The remarkable mechanical properties, biocompatibility, and large surface-specific area of most carbon materials make



• **Figure 1.3.5.19** Pyrolytic carbon (PyC) coatings used in orthopedic applications. (A) PyC coating (0.5–1.0 mm PyroCarbon) on a graphite substrate used in joint arthroplasty (Integra Life Sciences, USA). (B) The Eclypse partial ulnar head replacement (Tornier Surgical Implants, France) consists of an expandable titanium stem with a mobile PyC spacer (*left*). When implanted, the prosthesis preserves the ulnar styloid and attachment of the triangular fibrocartilage complex (*right*). Adapted from (Garcia-elias et al., 2007).

them perfect candidates to explore in the orthopedics field, either as composites or coatings, decreasing wear-related failures and adverse tissue reactions (bone resorption), while sustaining compatibility with cartilage and bone tissues.

Long-Term Implants

PyC implants are commonly used in hand and wrist arthroplasty, with some having more than 10 years of clinical follow-up. As an alternative to silicone, Dr. Beckenbaugh developed the first PyC metacarpophalangeal (MCP) implant, which was tested in patients between 1979 and 1987 resulting in improved function and esthetics. MCP implants were first commercialized by Ascension Orthopedics (USA). Several PyC-coated implants are currently marketed by Integra Life Science (USA) and Tornier/Wright Medical (France) (Fig. 1.3.5.19). These PyC hand and wrist implants for replacement of MCP, proximal interphalangeal and carpometacarpal (CMC) joints, radial head, lunate, and interpositional articulating surface spacers for use in CMC joints have overcome the previously mentioned implant-associated complications verified when using materials such as silicone, metal, and polyethylene. Moreover, follow-up studies usually report good pain relief, improved grip and pinch strength, and better appearance (Bellemere, 2018; Ross, 2008). PyC has also been investigated for use in scaphoid trapezium implants, in the femoral head-articulating surfaces of hip joint prostheses, and in femoral implants to enhance bone ingrowth (Bohem et al., 2011).

Due to its excellent tribological properties, DLC has been extensively investigated in the last few decades as a coating to decrease wear and corrosion of orthopedic materials. Several studies have shown considerable wear rate improvement, markedly reduced corrosion and leaching of metal into body fluids, good osteointegration, low immunoreactivity, and harmless debris release when DLC coatings are applied. In 2001, Diamond Rota Gliding (Implant Design, Switzerland), a DLC-coated ultrahigh molecular weight polyethylene (UHMWPE) knee joint, was commercialized. However, some of the implants showed increased wear and partial delamination, with the residual coating on the upper side of the implant leading to inadequate bone ingrowth. As such, the use of this implant was forbidden. In 2003, results were published from an 8-year clinical follow-up of 100 patients implanted with DLC-coated Adamante (Biomécanique, France) femoral heads, articulating against polyethylene. After 1.5 years, aseptic loosening was found, with implant revision being needed, and after 8 years almost half of the implants had to be replaced. DLC coatings presented numerous small pits, and delamination of the carbon layer led to excessive release of polyethylene debris, and in some cases even of the metallic substrate of the heads. Despite DLC coatings having high potential to be used to enhance orthopedic implant performance, instability caused by their high level of residual stress and poor adhesion in aqueous environments must be addressed (Ma et al., 2009; Roy and Lee, 2007; Dearnaley and Arps, 2005; Taeger et al., 2003).

UNCD coatings usually reveal appropriate interfacial structure and chemistry, presenting good adherence on a variety of steels. Also, they enhance the growth of osteogenic cells, including mesenchymal stem cells (MSC). Control of cell adhesion, proliferation, and subsequent bone formation can be achieved by altering UNCD surface properties, influencing protein adsorption toward a beneficial biointeraction. Despite UNCD coatings being able to reduce friction and wear of metallic implants, increasing their longevity, the *in vivo* response of macrophages to the possible wear debris and the fate of phagocytosed nanoparticles are not well understood. For that reason, further toxicological studies are needed (Catledge et al., 2013).

The use of CNT as coatings has also been attempted using a hydroxyapatite/CNT composite coating on Ti alloys produced

by laser-surface alloying, revealing that it hardens the surface and makes it more resistant to wear (Chen et al., 2007).

Being impermeable, GBM meet the most relevant requirements for orthopedic implant coating materials, such as good biocompatibility, excellent mechanical strength, and tribological properties. GBM-based coatings have been shown to prevent bacterial adhesion and proliferation, potentially preventing implant-related infections (Henriques et al., 2018; Shadjou and Hasanzadeh, 2016).

Regarding the use of composites containing carbon biomaterials, commercially available prosthetic foot designs for patients with regular activities and elite running and jumping events are constituted by CF in their keel and/or heel part. These prostheses need to resist impact and at the same time should be lighter than an intact limb so that amputee athletes may have a similar energy cost to nondisabled athletes (Nelham, 1981; Saito et al., 2011). For this, fiber alignment in angles concerning applied stress is essential to fit the required properties (Nelham, 1981). Besides their usage in this type of prosthesis, CF were also incorporated in polyether ether ketone (PEEK) and calcium phosphate composites, reinforcing their mechanical properties to improve their performance for bone replacement (Park and Vasilos, 1997; Scotchford et al., 2003). CF/PEEK composites are currently commercialized as spinal fixation cages, hip joint sockets, and knee, limb, and foot prostheses (Table 1.3.5.1). Compared with titanium or stainless-steel prosthesis, CF/PEEK composites exhibit similar mechanical properties but prevent interface disruption and bone loss (Scotchford et al., 2003). However, when CF were incorporated in UHMWPE, the resulting scaffolds did not show good performance for the development of artificial hip and knee joints. This has been associated with the loss of interaction between CF and polyethylene over time (Saito et al., 2011; Kurtz et al., 1999; Korkala and Syrjanen, 1998).

Given the promising results of CF/PEEK composites, the use of CNT was also attempted for PEEK reinforcement. These composites exhibit high strength and low wear, enabling their application as orthopedic implants, essentially in joint replacement (Diez-Pascual et al., 2009). Incorporation of MWCNT into polymethyl-methacrylate led to the reinforcement of neat polymer exhibiting a lower crack propagation (Marrs et al., 2006). GO incorporation in pHEMA suppressed its mechanical limitations, allowing uses in load-bearing applications, such as orthopedic implants (Pereira et al., 2019).

Tissue-Engineering Approaches

Besides the remarkable ability of bone to regenerate and heal itself, large bone defects are still a difficult issue in the biomedical field (Roseti et al., 2017; Agarwal and Garcia, 2015). Bone remolding is a dynamic process that involves formation of bone matrix by osteoblasts and resorption of bone tissue by osteoclasts. In bone tissue engineering, most of the strategies aim to promote the natural process of bone remodeling and regeneration, meaning that an ideal scaffold must have the required mechanical properties, promote cell adhesion, proliferation and differentiation, and enhance intravascularization and host integration (Roseti et al., 2017; Agarwal and Garcia, 2015). The regenerative capacity of cartilage is limited due to its lack of vascularization. Cartilage development shares several growth factors with bone development, namely the bone morphogenic proteins. Thus development of scaffolds for cartilage regeneration have the additional challenge of privileging the development of cartilaginous tissue instead of ossification (Kessler and Grande, 2008).

NCD films proved to be excellent substrates for the adhesion, growth, and functioning of bone cells, which has been attributed mainly to the surface nanostructure of these films (Grausova et al., 2008, 2009). When functionalized NCD is used, cells tend to adhere preferentially to *O*-terminated domains (Rezek et al., 2010). The roughness of UNCD surfaces promotes high adsorption of apatite at the surface (Fox et al., 2013).

Unlike freshly produced fullerene films that do not show much potential to adhere to osteoblasts (Bacakova et al., 2014), aged fullerene films or Ti/fullerene films lead to improvement in osteoblast adhesion compared with glass subtrate (Vandrovcova, 2008).

GBM have been used as films, revealing that the high surface/area ratio of GBM allows effective adsorption of osteogenic inducers at their surface, such as dexamethasone, β-glycerophosphate, and ascorbic acid, which promote osteogenic differentiation (Lee et al., 2011; Akhavan et al., 2013). Moreover, by playing with the surface chemistry of GBM it is possible to modulate the adsorption of different osteogenic markers at their surface: while rGO adsorbs higher amounts of dexamethasone and β-glycerophosphate, GO adsorbs more vitamin C (Lee et al., 2011). Also, negatively charged GO promotes higher calcium absorption, while amine-functionalized GO promotes higher phosphate adsorption (Kumar et al., 2015). Osteogenic differentiation of human MSCs has also been induced by 3D-G aerogels (Crowder et al., 2013b).

Regarding cartilage repair, aligned sheets of CNT induce growth of primary chondrocytes, particularly under electrical stimulation (King et al., 2017).

Application of CF for cartilage regeneration was first attempted by incorporation of these fibers in an osteochondral defect, revealing excellent repair capacity (Kaar et al., 1998; Minns and Muckle, 1989). Since then, many papers have reported *in vivo* the potential of CF as scaffolds for bone regeneration and cartilage repair as reviewed by Saito et al. (Saito et al., 2011). The dimension of CF has a high impact on osteoblast activity, being higher for fibers with diameters <100 nm (Saito et al., 2011).

Regarding the use of composites, incorporation of ND in PLGA and poly(L-lactic acid) leads to improved mechanical properties of both polymers, despite having an adverse effect on cell viability and the production of osteodifferentiation factors, which could be explained by the release of ND for cell culture medium (Parizek et al., 2012; Bacakova et al., 2014). However, when ND are coated with phospholipids and then incorporated in PLGA, the high mechanical properties, good

in vitro and *in vivo* biocompatibility, acceptable immune response, and increased mineralization capability suggest that these biodegradable composites may potentially be useful for bone tissue engineering (Zhang et al., 2016).

EMO-GO/poly(lactic acid) fibrous scaffolds promote MSC attachment and proliferation through provision of a 3D porous environment, showing no acute toxicity when implanted *in vivo* (Ding et al., 2014).

The improvement of the mechanical properties and/or conductivity of CNT-containing scaffolds induces higher cell adhesion, growth, differentiation, and elongation (Newman et al., 2013; Wang et al., 2014; Lin et al., 2011; Mikael et al., 2014). Moreover, incorporation of MWCNT in a scaffold has decreased the number of osteoclasts, inhibiting the resorption of bone (Abarrategi et al., 2008; Tonelli et al., 2012). Surface chemistry of CNT seems to affect the *in vivo* inflammatory response, since when incorporated in PLGA scaffolds, OH-modified MWCNT are less reactive, followed by unmodified MWCNT, with COOH-modified MWCNT exhibiting the highest response (Mikael et al., 2014). CNT were also used to substantially enhance the mechanical properties of decellularized articular cartilage (Ghassemi et al., 2017) and poly(3-hydroxybutyrate)/CS electrospun scaffolds (Karbasi and Alizadeh, 2017) while maintaining their biocompatibility.

GO incorporation in polymer matrices such as CS (Depan et al., 2011), CS/gelatin (Saravanan et al., 2017), and PCL (Kumar et al., 2015) leads to an increase in mechanical properties, protein absorption, and apatite deposition compared with neat polymers. Likewise, GBM incorporation in bioceramic matrices, such as hydroxyapatite and calcium phosphate (Wu et al., 2015), has resulted in mechanical improvements. In hydroxyapatite/rGO composites, rGO leads to an increase in fracture toughness, enabling its application for bone repair (Lee et al., 2015b) and improvement of proliferation and alkaline phosphatase activity of MSC (Nie et al., 2017). *In vivo* studies showed that these scaffolds have accelerated the healing process of circular calvarial defects in rabbits (Nie et al., 2017).

Dental Applications

DLC-coated nitinol orthodontic archwires show excellent mechanical and adhesion properties under the mechanical brushing test. Coatings significantly decrease corrosion and Ni release in degradation tests in physiological saline (Kobayashi et al., 2005).

A carbon coating produced by ion-beam deposition using C_{60} fullerene molecules presents a unique nanocomposite structure, reduced internal stress, high adhesion to substrate, and few defects. It results in a 100–400-fold higher wear resistance compared to Co/Cr and Ti alloys, and improved biocompatibility regarding tissue regeneration, absence of necrosis, and demineralization (Penkov et al., 2016).

Some studies show GBM potential to be used as coatings to prevent bacterial adhesion and biofilm formation in dental implant material (Guazzo et al., 2018).

Composites containing diamond have been commercialized as a nanohybrid filler system (Charisma Diamond) and also as a polishing paste (DiaSheen, Couture Polishing Paste). Charisma Diamond has high strength, conferred by diamond incorporation, which allows perfect handling of this bonding material. Polishing paste containing diamonds has been shown to promote a smooth dental surface, limiting bacteria adherence and therefore preventing the development of gingivitis and periodontal disease. Gutta percha is a filler used to load root canal space that reveals poor mechanical properties, leakage, and occurrence of infection when tested in mice. However, the incorporation of amoxicillin-functionalized ND improved its mechanical performance and inhibited bacterial growth (Lee et al., 2015a).

Incorporation of FLG in poly(acrylic acid) revealed mechanical performance suitable to develop dental prosthesis (Malik et al., 2018). However, it is important to point out that incorporation of GBM in polymeric matrices leads to color change, turning them gray, which could be an issue in the development of dental implants.

Neurological Applications

Due to central nervous system complexity, repairing and recovering the full function of injured nerves are authentic riddles in the tissue engineering field (Bosi et al., 2013). Neuronal scaffolds should mimic the natural structure of the nerve pathway within the brain and spinal cord, namely their physical–chemical (conductivity, porosity, and permeability), mechanical (flexibility and resistance), and biological (biocompatibility and nonimmunogenicity) properties.

Carbon materials have been revealed as promising materials, namely CNT, due to their tubular structures, which resemble natural structures such as microtubules, ion channels, and axons. Moreover, several studies have reported that electrical stimulation could improve neuronal stem cell proliferation and differentiation and boost neuronal outgrowth, which are promoted in scaffolds containing CNT and GBM.

ND- and UNCD-coated subtracts have shown remarkable capacity to sustain cell attachment and neurite outgrowth, as well as to promote neuronal excitability and function (Chen et al., 2008; Erriquez et al., 2005). The topography of the ND film is an important feature to promote cell adhesion since it is much lower on flat surfaces. Moreover, UNCD presents the capacity to guide neural stem cell differentiation (Chen et al., 2009; Pradhan et al., 2006), an effect that has been associated with the capacity of NCD and UNCD films to adhere proteins at their surface, influencing the cell phenotypes (Ariano et al., 2009, Chen et al., 2013a).

Fullerene films can differentiate and develop neurons, indicating their possible application as scaffolds for neural tissue engineering (Hsieh et al., 2017; Krishnan et al., 2015).

CNT films support neuronal cell growth, increase the area of the cell body, and promote the neurite outgrowth

(Malarkey et al., 2009; Galvan-Garcia et al., 2007; Bosi et al., 2013). By controlling CNT orientation, it is possible to guide the growth of neuronal cells, as they tend to orient in the direction of the electrical signal. Moreover, neuronal cells seem to adhere preferentially to the edges of long CNT, which has been associated with their extreme flexibility (Zhang et al., 2005).

Similarly to CNT, 2D films of GBM promote cell attachment and differentiation (Bramini et al., 2018). The surface chemistry of GBM influences cell differentiation, with GO promoting a better neuronal differentiation of MSC despite its lower conductivity compared to rGO (Feng et al., 2018; Halim et al., 2018). These features are maintained in 3D free-standing GBM scaffolds (Zhang et al., 2018b). *In vivo* implantation of these scaffolds in spinal cord injury promotes partial axonal regeneration and angiogenesis without causing toxicity (Lopez-Dolado et al., 2016).

CF films containing fibers with larger diameter (>100 nm) and low surface energy are associated with poor adhesion of astrocytes. A lower adhesion and function of astrocytes leads to a decrease in glial scar tissue formation, which could facilitate neuronal regeneration (Mckenzie et al., 2004). An analogous behavior has been observed in CF/polycarbonate urethane composites (Khang et al., 2004).

Similarly to what is observed with other carbon material composites, incorporation of graphite in PCL increases electrical conductivity and roughness of base polymer showing the highest attachment and proliferation of PC12 cells (Gopinathan et al., 2016).

Composites incorporating CNT or GBM in different polymeric matrices have been developed for neuronal repair using polymers such as agarose (Lewitus et al., 2011), CS (Gupta et al., 2015; Wu et al., 2017; Kim et al., 2013a), collagen (Cho and Borgens, 2010; Ryan et al., 2018), gelatin (Wan et al., 2011), PCL (Gattazzo et al., 2015; Fan et al., 2010), collagen/PCL (Yu et al., 2014), poly(ethylene glycol) (Shah et al., 2015), poly(lactic acid) (Scapin et al., 2015), PLGA (Lee et al., 2009), poly(L-lactic acid-*co*-caprolactone) (Lee et al., 2009), and poly(3,4-ethylenedioxythiophene) (Tian et al., 2014), showing an increase in cell attachment, differentiation, and neurite outgrowth.

Ophthalmologic Applications

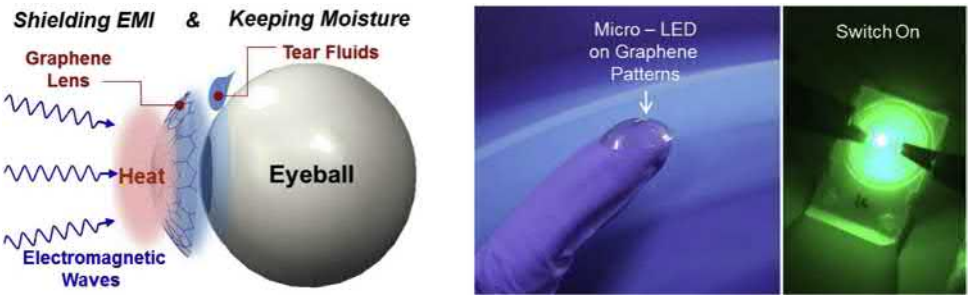
Contact Lenses

Contact lenses and contact lens cases are prone to bacterial contamination and biofilm formation. DLC thin coatings (20–200 nm) were shown to be free of any bacterial contamination after 1 year in contrast to original materials. Besides presenting antibacterial properties, DLC coatings improve biocompatibility, chemical inertness, and resistance to sterilization, as well as mechanical properties, extending poly(methyl methacrylate) lens usage time. The main disadvantage might be some light transmission reduction, whose extension depends on coating thickness (Roy and Lee, 2007; Elinson et al., 1999). Smart contact lenses based on a CVD-transferred G coating were shown to be effective at shielding electromagnetic waves, which may cause eye disease such as cataracts, as well as protecting eyes from dehydration. Also, the assembly of a functional LED on G-coated lenses was achieved (Fig. 1.3.5.20) (Lee et al., 2017).

Drug-loaded contact lenses have been developed for the treatment of ocular diseases, aiming to replace traditional eye drops and drug-soaked lenses without continuous therapeutic delivery. Timolol maleate-containing ND embedded in CS were incorporated in poly(2-hydroxyethyl methacrylate), the conventional polymer used in contact lenses, allowing a controlled release of timolol maleate (used in glaucoma treatment) in the presence of lysozyme. It was shown that ND incorporation in drug delivery systems helps to elute therapeutic compounds (Kim et al., 2014).

Catheters

DLC coatings on PU and nylon, polymers used in catheters, resulted in improved coefficient of friction, abrasion, and puncture resistance and also reduced fibrinogen adsorption, which might lead to reduced thrombogenicity (Nakagawa et al., 2009). Another study also showed that DLC coatings on a PU surface present good adhesion without delamination and prevent *C. albicans* biofilm formation (Santos et al., 2017). Double-J urethral stents were coated with DLC and tested in 10 patients with previous heavy encrustation with crystalline bacterial microfilm. The mean stent indwelling



• **Figure 1.3.5.20** Graphene-coated poly(methyl methacrylate) contact lens advantages, and working demonstrator integrating an LED. *EMI*, Electromagnetic interference. Adapted from (Lee et al., 2017).

time was 97 days, with no primarily stent-related complications or biofilm formation. Facile handling and less painful replacement were reported due to lower friction (Laube et al., 2007). Ureteral stents (CarboSoft) are currently commercialized by Optimed (Germany).

Silicone rubber (SR)/oxidized graphene-nanoplatelets coatings on SR revealed good surface adherence, preserving bacterial adhesion levels of silicone while increasing bacterial death to around 80%. GBM degree of oxidation and SR coating methods influenced the antibacterial properties (Gomes et al., 2018). In general, increased GBM edge exposure and oxidized state contribute to a more effective antibacterial effect (Henriques et al., 2018). GO incorporation in polyethylene, a material also used in catheter fabrication, generates a hemocompatible and bacteriostatic material (Jin et al., 2013).

Guidewires

Medical guidewires are used to introduce stents, catheters, and other medical devices through blood vessels. They are often made of stainless-steel coated with polytetrafluoroethylene or silicone rubber. These coatings can be released due to poor adhesion and are sometimes not uniform. Due to their optimal tribological properties, DLC coatings have been proposed to enhance the performance of guidewires. Studies show that DLC coatings present better adhesion to the substrate, uniformity, and lower coefficient of friction than polymer coatings and are less inflammatory and less thrombogenic than stainless steel (Dearnaley and Arps, 2005; Roy and Lee, 2007).

Other Biomedical Applications

Fullerenes present high electron accommodating capacity and strong electron-withdrawing ability. For that reason, fullerene derivatives act as free radical sponges, having the potential to be used for the treatment of diseases like diabetes, neurodegenerative disorders, atherosclerosis, and autoimmune diseases, among others where free radicals play a role in pathology (Bakry et al., 2007; Rasovic, 2017; Torres and Srdjenovic, 2011; Castro et al., 2017). Carboxyfullerenes and polyhydroxyfullerenes are the most advanced classes in current clinical and pharmaceutical research (Torres and Srdjenovic, 2011). Dendrofullerene has been shown to be as effective as FDA-approved radioprotector amifostine, preventing radiation-induced ROS in zebrafish, without causing detectable adverse effects (Daroczi et al., 2006). Several studies report that fullerenes possess immunomodulatory properties, with different functionalization eliciting either proinflammatory or immunosuppressive responses, enabling the development of therapeutic biomaterials for different goals (Torres and Srdjenovic, 2011; Castro et al., 2017).

ND increase the bioactivity of pharmaceutical formulations acting as nanocarriers and provide protection from UV light in a similar way to titanium and zinc oxide, which are used in sunscreen formulations. Even after intensive UVB irradiation, ND do not penetrate the deeper layers of the skin, and further study of their long-term fate is still needed (van der Laan et al., 2018). After injection into mice, ND can carry and maintain the conformational stability of the antigen mussel adhesive protein, leading to antibody production (Passeri et al., 2015). Finally, ND have been found to be highly effective binding to aflatoxins, therefore they have the potential to be explored as enterosorbents for toxic substances when ingested by the oral route or for accidental spills (Schrand et al., 2009). Activated charcoal has been used for a long time in this role as a sorbent for detoxification.

GBM 2D films revealed the capacity to adhere and promote differentiation of skeletal muscle cells (Zhang et al., 2018b). Surface chemistry of these films plays a critical role in the differentiation of stem cells into skeletal muscle cells, with rGO being more efficient than G (Ahadian et al., 2014; Zhang et al., 2018b). GBM composites have improved myoblast growth and myogenic differentiation, forming multinucleated myotubes (Patel et al., 2018; Du et al., 2018; Zhang et al., 2018b).

Regarding skin tissue, 3DG foams containing MSC implanted *in vivo* in a wound promoted upregulation of neovascularization and reduced the scarring effect, revealing promise as a material for skin wound healing (Li et al., 2015b). It has also been shown that rGO/polydimethylsiloxane composite induces reepithelialization and granulation tissue formation *in vivo*, accelerating wound healing (Qian et al., 2018). Composites of PLGA/GO, CS/GO (Azarniya et al., 2016), and extracellular matrices/GO (Nyambat et al., 2018) are also being extensively studied for skin wound healing. Similarly, the incorporation of GO into CS-/polyvinylpyrrolidone-based electrospun porous membranes not only improved the mechanical properties of the resulting membranes, but also enhanced interactions with human fibroblasts, accelerating the wound healing rate on rat skins by more than 90% (Zhang et al., 2017).

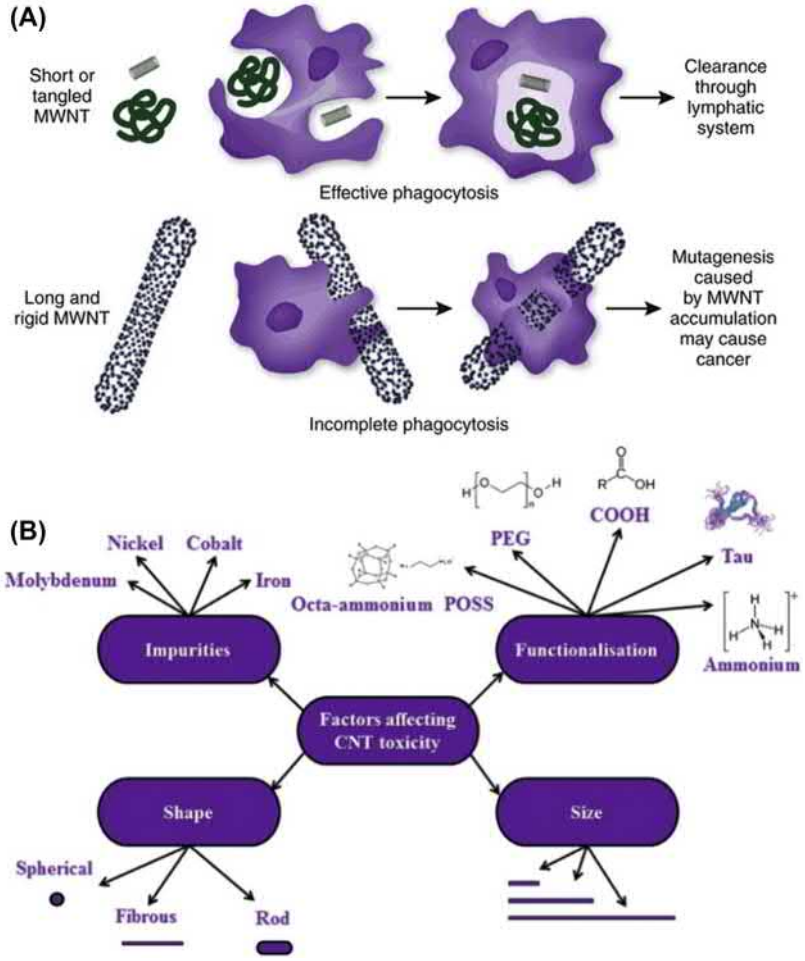
Safety of Carbon Biomaterials: Short Considerations

Carbon biomaterials have been used in clinics for more than 50 years. PyC containing mechanical heart valves and orthopedic implants, stents coated with PyC or DLC, and DLC-coated ventricular-assisted devices are available on the market without toxicity being reported so far. This opens the door for the development of implant material composed of or coated with other carbon material types. However, care should be taken as DLC commercial orthopedic implant failure has happened in the past. Thus long-term stability of carbon implants and coatings is paramount to prevent delamination, wear, and eventual release of toxic particles. To minimize toxicity risks, it is also important to assure proper removal of contaminants (e.g., metals, graphitic materials, solvent residues) resulting from carbon biomaterial manufacturing processes (Zhang et al., 2016). Possible mechanisms for carbon nanomaterials toxicity have been proposed, including damage to membrane integrity, lipid and protein destabilization and oxidation, cell damage via

ROS, and release of metal ions (Chen and Wang, 2016). However, different carbon materials and their derivatives vary substantially (e.g., carbon structure, carbon number, size, thickness, charge, aggregation, degree of functionality) and can be altered *in vivo*. Therefore individual characterization is advisable over results extrapolation (Dellinger et al., 2013; Zhang et al., 2016).

FDA guidance documents on the application of nanotechnology products state that the specific characteristics and effects of nanomaterials in the particular biological context of each product and its intended use should be accessed. The International Agency for Research on Cancer released a report mentioning that only certain types of rigid MWCNT can be classified as being possibly carcinogenic to humans (Bengt Fadeel et al., 2018). Despite CNT being the carbon biomaterial generally raising more toxicity issues, they can be designed to improve biocompatibility and be biodegradable and body clearable (Fig. 1.3.5.21). Besides their dimensions, other concerns should be taken into consideration when it comes to the safety of CNT, such as preventing aggregation and increasing their solubility, which makes excretion easier, preventing accumulation. Similar strategies can be applied to other carbon biomaterials.

GO and graphene showed potential to be degraded by active molecules present in blood plasma (e.g., •OH and •O2) being the degradation rate higher for GO since these molecules attack oxygen-containing groups (Li et al., 2019). GO has also been reported to be intra- and extracellularly degradable by immune system cells. Degradation of graphene with lateral size < 200 nm was also reported *in vivo* (Girish et al., 2018). GO generally elicits less lung toxicity than certain CNT. However, reports on toxicity towards neural cells have been made. Therefore further study is needed on GBM toxicity (Bengt Fadeel et al., 2018). Most fullerenes are usually not toxic unless photoexcited or used at very high concentrations, which is hard to achieve in the environment or during therapy. However, some reports on inflammation and genotoxicity have been found, raising some concerns about their use (Singh and Nalwa, 2007; Rasovic, 2017). Well-purified and dispersed ND are better tolerated by cells than



• **Figure 1.3.5.21** Factors affecting carbon nanotube (CNT) toxicity and elimination. (A) Illustration showing how the structure of CNT can affect phagocytosis by macrophages and tissue clearance. Low aspect ratio multiwalled carbon nanotubes (MWCNT) can be engulfed by macrophages, while it is not the case with high aspect ratio MWCNT. (B) Schematic illustration of the factors affecting CNT toxicity (Alshehri et al., 2016). *PEG*, poly(ethylene glycol); *POSS*, polyhedral oligomeric silsesquioxane.

fullerenes or CNT. They have proven to be generally biocompatible in several *in vivo* studies. However, inflammation, embryotoxicity, and teratogenicity reports have been made, therefore detailed study is needed on those subjects for each newly designed ND-based biomaterial (Zhang et al., 2016). When administered through different routes, CD are readily cleared out of mice through the renal route, with no detectable toxicity, due to being small and biodegradable. However, a more comprehensive toxicological evaluation is still needed on this carbon biomaterial class (Chen and Wang, 2016).

Carbon nanomaterials have become the most common nanoproducts according to "The Nanotechnology Consumer Products Inventory." Their production, use, and disposal inevitably lead to environmental release (Chen and Wang, 2016). Therefore biocompatibility evaluation is pertinent not only in the context of their incorporation in biomaterials, but also regarding environmental exposition.

Summary

The different forms of carbon biomaterials differ in crystallinity, dimension, and carbon hybridization. This variation, along with their different physical–chemical properties, allows a wide range of biomedical applications.

PyC and DLC are both amorphous forms of carbon, being applied as coatings for biomedical devices. PyC has been used for more than 50 years in commercially available MHV and orthopedic implants, due to its outstanding mechanical, tribological, and hemocompatibility properties. PyC- and DLC-coated vascular stents and DLC-coated urethral stents and VAD are also currently marketed. Coatings with other carbon biomaterials such as DLC, NCD, UNCD, fullerenes, CNT, and GBM are under investigation for MHV, orthopedic implants, catheters, contact lenses, oral implant guidewires, biosensors, neuronal tissue engineering, and antimicrobial materials.

The hexagonally bonded carbons - fullerenes, CNT, GBM, and CF - are also being investigated for use as freestanding films or scaffolds in bone implants, antimicrobial materials, skin wound healing, and cardiac, bone, neuronal, and muscle tissue-engineering approaches.

Carbon materials can also be combined with polymers, ceramics, or metals to produce composites with improved biocompatibility and/or mechanical, conductive, and antimicrobial properties. ND-containing dental fillers and polishing pastes are already commercialized, as well as a wide variety of PEEK/CF composite orthopedic implants for joint replacement. Along with ND and CF; G, fullerenes, CNT, GBM, or CD/GQD are under research for use as MHV, biosensors, orthopedic implants, drug delivery systems, antimicrobial materials, contact lenses, skin wound healing, and different tissue-engineering applications (cardiac, bone, cartilage, neuronal, and muscle).

Due to their small size, radiation absorption properties, large surface area, and tunable surface properties, carbon biomaterials can also be used for bioapplications in the form of micro/nanocolloids. Fullerenes, CNT, and CD/GQD are applied to drug delivery, imaging, PTT and PDT, and antimicrobial applications. These uses are also under investigation using ND and GBM, except for ND-based phototherapy (poor radiation absorption) and GBM-based imaging (low quantum yield). Additionally, fullerenes have also been applied in sunscreen formulations.

Besides the successful use of some carbon biomaterials in commercially available products, new materials and many applications have arisen in the past years and therefore toxicological studies are still lacking to guaranty their safety and to reach the market.

Chapter Questions and Answers

1. Classify the following carbon materials regarding their dimension (size/grain size) and carbon hybridization

	DIMENSION (size/grain size)				HYBRIDIZATION RATIO	
	0D	1D	2D	3D	$\frac{Sp2}{Sp3}>1$	$\frac{Sp2}{Sp3}<1$
Diamond				X		X
MCD				X		X
NCD	X					X
UNCD	X					X
ND	X					X
DLC				X		X
PyC				X	X	
Graphite				X	X	
Fullerene	X				X	
CNT		X			X	
Graphene			X		X	
CF				X	X	
CNF		X			X	
GNR		X			X	
CD	X					X
GQD	X				X	

2. One of the major constraints associated to the application of carbon materials colloids in biological systems is their aggregation in aqueous media. Describe a currently used strategy to improve it, explaining the changes in interfacial properties.

Answer: Due to the high content of carbon atoms, carbon materials exhibit a high hydrophobicity which compromises their solubility and/or dispersion in aqueous media, such as the biological systems. The most common strategies to prevent aggregation are carbon materials oxidation or their functionalization with hydrophilic molecules such as polyethylene glycol, since these will increase their oxygen containing groups and therefore make them more hydrophilic.

3. Classify the following sentences as true (T) or false (F)
   - 3.1. Discovery of PyC, fullerene and G is associated to attribution of three Nobel prizes. **F**
   - 3.2. For biomedical applications, carbon materials can be used as colloids, free-standing materials, coatings, or composites. **T**
   - 3.3. PyC, and MCD, NCD and UNCD are synthetized as a film being frequently used as a surface coating of biomaterials. **T**
   - 3.4. DLC, PyC and ND are carbon materials already applied in commercially available biomaterials. **T**
   - 3.5. Despite their small size, fullerenes can't penetrate the mammalian cell membrane. **F**
   - 3.6. Drugs can only interact with carbon materials by covalent interaction. **F**
   - 3.7. Due to their high surface area and aspect ratio, CNT can be loaded with high amounts of molecules (e.g., drugs, antibodies, peptides) and used to deliver them intracellularly, by permeating cell membranes. **T**
   - 3.8. The good dispersion in water and biocompatibility of CD and GQD are attributed to their small size (<10 nm) and oxygen content. **T**
   - 3.9. ND present strong absorption and fluorescence in the UV region, and strong Raman signals. **T**
   - 3.10. GBM outstanding optical properties perspective their application in bioimaging. **F**
   - 3.11. CNT and GBM have strong absorption of NIR radiation, enabling their use in photothermal therapy. **T**
   - 3.12. Most colloidal carbon based materials have antibacterial effect by acting on bacterial membrane. **T**

4. Select the correct answer:
   - 4.1. Carbon-based coatings:
     - a) have been used for decades to enhance biomaterials performance.
     - b) of DLC are used in commercially available orthopedic implants.
     - c) of DLC are used in commercially available stents and ventricular assisted devices.
     - **d) Two of the above.**
     - e) All of the above.
   - 4.2. Carbon materials composites:
     - a) of CNT and GBM are used to improve the polymer conductivity.
     - b) of CNT and GBM are used to improve the polymer mechanical properties.
     - c) of ND are commercially available for dental applications.

d) of CF are commercially available for dental applications.
e) all of the above.

4.3. Mechanical heart valves that contain carbon materials:
a) can be made of PyC.
b) are commercially available.
c) have good hemocompatibility and therefore do not require systemic anticoagulation therapy.
d) Two of the above.
e) All of the above.

4.4. Considering carbon materials application in phototherapy:
a) ND with ideal crystalline structure are fluorescent.
b) Fullerenes present strong absorbance at wavelengths above UV region.
c) Graphene decreases fluorescence quenching of dyes and sensitizers.
d) CD have poor photostability.
e) None of the above.

4.5. Considering application in biosensors, carbon materials:
a) can be used as the receptor that detects the molecule.
b) can be used as the signaling transducer which converts the physical/chemical signal.
c) can be used as a signal processor.
d) Two of the above.
e) All of the above.

4.6. Considering carbon materials application in antimicrobial therapy:
a) Fullerenes have an inherent antiviral action.
b) GBM antimicrobial mechanisms of action are different for GBM colloidal dispersions and GBM containing-surfaces.
c) The coating production technique influences the antibacterial outcome of the surface
d) Two of the above.
e) All of the above.

5. Identify the main applications under study or commercially available for the carbon biomaterials presented in the table below:

	Drug delivery	Phototherapy	Imaging	Biosensors	Antimicrobial	Cardiovascular	Orthopaedics	Neuronal	Dental
NCD/UNCD					X	X	X	X	
ND	X		X		X			X	X
DLC					X	X	X		
PyC						X	X		
Graphite								X	
Fullerene	X	X	X	X	X	X	X	X	X
CNT	X	X	X	X	X	X	X	X	
GBM	X	X		X	X	X	X	X	X
CF				X			X	X	
CD/GQD	X	X	X	X	X				

6. Using a carbon nanomaterial of your choice, describe its main properties and give an example of a biomedical application, explaining how/why it can be used.

Answer: This question can have numerous possible answers. However, it should be taken into account that carbon nanomaterials have at least one dimension smaller than 100 nm, so only 0D, 1D or 2D carbon materials should be selected. Students are intended to highlight the main properties of one of these nanomaterials and correlate them with a selected biomedical application, explaining the rational for the design of the medical device.

7. Provide example of one success and one failure on carbon-based materials applications in clinics.

Answer: For more than 50 years, pyrolytic carbon has been used in more than 25 different mechanical heart valves (MHV) designs, and nowadays 95% of all MHV have at least one structural component made of this carbon biomaterial. The balance between blood compatibility, physical and mechanical properties, and durability made PyC the best material option available in MHV. A 17-year follow-up study in 500 patients implanted with Sorin MHV revealed that only five reoperations were necessary, and that there was a total of 15 valve-related deaths.

Failures were observed in diamond-like carbon (DLC) coated implants for orthopaedics. In 2001, Diamond Rota Gliding (Implant Design, Switzerland), a DLC-coated ultra-high molecular weight polyethylene (UHMWPE) knee joint, was commercialized. However, some of the implants showed increased wear and partial delamination, with the residual coating on the upper side of the implant leading to inadequate bone ingrowth. As such, the use of this implant was forbidden. In 2003, results were published from an 8-year clinical follow-up of 100 patients implanted with DLC-coated Adamante (Biomécanique, France) femoral heads, articulating against polyethylene. After 1.5 years, aseptic loosening was found, with implant revision being needed, and after 8 years almost half of the implants had to be replaced.

Introduction to Natural Materials

The use of naturally occurring materials as matrices or scaffolds to support cell growth and proliferation significantly impacted the origin and progress of tissue engineering and regenerative medicine (TERM). However, the majority of these materials failed to provide adequate cues to guide cell differentiation toward the formation of new tissues. Over the past decade, a new generation of multifunctional and smart natural-based materials has been developed to provide biophysical and biochemical cues intended to specifically guide cell behavior.

Natural-based polymers originate from millions of years of nature's evolution in different environments, which resulted in an outstanding range of well adapted macromolecular designs to perform multiple structural and biological functions (Mano et al., 2007). In general, these can be categorized into three types of biopolymers: (1) proteins–chains of amino acids (e.g., collagen, elastin); (2) polysaccharides–chains of sugar (e.g., chitin, cellulose, glycosaminoglycans); and (3) nucleic acids–chains of nucleotides (DNA, RNA) (Table 1.3.6.1). From the point of view of origin, they might be derived from plants, animals (xenogenic), or humans (allogenic and autologous). Natural polymers offer several advantages with respect to synthetic polymers (Fig. 1.3.6.1): (1) they frequently avoid the immunogenic response and toxicity typical of synthetic polymers, thus presenting higher biocompatibility; (2) they contain bioactive motifs enabling local remodeling and cell spreading and a fibrillar architecture that can be deformed by cells, thus better mimicking the extracellular matrix (ECM); and (3) they can be recognized and metabolically processed by the body. However, natural polymers have historically been associated with some disadvantages, including batch-to-batch variability, lower modularity, and inadequate biomechanical properties. Recent developments in the field have led to a reduction in these drawbacks, and allowed exploration of the full potential of naturally occurring polymers to develop a number of biomaterials that mimic key aspects of the native ECM (Mano et al., 2007).

In this chapter, we first review the use of ECM proteins and blood-derivatives intrinsic capacity to mimic the biophysical and biological characteristics of native tissues. Furthermore, the design of a variety of nanostructures using the well-explored characteristics of nucleic acids is summarized. In the second section, the exploitation of supramolecular chemistry to create new dynamic functional hydrogels that mimic the ECM structure and/or composition is surveyed. Finally, we focus on the incorporation of nanoelements in polymeric networks for the design of smart nanocomposite materials with tailored functionalities to guide cell behavior.

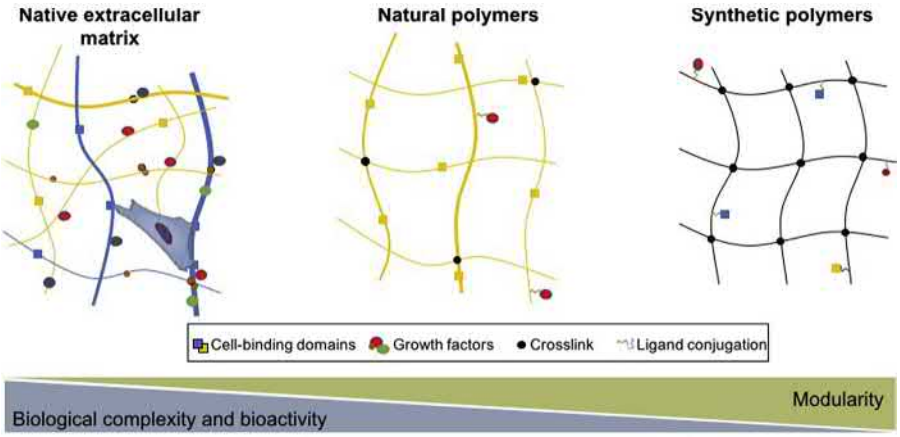
Natural Based-Biomaterials Exploring Structural Molecules

Extracellular Matrix-Based Biomaterials

The ECM comprises a complex milieu of proteins and glycosaminoglycans (GAGs) that provides a physical scaffold for maintaining the structural integrity of tissues, serves as an adhesive substrate for cell attachment and organization, and as a reservoir for biochemical cues to support cell survival and differentiation (Hussey et al., 2018; Mecham, 2001). These results in the establishment of specialized environments that contribute to the specific cell phenotypes and functions, making the ECM composition

TABLE 1.3.6.1 Origin and Relevant Properties of Selected Natural Polymers

Natural Material	Source	Relevant Properties
Proteins		
Collagen or denatured collagen (gelatin)	Animal tissues/cell culture	ECM protein. Provides cell-binding sites. Thermal gelation. Easy chemical modification
Decellularized ECM	Animal tissues/cell culture	ECM composition and structure mimetic. Tissue-specific. Provides cell-binding sites
Blood derivatives	Blood	ECM mimetic. Provides biochemical cues related to tissue healing/regeneration. Natural enzymatic gelation with thrombin (clot formation). Provides cell-binding sites
Polysaccharides		
Chondroitin sulfate	Animal tissues	Sulfated GAG present in connective tissues. Different sulfation patterns/growth factors affinity depending on source
Hyaluronic acid	Animal tissues/bacterial fermentation	ECM component. Nonsulfated GAG. Easy chemical modification
Cellulose nanocrystals	Plants, bacteria and tunicates (marine invertebrate animal)	High strength and aspect ratio. Used as nanofiller and reinforcement element
Nucleic acids		
DNA	Cells	Predictable biophysical and biochemical behavior. Different applications



• **Figure 1.3.6.1** Native extracellular matrix is a heterogeneous fibrillar network that provides biochemical and biophysical cues to cells. The use of natural polymers aims to mimic the native ECM complexity, which is very difficult to achieve using synthetic polymers. On the other hand, the modularity and chemical modification possibilities are wider on synthetic polymers.

tissue/organ-specific. Most ECMs are formed by a hydrogel-like porous network of fibrous proteins and linear GAGs. This fibrillar structure of the ECM influences its physical properties, signaling of growth factors (GFs), cell fate, and transport of nutrients and waste (Prince and Kumacheva, 2019). In order to recreate the biophysical and biochemical characteristics of the native tissues, the use of ECM-based biomaterials has gained interest in the last few years.

Proteins

Naturally occurring materials processed from purified or recombinant ECM proteins, such as collagen, laminin, fibrin, fibronectin, or elastin, have been widely used to create a myriad of biomimetic hydrogels and scaffolds for diverse TERM applications. The most abundant and well-studied protein of mammalian ECM is collagen, which accounts for nearly 90% of the dry weight of most tissues and organs. Other abundant ECM proteins include fibronectin and elastin. Collagen and its partially hydrolyzed form, gelatin, are among the most preferred ECM proteins used in TERM due to their wide availability in nature (bovine, porcine, and marine), and ease of processing and modification using various techniques and chemistries. For example, the modification of gelatin with methacryloyl residues (also known as GelMA) has been

widely used to generate constructs with controlled architectures using micromolding, photomasking, bioprinting, self-assembly, and microfluidic techniques. The derived structures have been explored in a wide range of applications including bone, cartilage, cardiac, vascular tissues engineering, and drug and gene delivery (Yue et al., 2015).

Elastin is an extremely durable ECM protein responsible for the repetitive and reversible elastic recoil of tissues. The insoluble nature of elastin makes its processing challenging and incompatible with some techniques, which restricts its use in TERM approaches. Tropoelastin, on the other hand, is the soluble precursor of elastin and combines the similarities to elastin with easy handling, making this monomer a versatile building block to engineer biomaterials (Mithieux et al., 2013; Wise et al., 2009). It has been incorporated as a bulk material to build highly elastic hydrogels (Annabi et al., 2017, 2010), films produced through casting (Hu et al., 2011), or electrospun fibrous scaffolds (Machula et al., 2014; Nivison-Smith et al., 2010) to enhance cell adhesion, proliferation and migration, neovascularization, and even direct stem cell commitment (Yeo and Weiss, 2019). It has also been used as surface coatings to enhance cell interaction with the interface and to potentiate integration within the body (Yeo et al., 2017, 2012). In a different approach, recombinant and synthetic elastin-like polypeptides [repetition of the pentapeptide valine-proline-glycine-valine-glycine (VPGVG) from elastin], which mimic the extensibility and thermal properties of natural elastin, have been used to produce a range of biomaterials, including nanoparticles, electrospun fibers, and hydrogels cross-linked used different chemical strategies (Rodríguez-Cabello et al., 2018). These polypeptides also have been modified to incorporate "clickable" sequences (azides and alkynes) that react orthogonally to form an irreversible covalent bond, which resulted in hydrogels with fully tunable viscoelastic properties (González de Torre et al., 2014; Testera et al., 2015).

In order to recapitulate the cell-binding properties of ECM proteins, different biomaterials/formats have been conjugated with the bioactive domains of these proteins. The majority of the published studies (89%, from 1979 to early 2018) used the tripeptide arginine-glycine-asparagine (RGD), which is the minimal binding domain of some ECM proteins such as fibronectin, vitronectin, and laminin to integrin receptors (Huettner et al., 2018). Beyond this, many binding domains derived from ECM proteins have been recently described, which has opened new avenues for designing complex strategies to target diverse cell receptors (Huettner et al., 2018). For example, PCL scaffolds coated with RGD and tyrosine-isoleucine-glycine-serine-arginine (YIGSR) promoted axonal regeneration, functional recovery, and vascularization within regenerating nerve tissues in vivo through the activation of independent signaling pathways (Zhu et al., 2017a). Nevertheless, although the short binding domains can support cell attachment, migration, and activation of specific pathways, they have severely reduced binding affinity and specificity compared with the same peptide presented within its associated full-length 3D protein structure (Li et al., 2017; Martino et al., 2009). Interestingly, the presentation of RGD in fibronectin sequences containing the major integrin-binding domain has been shown to improve binding affinity and modulate GF signaling (Martino et al., 2011). Therefore, the presentation of multiple cell-adhesion domains in their correct three-dimensional (3D) structural context can open new avenues for precisely controlling cell function and identifying synergistic effects that promote tissue regrowth and regeneration.

In addition, decellularized ECM (dECM)-based hydrogels have emerged as promising "game-changer" materials to develop biomimetic bioinks for 3D bioprinting (Choudhury et al., 2018). These bioinks are prepared from decellularized tissues and organs that are typically mixed and/or cross-linked using different natural and synthetic polymers or cross-linking agents to make them printable alone or in combination with biocompatible thermoplastics (e.g., PCL) to obtain mechanically reinforced scaffolds (Fig. 1.3.6.2). So far, different dECM bioinks have been derived from various organs such as heart, liver, fat, cartilage, skeletal muscle, skin, and vascular tissue (Choudhury et al., 2018). In a pioneering work, heart dECM bioink was developed, which allowed myoblasts to produce the cardiac-specific proteins actinin and fast myosin heavy chain-6, when compared with a collagen bioink (Pati et al., 2015, 2014). Thus, dECM bioinks have great potential to direct and mediate the differentiation of stem cells to create biomimetic and functional tissues, which would have applications in drug screening, disease modeling, and regenerative medicine. Nevertheless, since dECM is prepared either from human donors or animals, immunological issues need to be considered as well as the batch-to-batch high variability and limited availability of tissues. In order to overcome these issues, the use of cell-culture-derived matrix to produce dECM could offer a reliable alternative (Hussey et al., 2018). Using this approach, autologous cells can be cultured to obtain specific ECMs, avoiding concerns about the immune response. Furthermore, it could be obtained on a larger scale with higher reproducibility using cell expansion factories, although it remains very far from clinical translation.

Glycosaminoglycans

GAGs are negatively charged linear polysaccharides frequently found in the ECM conjugated with proteins, forming proteoglycans. They play important structural and regulatory roles in the ECM and are involved in many important cellular signaling processes governing tissue growth and development. Important types of GAGs that differ in chemical composition, structure, and function include the nonsulfated hyaluronan, the sulfated heparan sulfate and the closely related heparin, the sulfated chondroitin sulfate and the related dermatan sulfate, and keratan sulfate. Considering the diverse cell-instructive roles of GAGs in native tissues, GAG-based biomaterials have attracted huge attention in the field of TERM (Dinoro et al., 2019; Freudenberg et al., 2016).

Printing three-dimensional tissue analogues with decellularized extracellular matrix bioink. Nat. Commun. 5, 3935. https://doi.org/10.1038/ncomms4935.)

Chondroitin sulfate (CS) is composed of repeating glucuronic acid and N-acetylgalactosamine units and has a high negative charge density. The main sources of CS for biomedical applications are cartilaginous tissues from bovine trachea and, in recent years, also from marine sources such as shark cartilage (Valcarcel et al., 2017). CS is a very heterogeneous family of polysaccharides with high variability in terms of sulfation pattern and chain length, which depend mainly on their sources. CS has traditionally been used for polyelectrolyte complexation strategies to build, e.g., membranes, fibers, and nanoparticles (Costa-Almeida et al., 2016; Santo et al., 2015; Silva et al., 2016).

Hyaluronic acid (HA) is the only nonsulfated GAG, and consists of repeating disaccharide units of N-acetylglucosamine and glucuronic acid. For biomedical and biotechnological use, it has been traditionally isolated from animal sources, mainly rooster combs, but in recent years microbial fermentation has emerged as the preferred alternative in industrial production of HA (Liu et al., 2011). Although HA is among the preferred polymers for hydrogel matrices in the biomedical field, it does not have any natural and effective physical mechanisms of gelling (e.g., thermal, ionic) and therefore, chemical modification is required for this type of application (Highley et al., 2016). Readers are addressed to the section "Dynamic Hydrogels Exploring Supramolecular Chemistry" of this chapter and to the excellent reviews from Burdick's group to gain a better overview of HA-based biomaterials for biomedical applications (Burdick and Prestwich, 2011; Highley et al., 2016). Among several strategies, recent works have developed an injectable hydrogel using a combination of dynamic covalent cross-linking with thermoresponsive engineered proteins provided by hydrazine-modified elastin-like protein and aldehyde-modified HA. This biomaterial allowed the encapsulated cells maintain their ability to differentiate into multiple lineages after injection (Wang et al., 2017) and the increase in cartilage-marker gene expression and GAG deposition while minimizing undesirable fibrocartilage phenotype (Zhu et al., 2017b).

Blood Derivatives as a Source of Bioinstructive Materials

Upon tissue injury, blood components, together with the provisional fibrillar matrix, are crucial to achieve hemostasis, to support cell infiltration, and to establish a spatial-temporal chemotactic gradient of proteins (e.g., GFs, cytokines, morphogens) that can tightly regulate the complex wound healing microenvironment (Anitua et al., 2019; Mendes et al., 2018a). During normal wound repair, the mimetic fibrillar network embedded with biologically active proteins is remodeled, being gradually degraded and replaced by mature ECM, until tissue repair is achieved. In a biomimetic approach, blood derivative formulations have been extensively studied to guide the wound healing process into regenerative pathways by tailoring the biophysical and biochemical cues present on the biomimetic ECM (Mendes et al., 2018a). In particular, platelet-rich blood derivative strategies led to the development of a panoply of novel human-based biomaterials that are making their way to clinical application.

Under physiological conditions, activated platelets release an enriched milieu of proteins, while circulating fibrinogen is polymerized, producing an insoluble fibrin matrix (clot) through multiple molecular mechanisms (Piechocka et al., 2010; Ryan et al., 1999). Briefly, fibrin polymerization is initiated by thrombin cleavage, which exposes the central domain of fibrinogen-binding sites to interact with

complementary sites at the terminal domains of other fibrin molecules. These noncovalent interactions induce the self-assembly of fibrin monomers and the formation of half-staggered two-stranded protofibrils. When protofibrils achieve a threshold length, they start to associate laterally to form fibers that branch into a stable three-dimensional network due to plasma transglutaminase (factor XIIIa) covalent cross-linking and calcium ions presence. It is clear that the self-assembled fibrin matrix not only provides a provisional hierarchical ECM to facilitate cellular infiltration, but also contains numerous binding domains for the cells, ECM proteins, and secreted GFs (Brown and Barker, 2014; Laurens et al., 2006). Interestingly, fibrin contains binding sequences for integrins, which facilitate the adhesion of platelets, endothelial cells, smooth muscle cells, fibroblasts, and leukocytes (Lishko et al., 2004). Moreover, fibrin through its heparin-binding domain shows a promiscuous high affinity to bind platelet-derived GF (PDGF), vascular endothelial GF (VEGF), and fibroblast GF (FGF), which can be released from the activated/disrupted platelets (Martino et al., 2013). The complex and hierarchical fibrin structure, in combination with the unique molecules binding interactions, highlight the important and ubiquitous role of fibrin as a bioinstructive platform that provides the biophysical and biochemical cues to modulate a number of complex cellular responses.

In a biomimetic regenerative medicine approach, blood derivatives composed by a high content of structural proteins have been easily produced from autologous or heterologous whole blood samples (Mendes et al., 2018a). Thus, blood derivative formulations can be used directly as a liquid or a liquid-to-gel fibrin-based scaffold through the activation of collagen, calcium, or/and thrombin. The modulation of fibrinogen, thrombin, and calcium/salt concentrations has a marked impact over fibrin polymerization dynamics and the resulting fibrin scaffold properties, namely on fiber diameter, mechanical properties, and bioactive molecule sequestration (Brown and Barker, 2014; Dohan Ehrenfest et al., 2012; Piechocka et al., 2010). Throughout the last few decades, fibrin-based blood derivative formulations have been already successfully translated to the clinics (e.g., fibrin glue) due to their positive effects in the localized and sustained delivery of therapeutic GFs in the treatment, for instance, of periodontal and soft tissue wound healing (Anitua et al., 2019; Heher et al., 2018; Miron et al., 2017; Weisel and Litvinov, 2013). However, the lack of standardization in the formulations' preparation, poor characterization of formulations, and conflicting codelivery of multifunctional biomolecules led to conflicting results in the therapeutic outcomes, opening a debate on their real potential within the field (Marx, 2004; Wang and Avila, 2007). Moreover, the use of fibrillar gels produced from blood derivative precursors has attracted significant interest in the promotion of vascularization in regenerative strategies due to their natural reservoir in angiogenic GFs (e.g., VEGF) (Fortunato et al., 2016). Nevertheless, these strategies also exhibit limited ability to protect biomolecules from fast clearance and proteolytic degradation, have low mechanical properties, and show a high contractile effect upon cell encapsulation, which severely limits their potential as wound-healing modulators (Robinson et al., 2016; Sadeghi-Ataabadi et al., 2017).

In order to overcome the above-mentioned drawbacks, a wide range of natural and synthetic polymers, inorganic materials, or their blends have been recently combined with blood derivatives to tightly modulate spatiotemporal biomolecules delivery and to reinforce its inherent mechanical and structural properties (Mendes et al., 2018a). Recently, Faramarzi et al. embedded the inert alginate polymer matrix with the enriched bioactive milieu of platelet-rich plasma (platelets suspended in platelet-poor plasma at 1×10^6 platelet μL^{-1} concentration) to obtain a biofunctional alginate bioink for 3D bioprinting (Faramarzi et al., 2018). The engineered patient-specific bioink exhibited a gradual release of bioactive proteins and positively affected the function of mesenchymal stem cells and human umbilical vein endothelial cells, which could be explored to induce a healing response in cardiovascular and musculoskeletal bioprinted tissue constructs. Our research group has been focused on the modulation of biomolecule release kinetics from platelet lysate (platelet disruption by freeze–thaw cycles) hydrogels in a timely and a controlled space by solely using magnetic stimulation (Silva et al., 2018). The incorporation of magnetic nanoparticles in a methacrylated chondroitin sulfate hydrogel loaded with platelet lysate enabled the modulation of hydrogel physical properties (swelling, matrix stability, and degradation) and control over the GF profile release. This magnetic stimulation control led to a synergistic impact on cell morphology and synthesis of tendon- and bone-like matrix in an in vitro interfacial coculture model. In a different work, using polyelectrolyte complexation between two oppositely charged polysaccharides——chitosan and CS—resulted in the formation of nanoparticles that were loaded with PL and human adipose-derived stem cells. These particles showed an initial burst release of growth factors that correlated with higher cell proliferation, compared to cultures on unloaded particles and in the form of cell pellets (Santo et al., 2015). Along the modulation of bioactive molecules profile release, nanomaterials have also been explored to fine-tune hydrogel mechanical properties to trigger specific cellular responses (Memic et al., 2015). This concept was explored on the development of an injectable fibrillar nanocomposite hydrogel based on platelet lysate combined with cellulose nanocrystals (CNC) (Mendes et al., 2018b). Here, by increasing CNC loading it was possible to increase stiffness, improve biomolecule sequestering, and hinder the typical extensive retraction upon 3D cell culture, enabling therefore the modulation of encapsulated human adipose-derived stem cell behavior.

The development of blood derivatives-based biomaterials with biochemically, mechanically, and structurally tunable properties will clearly improve control over the proteins' milieu composition and kinetics release profile. These findings can be explored to fine-tune stem cell behavior toward specific

lineages and, in combination with recent developments in the regenerative mechanisms, to engineer the wound-healing microenvironment toward tissue regeneration.

Multifunctional Biomaterials Based on DNA

Deoxyribonucleic acid (DNA) is a very old and well-known molecule due to its role as genetic information carrier. However, recently, it has also become a key player in materials science. Exploiting the biophysical and biochemical features of single- and double-stranded DNA, a variety of DNA-based materials showing programmable and multifunctional characteristics are used for biomedical applications (Ke et al., 2018; Shahbazi et al., 2018; Zhang et al., 2018). In this section, we focus on hydrogels, aptamers, and nanostructures based on DNA for tissue engineering applications.

The hydrated nature of DNA hydrogels, which can mimic the properties of natural tissues, has awakened the interest in the design of DNA-based tissue engineering scaffolds. DNA hydrogels are normally created using ligase cross-linking or self-assembly reactions, enabling the gelling to occur under physiological conditions and, thus, the encapsulation of cells. These gels have shown excellent biocompatibility and biodegradation (Stoll et al., 2017). In addition, they have been designed to respond to a variety of stimuli, such as temperature, pH, enzymes, light, or magnetic forces to alter their conformation (Shahbazi et al., 2018; Zhang et al., 2018). For example, Liu's group reported a DNA hydrogel that undergoes a pH-driven conformational transition (called the DNA motor), which influences the spatial distance between cross-linking points and subsequently the stiffness of the hydrogel. By changing the pH between 5.0 and 8.0, the storage modulus of the hydrogel could be tuned reversibly from 1000 to 250 Pa (Zhou et al., 2016).

The aptamers, also known as "nucleic acid antibodies," are designed to specifically bind with high affinity to a target molecule, have been classically used for disease diagnosis and therapy (Keefe et al., 2010; Zhang et al., 2018). DNA aptamers are generated using SELEX, an in vitro selection and evolution process, it being theoretically possible to create aptamers that target any molecule of interest (Gelinas et al., 2016). Unlike antibodies, the generation of aptamers is much cheaper and easier and reduces ethical and immunogenic constraints, offering new perspectives in biomedical applications. In a pioneering work using DNA aptamers to design GF mimetics for regenerative medicine, an aptamer for the hepatocyte GF (HGF) receptor (also known as c-Met), which plays a key role in cancer metastasis, inhibited HGF-induced c-Met activation, which suppressed cancer cell mobility in vitro (Ueki and Sando, 2014). More recently, aptamers were engineered to bind the PDGF-BB and VEGF. One end of the aptamer was linked to an RGD peptide and the other end to a functional group able to covalently link the aptamer to different material systems such as glass, polymers, or collagen scaffolds. In this new strategy the specific GFs are delivered using cell traction forces on the ECM, avoiding the need for exogenous triggers (Stejskalová et al., 2019).

Exploiting nitrogenous bases complementarity and DNA predictable folding, the DNA origami technique provides a versatile platform to engineer nanoscale structures and devices that can sense, compute, and actuate (Hong et al., 2017; Zhang et al., 2018). This has opened a wide range of applications in chemistry, biology, physics, material science, and computer science (Hong et al., 2017). In the field of biomedicine, the most frequent application of these nanostructures is for targeted drug delivery of anticancer drugs, while its use in classical tissue engineering approaches is still limited to a conceptual stage, which is addressed in the last section of this chapter.

Dynamic Hydrogels Exploring Supramolecular Chemistry

A plethora of biocompatible hydrogel cross-linking mechanisms have been developed along the years to recreate hydrated mesh-like architectures of native tissue ECM. Nonetheless, conventional hydrogel systems typically rely on stable, permanent covalent cross-linking bonds that do not capture its highly dynamic character. The inability to relax and dissipate stress, a phenomenon that happens in native ECM by reorganization of physical cross-links or entanglements, or the restrictions that they pose to the spreading, migration, and proliferation of encapsulated cells, are limitations of most static hydrogels (Rosales and Anseth, 2016). In some cases, hydrogel degradation may proceed through hydrolytic or cell-mediated enzymatic degradation (Kharkar et al., 2013). However, the degradation of permanently cross-linked hydrogels presents several drawbacks in TERM applications, such as fast disappearance or deterioration and spatial inhomogeneity of mechanical properties over time. These features pose significant challenges in studying and controlling how cells respond to local biophysical cues, which is increasingly recognized as a key parameter in determining the fate of cells (McKinnon et al., 2014; Rodin et al., 2010).

Reversible Hydrogels Based on Supramolecular Cross-Linking of Polymeric Precursors

Hydrogels based on reversible (or adaptable) linkages that can be broken and reformed in a reversible manner (self-healing) under physiological conditions without external triggers (such as changes in pH or temperature) are becoming increasingly popular in the design of biomaterials (Fig. 1.3.6.3). Several comprehensive reviews covering this topic can be found in the literature (Mann et al., 2018; Saunders and Ma, 2019; Wang and Heilshorn, 2015). The dynamic nature of the linkages (built through physical associations or dynamic covalent bonds) applied to obtain reversible hydrogel systems has significant advantages over static hydrogels. Inherently, it enables the spatiotemporally controlled addition and removal of biochemical signals, repeated changes in matrix mechanics and, having shear-thinning (viscous flow under shear stress) and self-healing (time-dependent

Mater. 27, 1605122. https://doi.org/10.1002/adfm.201605122.)

recovery upon relaxation) characteristics, they allow the encapsulation and delivery of cells though minimal invasive strategies (Guvendiren et al., 2012; Rosales and Anseth, 2016). This set of characteristics further makes them interesting materials to be applied as bioink for 3D bioprinting (Wang and Heilshorn, 2015). This biofabrication strategy is an emerging and rapidly expanding field of research in which additive manufacturing techniques in combination with cell printing are exploited to generate hierarchical tissue-like structures. In fact, the bioinks, materials that combine printability with cytocompatibility, are currently one of the biggest bottlenecks of 3D bioprinting technology. Thus, new polymeric biomaterials that can overcome these limitations are particular needed, making reversible hydrogel systems appealing alternatives in this field. Moreover, self-healing hydrogel with rapid self-integrating properties may provide a novel injectable solution for the regeneration of tissue interfaces needing different spatiotemporal biochemical and biophysical cues but that seamlessly integrate at their interfaces (e.g., bone–cartilage tissue complex).

Among the possible approaches to produce reversible hydrogels, systems based on transient polymeric networks formed through supramolecular cross-linking of polymer chains such as host–guest inclusion complexes (Fig. 1.3.6.3A), multiple hydrogen bonding, or metal–ligand coordination (Fig. 1.3.6.3B–C) are currently among the most promising strategies (Appel et al., 2012; Webber et al., 2016). Here, we highlight some representative studies exploring these reversible hydrogel design strategies with potential application in TERM.

Functionalization of polymers and macromeres with pendant host–guest motifs has been among the preferred strategies to produce building blocks of reversibly cross-linked hydrogels. Examples of these systems are the host–guest inclusion complexes using macrocyclic host molecules such as cyclodextrin (CD) and cucurbit[n]uril (CB[n], n = 5–8), showing high affinity for small hydrophobic guest molecules (Mann et al., 2018; Wang and Heilshorn, 2015; Webber et al., 2016). Although other macrocyclic hosts have been explored (e.g., crown ethers, catenanes, and cyclophanes), CD and CB[n] are the most commonly applied in TERM. This is mainly because of their compatibility with aqueous use since the interaction between host and guest occurs in a hydrophobic cavity that minimizes

polar solvent interactions (Assaf and Nau, 2015; Mann et al., 2018). Both CD and CB[n] bind guest molecules through hydrophobic and van der Waals interactions in the hydrophobic cavity. However, CB[n] has a higher bind versatility. Whereas CB[6] tends to bind neutral and positively charged organic guests, CB[7] binds larger amphiphilic guests, and CB[8] binds positively charged and large organic guests (Assaf and Nau, 2015; Mann et al., 2018). These different affinities contribute to widening the number of possible hydrogel designs. Moreover, different binding affinities exist not only between CB[n], but also between the host and different guest molecules, a particular behavior that has been recently explored to develop hydrogels with a broad range of bulk dynamic properties without changing network topology (Zou et al., 2019). Both natural (e.g., HA) and synthetic polymeric (e.g., polyacrylamide or PEG) precursors have been cross-linked using these recognition motifs to produce reversible supramolecular hydrogels. The precursor polymers can be grafted with either a host or its complementary guest molecule to form hydrogels when the pairs are mixed. This cross-linking strategy has as an additional advantage the possibility of using the same grafted supramolecular motifs for the modular noncovalent functionalization of polymer hydrogel through biorthogonal synthesis pathways.

Numerous hydrogel systems based on these supramolecular cross-linking strategies have been developed and optimized in the past for 3D cell encapsulation and as injectable cell carries (Wang and Heilshorn, 2015). The β-CD–adamantane host–guest pair is perhaps one of most well-known cross-linking systems explored in the TERM field. For example, HA has been modified with these pendant moieties to produce a hydrogel that enables shear-thinning injection and high target site retention (>98%) (Rodell et al., 2015). Stabilization of the network through secondary Michael addition reaction (between thiol- and Michael-acceptor modified HA macromers) further improved the positive outcomes on the treatment of myocardial infarct in an in vivo mouse model. In a similar approach, the low stability and mechanical properties of β-CD–adamantane cross-linked HA has been improved by first promoting the host–guest complexation between monoacrylated β-CD host monomers and adamantane-functionalized HA guest polymers, to fabricate the supramolecular hydrogels by UV-induced polymerization of preassembled host–guest complexes (Wei et al., 2016). These hydrogels demonstrated self-healing behavior and showed promising results as injectable cell carriers, supporting chondrogenesis of human mesenchymal stem cells (hMSCs) and promoting cartilage regeneration in a rat model. Injectable and cytocompatible hydrogels have also been produced based on CB[6]-modified HA mixed with the respective complementary guest, diaminohexane conjugated HA (DAH-HA), that was applied for the controlled chondrogenesis of hMSCs (Jung et al., 2014). Interestingly, this host–guest pair was not only used to produce the hydrogel as a cell carrier, but was also leveraged to functionalize the polymer backbone with a prochondrogenic drug conjugated to CB[6], demonstrating the modular nature of these type of systems. The versatility of this strategy was later explored to support the long-term survival and prolonged transgene expression of bioengineered MSCs, a potential platform biomaterial that can be applied in the treatment of cancer and other intractable diseases (Yeom et al., 2015).

Functionalization of polymers or macromers with multiple hydrogen bonding motifs, such as the quadruple hydrogen bonding motif ureidopyrimidinone (UPy), is another widely reported strategy for the production of supramolecular hydrogels with viscoelasticity, shear-thinning, and self-healing behavior (Saunders and Ma, 2019; Webber et al., 2016). Several hydrogels based on UPy cross-linking have been used as biologic, and recently, also as cell delivery systems. A notable example of this strategy is a dextran-based hydrogel where the polymer backbone was functionalized with multiple pendant UPy units per chain (Hou et al., 2015). This supramolecular hydrogel was used as a cell carrier and drug-delivery system (chondrocytes, bone marrow stem cells, and bone morphogenetic protein 2). Moreover, due to its self-healing and shear-thinning nature, the system has the potential to be applied in the regeneration of complex tissue interfaces.

Metal–ligand interactions are an alternative cross-linking strategy that are gaining relevance in the biomaterials field. This class of supramolecular cross-linking, in which two or more ligands donate a nonbinding electron pair to empty orbitals in a transition metal cation, include the well-known Fe-catechol coordination complexes that have stability and strength approaching covalent bonds (Mann et al., 2018; Webber et al., 2016). Several mussel-inspired metal–ligand hydrogels based on Fe-catechol cross-linking have been developed in the past few years. For example, HA functionalized with pendent catechol can be cross-linked with Fe^{3+} ions, resulting in reversible, self-healable, and tissue-adhesive hydrogels (Lee et al., 2016; Park et al., 2016; Shin et al., 2015). These biocompatible injectable hydrogels were demonstrated to be effective for cell transplantation (Shin et al., 2015) and could potentiate the in vivo stem cell-mediated angiogenesis and osteogenesis potential in tissue defect models (Park et al., 2016), making them promising materials for TERM applications.

The unique rheology and gelation properties of the above-mentioned supramolecular hydrogels make them obvious candidates as bioinks materials for 3D bioprinting. Burdick's research group has published a representative example of such applications. Their approach explores an interesting printing strategy based on HA bioink that cross-links through supramolecular assembly of β-CD–adamantane host–guest complexes (Highley et al., 2015; Ouyang et al., 2016). Since the host–guest supramolecular bonds can be disrupted by the shearing stress applied during the extrusion process and rapidly reform after printing without any further trigger, this system allows reaching new levels of 3D printing complexity, such as the direct writing of shear-thinning bioinks at any position of a 3D space into

supporting self-healing hydrogels made of similar materials. The printed structures can be further stabilized by secondary cross-linking by, e.g., introducing methacrylates into the HA and post-printing photopolymerization. The versatility of this platform has shown that supramolecular cross-linked hydrogels are biomaterials with new and existing properties to be explored in the field of 3D bioprinting.

Hydrogels Based on Natural Supramolecular Self-Assembly

Based on DNA self-assembly capacity, hybrid DNA hydrogels can be developed using short DNA sequences mixed or coupled onto the polymer backbones physically or chemically. Contrary to DNA-based hydrogels addressed in the section "Multifunctional Biomaterials Based on DNA," hybrid hydrogels only require a small quantity of DNA, and self-assembled DNA acts as both the cross-linker and switchable element (Shahbazi et al., 2018; Shao et al., 2017). For example, Li and colleagues combined single-stranded (ss) DNA attached to a polymer backbone with a double-stranded DNA with ending sequences complementary to the ssDNA to develop a biodegradable bioink with encapsulated cells (Li et al., 2015). The hydrogel was biocompatible and could be used for rapid formation of 3D constructs for tissue engineering.

In another very interesting approach, a stimuli-responsive liposome–DNA hydrogel was created by the functionalization of polyacrylamide with cholesterol-modified DNA motifs (Lyu et al., 2018). The cholesterol interacts with the lipid bilayers of the liposomes and cross-links the polymer in a reversible manner (sol–gel–sol transitions) due to the thermosensitive nature of DNA motifs. Moreover, the system can serve as a release system upon the presence of a restriction endonuclease enzyme.

Peptides are versatile building blocks for supramolecular assembly of tissue engineering constructs. The use of peptides to create biomaterials provides a number of advantages such as natural biodegradation, and the possibility to mimic the structural and functional aspects of native ECM. Peptides can be used alone, or designed for conjugation or coassembly with polymers in order to improve bioactivity and structural complexity. In particular, the supramolecular assembly capacity of peptide amphiphiles (PAs), consisting of a charged hydrophilic head, a β-sheet forming domain, and a hydrophobic alkyl tail (Fig. 1.3.6.3D), has been used to create one-dimensional self-assembled fibrillar structures with many applications in biomedicine (Borges et al., 2017; Brito et al., 2019; Radvar and Azevedo, 2019; Webber et al., 2016). Although not covered in this chapter, for more information readers are directed to a recent review on the topic by the Stupp's group, pioneers in the field (Hendricks et al., 2017).

PA also can be coassembled with hydrophobic polymer tails or polypeptides to construct self-assembling bioactive and biomimetic hydrogels (Borges et al., 2017; Radvar and Azevedo, 2019). In a recent work, a biodegradable self-healing polymer–peptide hydrogel consisting of a poly(γ-glutamic acid) polymer network was physically cross-linked via conjugated β-sheet peptide sequences (Clarke et al., 2017). The authors could tailor the mechanical properties of the hydrogels over an order of magnitude range of 10–200 kPa, which is in the region of many soft tissues, by altering the β-sheet peptide graft density and concentration. In a different approach, using hybrid PA–protein systems, Mata and colleagues produced complex hierarchical fibrillar membranes and 3D printed constructs for tissue engineering applications. On one hand, hybrid PA–elastin-like polypeptides were used as building blocks to fabricate foldable bioactive membranes that guide the growth of endothelial and adipose-derived stem cells into tubular structures (Inostroza-Brito et al., 2015). In a later work, using a range of ECM biomolecules as the protein component of the hybrid system, adipose-derived stem cells were bioprinted with high viability into complex hierarchical structures, demonstrating that the combination of self-assembly with 3D bioprinting has a huge potential in the field (Hedegaard et al., 2018).

Soft Nanocomposite Smart Materials

The nanoscale interactions between the cells and the tissue microenvironment control the function and fate of the cells. Hence, the rational design of biomimetic and functional biomaterials is subjective to these cues (Memic et al., 2015). The design of "smart materials," stimuli-responsive materials that respond to external stimuli such as pH, temperature, magnetic, electric, or any other stimulus, is gaining increased relevance in the biomedical field (Merino et al., 2015). Among the numerous strategies to incorporate new and tunable functionalities in biomaterials, the incorporation of nanoparticles in hydrogels has become a popular option, not only as mere reinforcement nanofillers, but also as functional nanoelements to meet the specific needs of the different tissues (Alarçin et al., 2016). These nanoelements can be manipulated to interfere with cell processes like growth, differentiation, proliferation, and alignment in a controlled manner (Carrow and Gaharwar, 2015). In this section, we highlight some of the latest developments on soft nanocomposites developed using natural materials.

Stimuli-Responsive Soft Nanocomposites

The intrinsic properties of iron-based magnetic nanoparticles (MNPs) are highly attractive to produce responsive biomaterials providing the liberty to control the spatial distribution and orientation of MNPs through remote magnetic fields (Tibbitt et al., 2015). For example, a hybrid hydrogel composed of type II collagen, hyaluronic acid, and polyethylene glycol, incorporating MNPs was guided to defect tissue sites using a remote magnetic field (Zhang et al., 2015). This work paves a path for further investigation of tunable magneto-responsive nanocomposites for minimally invasive tissue engineering strategies.

Furthermore, the use of rod-shaped CNC, the nature's "carbon nanotubes," has been explored by our group and others to cross-link and reinforce soft HA hydrogel networks (Domingues et al., 2015) and to produce anisotropic domains within natural and synthetic 3D hydrogels (Araújo-Custódio et al., 2019; De France et al., 2017). These CNC could also be decorated with MNPs to create injectable gelatin hydrogels presenting an aligned microstructure, which was achieved by the alignment of the nanoparticles under the influence of low magnetic fields (106 mT) (Araújo-Custódio et al., 2019). At the same time, hydrogel 3D anisotropy induced the alignment of encapsulated and seeded adipose tissue-derived stem cells, when compared with isotropic hydrogels.

In a different approach, the incorporation of electroconductive nanoelements can play a key role in the improvement of regenerative strategies for electro-responsive organs/tissue, such as the heart, muscles, and neural tissue (Palza et al., 2019). For example, an electro-responsive nanogel was achieved via incorporation of gold nanoparticles in a chitosan hydrogel. The amount of nanoparticle in the hydrogel was directly proportional to electrical conductivity. Mesenchymal stem cells seeded on these hydrogels showed high viability and were able to migrate and proliferate, while showing evidence of accelerated cardiomyogenic differentiation in compassion with control hydrogels (Baei et al., 2016).

Future Perspectives

Tissue engineering was born with the promise of revolutionizing health care by providing artificially engineered functional tissue and organ substitutes (Langer and Vacanti, 1993). During the last few decades, extraordinary accomplishments have been achieved and significant scientific knowledge spanning from cell biology up to advanced biomaterials synthesis and processing technologies has been produced. However, the vast majority of strategies has been developed as "one-size-fits-all." Addressing the increasing demand for precision and personalized medicine treatments, in which health care is tailored on the basis of individual complexities (Hodson, 2016), the extension of this concept to the field of TERM will allow to produce biomaterials with precise and specific functions that will be integrated with technological advances such as microfabrication, 3D bioprinting, and stem cells, to select the most suitable approach to treat diseases or injuries in a specific patient or subset of patients (Aguado et al., 2018). Furthermore, using the same principles, personalized tissue constructs have the incomparable potential to be used as disease models that will change the future of drug-discovery pipelines in a manner that substantially deviates from traditional platforms, namely, 2D cell monolayer cultures and animal disease models (Skardal et al., 2016).

The combination of blood derivatives with biomaterials has emerged as a synergistic strategy to modulate the release of signaling molecules that orchestrate the swing between tissue regeneration, tissue repair, and scar formation (Mendes et al., 2018a). In this sense, the use of biomimetic biomaterials described in this chapter incorporating standardized blood derivatives might enable engineering the wound-healing environment toward tissue regeneration. In a translational perspective, we think that this strategy holds great potential to produce biomimetic and bioactive materials for different TERM applications due to the increasing trend on the production and use of standardized clinical-grade human PL as a xeno-free alternative to animal-derived serum in cell culture, which represents an advantage over similar materials such as dECM. This further strengthens the use of blood derivative formulations not only for research purposes, but also in terms of compliance with good manufacturing practices and clinical relevance.

DNA-based materials represent a forefront frontier for the biomaterials field due to their versatility. In particular, an underexplored area is the use of DNA origami for TERM applications. These nanostructures could be used to provide direct cell behavior on surfaces (2D) and hydrogel (3D) environments. For example, the creation of anisotropic DNA origami patterns, as shown in a chemically modified graphene surface (Yun et al., 2012), could be used to provide enough biophysical cues to guide the appropriate stem cells toward the regeneration of anisotropic tissues. Furthermore, the potential of DNA origami nanostructures to bind serum proteins could be explored for the selective/preferential binding of GFs and to control its delivery to target tissues.

In addition, so far mostly the methods to achieve anisotropy within hydrogel matrices depend on external stimuli such as magnetic or electrical, which is not universally practical for large-scale production (Chen et al., 2018). Hence, we believe that continued development in this area of soft nanocomposites is essential to acquire scalable orderly structures, with excellent mechanical properties, and novel responses to stimuli for use in innovative applications in the fields of biomedicine, sensors, actuators, and biomimetic materials.

Using an out-of-the-box concept, a new generation of living biomaterials that contain genetically modified bacteria have been proposed to modulate the microenvironment in a dynamic way. For this, bacteria are engineered to produce proteins and GFs triggered by external stimuli such as molecules and drugs, in a dose-dependent manner (Hay et al., 2018; Sankaran et al., 2018). Furthermore, the combination of additive manufacturing or other advanced technologies and bacteria (Liu et al., 2018; Schaffner et al., 2017) might bring a new generation of living responsive materials on demand, if serious bacterial safety concerns are addressed.

Despite the added functionalities that provide many new materials, the clinical translation of tissue-engineered products has been significantly slower than would be expected. The complexity of some strategies represents the main barrier for clinical translation, as practical, economic, and

regulatory barriers favor simplicity (Abou-El-Enein et al., 2017; Darnell and Mooney, 2017). However, tissues and organs have multiscaled architectures, multiple cell types and ECM components, and possess a complex vascular, neural, and lymphatic network to support cell activity in a finely orchestrated dynamic microenvironment. Balancing the need for simplicity with this natural complexity creates the necessity for biomaterials researchers to identify the strategies, within the large design space now available, with the minimum necessary complexity to recreate native tissues.

Questions

1. What strategies can be used to control the temporal, spatial, and type of released bioactive molecules from blood derivatives?
2. Which advantages and disadvantages do natural polymers offer?
3. What characteristics should an ideal ECM-mimetic hydrogel have?
4. What characteristics of DNA are critical to enable its use as a biomaterial?
5. Identify two different types of supramolecular cross-linking strategies that can be applied to produce reversible hydrogels using polymeric precursors.

1.3.6A
Processed Tissues

RAYMOND M. WANG[a], PAMELA DURAN[a], KAREN L. CHRISTMAN[*]

Department of Bioengineering, Sanford Consortium of Regenerative Medicine, University of California San Diego, La Jolla, CA, United States

Introduction

The prevalence of chronic tissue injuries and diseases has spurred extensive research into developing methods to preserve, process, and modify tissues for treating and understanding these sources of morbidity and mortality. Healthy donor tissue is consistently under heavy demand, with over 10,000 patients added annually to the organ transplant waitlist, which was over 110,000 in the United States in 2016 (OPTN/SRTR, 2018). Unfortunately, a large amount of viable tissue is not successfully transplanted before expiring. Standard practice preserving tissue before transplantation is on ice with a reported storage life of several hours. With logistical challenges, difficulty of surgical transplantation, and limited medical resources, utilizing all organs for transplant becomes impossible given the available time. Furthermore, the ever-growing patient population with chronic tissue diseases increases both demand and shortage of available healthy donor tissue, thus prompting investigation into methods for enhanced tissue preservation and alternative treatments. In particular, tissue decellularization methods isolating the extracellular matrix (ECM) scaffold have shown promise for developing novel proregenerative materials. These naturally derived materials provide biocompatible and bioactive scaffolds that can be improved by modification of native properties or utilization as a delivery vehicle. Processing methods also allow use of nonhuman tissue sources by masking or removing epitopes that initiate immune rejection responses from xenogeneic derived materials. We will discuss methods and developments in the preservation of tissue, methods of decellularization to isolate the tissue ECM scaffold, and finally, how decellularized tissues have been utilized to create new clinical treatments and improve understanding of tissue diseases.

Cryopreservation and Vitrification

In its ideal form, tissue preservation is the principle of maintaining quality of a biological sample outside its host for extended time periods and allowing relatively stable restoration to a healthy functional state upon reintroduction into a metabolically active system. As sustaining tissue by mimicking host system conditions ex vivo is impractical long term, technology has focused on cooling methods to halt unregulated processes within tissue samples. From a thermodynamic point of view, activity within an isolated system is a consequence of the motion of matter and transfer of energy among its constituents. As the temperature of a system is a measure of motion of molecular constituents, minimizing temperature to a low enough point provides a mechanism for diminishing the molecular motion in a system (Wowk, 2010). Based on a biochemical viewpoint, this logical approach similarly applies as temperature influences the rate of chemical reactions and enzymatic activity, with these processes effectively halting at sufficiently low temperatures.

For tissue preservation, two phases of the process are particularly sensitive: (1) the cooling of tissue and (2) restoration to normal conditions. Two cryogenic or cooling to low temperature methods for extended tissue preservation are cryopreservation and vitrification. Cryopreservation is the conventional idea of freezing biological samples for long-term storage. However, simple freezing of tissue alone is lethal as it mainly consists of water. Water organizes into ice crystals below 0°C that push away other tissue components, causing intracellular rupture, extracellular tearing, and osmotic shock as solute components are locally concentrated from displacement by crystal formation (Fig. 1.3.6A.1A and B). To minimize these effects, cryoprotectants (e.g., cell-permeable dimethyl sulfoxide) hindering organized ice crystal formation along with optimal cooling rates for equilibrating osmotic pressures are required (Gao and Critser, 2000). As optimal cooling rates are cell specific (Leibo and Pool, 2011), cryopreservation has seen limited preclinical and clinical success for densely packed multicellular organs (Bakhach, 2009). The large volumetric size of human tissue is also an issue as temperature changes do not permeate evenly throughout. Otherwise, cryopreservation is more conventionally utilized with cellular suspensions, most notably for preservation of red blood cell (Al-Otaibi et al., 2019), gamete (Cil and Seli, 2013), and stem

• **Figure 1.3.6A.1** Issues with ice crystal formation for tissue preservation by cryopreservation (*red arrow*) or vitrification and restoration through uneven thawing (*yellow arrows*) versus even thawing methods throughout the tissue (*green arrow*). (A) Tissue at 37°C homeostatic conditions with Brownian motion of components such as water molecules (H_2O), ions (I) and biomolecules (B). (B) Tissue classically cryopreserved using cryoprotectants (C) at low concentrations and slow cooling rates (1°C/min) allows water molecules to assemble into ice crystals causing cell lysis, disruption of cell–cell contacts, and toxic localized segregation of components. (C) Vitrification by rapid cooling rates (>1000°C/min) and high cryoprotectant concentrations creates a high-viscosity, glassy state preventing ice crystal organization and halting molecular motion and activity. However, restoration by uneven thawing with slow heating methods can allow ice crystal organization to arise. (D) Even thawing methods with magnetic nanoparticles provide distributed inductive warming for restoring molecular activity throughout and allow for return to the original tissue state.

cell storage (Jang et al., 2017b) with standardized guidelines for certain cell types readily available.

Clinical success utilizing cryopreserved arterial allografts has been demonstrated for vascular conditions such as peripheral artery bypasses for treating critical limb ischemia. Cryopreservation of arterial allografts minimizes tissue degradation, preventing calcification and dilation over time. Treatment of patients by cryopreserved arterial allografts for limb salvage and abdominal aorta reconstruction showed favorable results compared with outcomes from conventional

synthetic grafts (Castier et al., 1999; Gournier et al., 1995). Interestingly, lack of temperature control freezing and rapidly thawing grafts utilized in these studies is known to elicit extensive cellular damage and death (Pascual et al., 2001). However, these studies have speculated the rapid freeze–thaw procedure and extensive rinsing to remove dimethyl sulfoxide cryoprotectant partially acted as a decellularization method (Castier et al., 1999). Thus, these results could instead imply efficacy of decellularized ECM scaffold grafts for vascular reconstruction in humans versus actual cryopreservation of viable tissue. For other densely packed tissues that require viability throughout for functionality, cryopreservation has shown limited feasibility for translation.

Vitrification addresses biophysical issues from cryopreservation by solidifying tissue with high concentrations of nontoxic cryoprotectants such as sucrose or antifreeze proteins (Kim et al., 2017) forming a high-viscosity, glassy state with immediate cooling from physiological to −196°C liquid nitrogen storage temperatures in under a second, leading to minimal ice crystal formation. This method reduces mechanical disruption from freezing and does not require cell- or tissue-optimized cooling rates (Fig. 1.3.6A.1C). Following vitrification, long-term preservation theoretically only requires maintaining storage temperatures with relevant equipment (Fahy and Wowk, 2015). However, tissue damage is still a potential issue with larger volumes during the thawing process as uneven heating can create nonhomogeneous molecular arrangements and ice crystal formation with standard convection heating or slow thawing methods (Gao and Critser, 2000). Breakthroughs in heating nanotechnology, such as utilizing nanoscale mesoporous silica-coated iron oxide particles that excite with radiofrequency, have demonstrated scalable capabilities of evenly warming vitrified tissue throughout (Fig. 1.3.6A.1D). Porcine aortic heart valve leaflet and carotid artery tissue sample up to 50 mL volumes maintained similar cell viability and mechanical properties to fresh tissue, while standard convective methods caused extensive cell death (Manuchehrabadi et al., 2017).

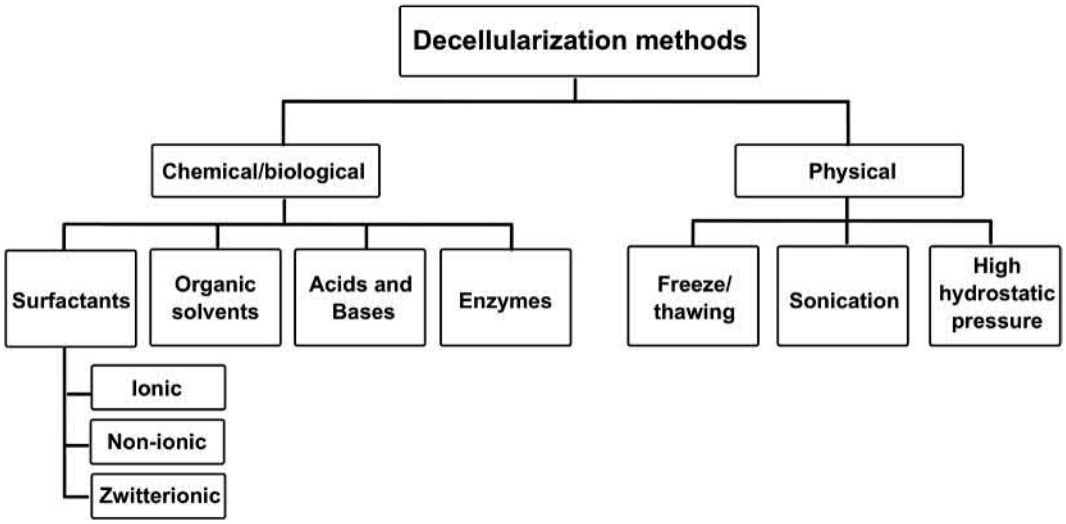
Since early attempts to preserve tissue, vitrification has made great strides in long-term preservation, and incorporation of nanotechnology has suggested the potential of tissue restoration with minimal damage. Continued testing and optimization for whole human tissue volumes and different architectural structures will need to be confirmed. Tissue functionality and suitability for transplantation still need assessment as high cryoprotectant concentrations and cold temperatures can elicit undesirable cellular shock responses (Corwin et al., 2009). Addressing clinical setting feasibility and logistical challenges will also be important for future translation of this technology (Giwa et al., 2017).

Tissue Cross-Linking

Different cross-linking methods have been utilized with tissue to augment the durability and decrease the rate of in vivo enzymatic degradation. Bioprosthetic heart valves have been extensively fabricated with various cross-linking methods. Glutaraldehyde-treated heart valves were introduced in the late 1960s (Jayakrishnan, 1996). Glutaraldehyde reacts with amino acids, such as histidine and tyrosine, forming covalent bonds between adjacent collagen chains. Aside from reducing biodegradation, glutaraldehyde preserves tissue viscoelastic properties (i.e., strength and flexibility). Allografts and xenografts, fabricated from porcine aortic valves or bovine pericardium, have been used for total valve replacement, with the former representing the largest proportion (Simionescu, 2004). However, glutaraldehyde-treated valves commonly cause long-term calcification after implantation. One reason for this calcification is the presence of cytotoxic aldehyde group residuals from incomplete binding of glutaraldehyde to the collagen network (Siddiqui et al., 2009). To prevent or reduce calcification, reagents to neutralize free aldehyde groups or different nonaldehyde cross-linker agents have been used. Amino acids with reactive primary amines can neutralize aldehyde residues, such as glutamine and lysine, aminobisphosphonates, toluidine blue, and alpha-amino-oleic acid. Even though these reagents elicit decreased calcification, associated host cellular reactions can occur. Glutaraldehyde-treated valves pretreated with alpha-amino-oleic acid induced chronic inflammatory responses characterized by macrophage, plasma cell, and lymphocyte infiltration at the host and porcine tissue interface (Butany et al., 2007). Inadequate fixation, leading to retention of antigenicity, might also induce a humoral immune response (Human, 2001).

Nonaldehyde fixation methods have also been investigated. The agent 1-ethyl-3-(3-dimethyl aminopropyl) carbodiimide hydrochloride (EDC) coupled with N-hydroxysulfosuccinimide (sulfo-NHS) cross-links nonspecifically all proteins by linking amine and carboxyl groups by amide bonds. The byproducts of the fixation process are water soluble, easily rinsed away, and nontoxic (Girardot and Girardot, 1996; Simionescu, 2004). EDC/NHS cross-linking with porcine aortic roots and porcine pericardium in a short-term study demonstrated decreased calcification after implantation in vivo in a rat model. However, long-term preclinical and clinical studies are still necessary to evaluate this technique (Girardot and Girardot, 1996; Timek et al., 2002). Other processes based on photochemical reaction provide an efficient and rapid method. Dye-mediated photooxidation consists of dye treatment (i.e., methylene blue) and delivering oxygen while exposing tissue to ultraviolet light. This results in modification of tyrosine, methionine, and histidine residues. Studies demonstrated successful calcification reduction after implantation of a bovine pericardium-derived prosthetic heart valve in a sheep model. While pericardial tissue tears occurred in clinical trials, issues stemmed from biomaterial design as higher compliance of cross-linked tissue lead to abrasion-induced tearing (Svendsen CA., 2000; Vesely, 2003).

Aldehyde-fixed bioprosthetic heart valves have been used for 50 years, demonstrating hemocompatibility and tissue compliance, however, there are still issues regarding clinical durability and biocompatibility. Other methods have been investigated, but long-term results are still an open question. To increase xenogeneic material biocompatibility,



• **Figure 1.3.6A.2** Schematic of decellularization methods.

decellularized scaffolds have become widely adopted not only for prosthetic valves, but also for reconstruction and treatment of different tissue types as discussed in following sections.

Decellularization

Over the past two decades, tissue decellularization has shown promise for tissue engineering and regenerative medicine approaches. Decellularized scaffolds retain non-cellular components (i.e., ECM) representative of native tissue. These characteristics promote cell growth, survival, and development (Hussein et al., 2018; Sasaki, 2009). An effective decellularization process depends on the type, age of tissue and method used. A summary of decellularization methods (Fig. 1.3.6A.2) is presented below, while in-depth reviews on methods and effects on composition and structure of decellularized scaffolds have been previously published (Crapo et al., 2011; Keane et al., 2015).

Decellularization Methods

Chemical/biological methods: Different chemical agents are commonly used as the main agent of the decellularization process; these include surfactants, organic solvents, acids, and bases. Enzymes are used in combination with these chemical agents to enhance removal of DNA (e.g., DNAse, RNAse, trypsin). Surfactants are classified as ionic, nonionic, or zwitterionic. They disorganize the phospholipid cellular membrane leading to cell lysing. Examples include sodium dodecyl sulfate (SDS), Triton X-100, and sodium deoxycholate. SDS, an ionic detergent, has been widely used in the decellularization process for diverse tissue types, from tissues to whole-organ decellularization. In the early 2000s, small intestinal submucosa (SIS) and urinary bladder were decellularized by mechanical delamination followed by treatments with acids and bases (Abraham et al., 2000; Hodde et al., 2002). SDS has been associated with efficient cellular removal, though loss of ECM components and structure to varying degrees are expected due to the strength of this agent. For additional preservation of the organ structure, perfusion of the surfactant through the native vasculature allows for whole-organ decellularization first demonstrated with a rat heart (Ott et al., 2008). Isolation of a whole decellularized organ initiated an entirely new field of study for recellularization of whole decellularized tissue as a potential alternative source of transplant tissue (see "Applications of Decellularized Tissues"). Similar methods for SDS perfusion have since been applied for numerous tissues including rabbit bladder (Miyazaki and Maruyama, 2014), liver (Shupe et al., 2010; Baptista et al., 2011), rat lung (Petersen et al., 2010), rat uterus (Miyazaki and Maruyama, 2014), porcine urethra (Simoes et al., 2017), porcine kidneys (Hussein et al., 2018), and rat spleen (Zheng et al., 2015). Alternatively, thin or minced tissue under agitation allows for diffusion of SDS throughout. Agitation of human tendon, with SDS, resulted in preservation of collagen content and ultimate tensile stress and elastic modulus similar to native tissue (Pridgen et al., 2011). Decellularized minced porcine skeletal muscle resulted in cellular removal and preservation of ECM components (e.g., sulfated glycosaminoglycans) (Ungerleider et al., 2015). In contrast, SDS (0.1%–1%) decellularization of minced porcine pancreas removed over 30% of ECM proteins compared to native tissue, as analyzed by mass spectrometry, leaving mainly fibrillar collagen (Gaetani et al., 2018). Loss of collagen fiber organization was also observed with 24 h SDS treatment of porcine heart valve leaflets (Zhou et al., 2010). Thus, selection of SDS based on efficient decellularization alone is not always an ideal choice due to tissue- and processing-specific effects on native ECM properties.

Triton X-100 is another surfactant that is used for the fabrication of acellular scaffolds. This nonionic agent has been mainly used in combination with other surfactants or enzymes. For whole-organ decellularization, such as rat kidneys, triton X-100 alone led to incomplete cellular removal, and disruption of basement membrane. However, triton combined with SDS resulted in efficient absence of nuclei, preservation of growth factors and underlying vasculature,

with a small loss of collagen IV (Caralt et al., 2015). Human urethra decellularization by triton and SDS preserved biomechanical properties compared to native tissue, defined by similar Young's modulus (Kajbafzadeh et al., 2017). Triton X-100 has also been used with another ionic surfactant, sodium deoxycholate, which dissociates cellular membrane protein interactions. Rat spinal cord decellularization with triton and sodium deoxycholate preserved collagen bundles and porous structure (Zhu et al., 2018).

Tri(n-butyl) phosphate (TnBP) is an organic solvent that disrupts protein–protein interactions (Keane et al., 2016). TnBP has been used in soft tissues, especially in tendon decellularization, due to high protein content. TnBP alone maintained ECM composition, and mechanical properties of porcine diaphragm tendon (Deeken et al., 2011). However, TnBP treatment alone can cause a decreased degree of collagen cross-linking, which may affect the long-term biomechanical properties of the tissue. Thus, surfactants can be used in combination with this organic solvent to stabilize it. TnBP with SDS resulted in preservation of collagen structure and elastic modulus (Xing et al., 2014).

Enzymes have been used in combination with chemical agents to break down DNA (DNAse) or RNA (RNAse) fragments, and to break cell–matrix interactions (trypsin). Decellularization of human cornea only by SDS led to cytoplasmic debris removal, but was inefficient for nuclear debris; addition of DNAse eliminated nuclear debris, resulting in increased tissue transparency (He, 2016). Enzyme agents have been used for blood vessel decellularization in rabbit, porcine, and human tissue sources. Combination of triton X-100, TnBP, and DNAse led to efficient cellular removal of human saphenous vein (Kumar Kuna et al., 2018). Rat sciatic nerve decellularization with DNAse and RNAse resulted in cellular removal, and preserved collagen and laminin content (Philips et al., 2018).

Physical methods: Mechanical processes decellularize ECM by eliminating cell–matrix interactions and lysis of cells. These methods include freeze and thawing, sonication by ultrasound, and high hydrostatic pressure. Alternating between freezing (at −80°C or immersion in liquid nitrogen) and thawing (37°C) cycles has been demonstrated to preserve ECM composition and biomechanical properties. Decellularization of bovine tendon after five cycles of this physical method, together with DNAse led to removal of cell nuclei, and preservation of collagen III and growth factors (Ning et al., 2017). However, the freezing and thawing method is often not efficient for other tissue types. Addition of this physical method to porcine uterus decellularization led to increased protein content, but also maintained nuclei content as compared to a chemical agent process without freezing/thawing (Campo et al., 2017).

Exposure of tissue to ultrasound at high frequencies can increase the effectiveness of the decellularization process. Sonication alone has been inefficient for cellular removal as demonstrated in human cornea processing (He, 2016). However, in skeletal muscle, combination of this method with enzymes efficiently removed cellular nuclei, retained sulfate glycosaminoglycans, and preserved biomechanical properties similar to native tissue (Lin et al., 2014).

Pressures around 1000 MPa, with an onset temperature set at 10 or 30°C, have also been applied to tissues as a decellularization method. After the applied pressure, porcine corneas were efficiently decellularized, with preservation of glycosaminoglycan content (Sasaki, 2009). In another study of porcine aortic blood vessels, the mechanical properties were also similar to native tissue (Funamoto et al., 2010). A further in vitro study with endothelial and smooth muscle cells demonstrated that a pressure of 200 MPa for only 10 min was enough to cause cellular disruption (Mahara et al., 2014).

Quality of Decellularization

Besides solely evaluating removal of cellular content, ideally decellularized material also retains the vast majority of extracellular components to most faithfully represent the native extracellular environment. Realistically, removal of cellular content with decellularization methods also strips ECM of its native components and structure to some extent. Therefore, complete removal of cellular content is impossible without excessive destruction of the ECM. Instead, decellularization methods require balancing preserving original ECM qualities and sufficient removal of cellular debris and other content that could stimulate undesirable responses. This can be accomplished by optimizing selection of the decellularization agents along with amount and time of exposure.

Commonly, ECM proteins are investigated for retention post-decellularization. Although largely consisting of structural proteins such as different isoforms of collagen, the ECM consists of a spectrum of proteins providing a multitude of functions including mechanical stiffness, elasticity, adhesion sites, and mechanotransduction signaling (Chapter 2.1.5). General composition can be assessed by histological or more specific immunolabeling staining, or breaking down the scaffold for gel electrophoresis. For broad coverage analysis, high-throughput proteomic methods such as mass spectrometry allow for determining the protein profile. Furthermore, targeted proteomics methods have demonstrated the potential for quantitative comparison of decellularized ECM protein composition to native tissue, which can measure the quality of ECM retention versus effective decellularization (Calle et al., 2016; Gaetani et al., 2018).

Carbohydrate structures maintained in decellularized ECM such as proteoglycans and glycoproteins provide additional functional properties including mechanical strength and compressive resistance, maintaining the charge and hydration of the ECM, regulating cellular activity through environmental cues, and growth factor retention by covalent binding or electrostatic interaction. These properties provide functional benefits such as enhanced local retention of heparin-binding growth factors from endogenous sources or exogenous growth factor delivery (Pieper et al., 2002; Seif-Naraghi et al., 2012; Sonnenberg et al., 2015). For quantification of the sulfated glycosaminoglycan content, Blyscan or dimethylmethylene blue assays can be used, while more specific assessment requires immunolabeling or mass spectroscopy methods (Klein et al., 2018; Noborn et al., 2016). In-depth evaluation of carbohydrate composition in

decellularized tissues and influence on downstream applications is an understudied area despite their known importance in the native tissue, and standardized evaluations could be important for future decellularized material development.

Remaining nucleic acid content such as microRNA encapsulated into matrix-bound nanovesicles has been implicated as a contributor to the bioactive responses of decellularized ECM scaffolds. Based on RNA-sequencing analysis, these responses have included proremodeling macrophage polarization, cell survival, cellular growth and development, and cell cycle progression (van der Merwe et al., 2017, 2019; Huleihel et al., 2016, 2017). Given these characteristics and observations of matrix-derived nanovesicles, their content might be another property that should be more commonly evaluated.

Besides compositional retention, structural and mechanical preservation is also important. Structural organization can be generally studied by histological staining (Aamodt and Grainger, 2016) or electron microscopy for high-resolution imaging of nanoscale architecture (Stephenson et al., 2016). Mechanical properties at the macroscale can be evaluated by biomechanics testing methods such as uniaxial, biaxial, or indentation loading for measuring the stress versus strain relationship of the processed tissue (Black et al., 2008; Griffin et al., 2016). Assessments of mechanical features relevant to the cellular microenvironment can be achieved by atomic force microscopy methods (Klaas et al., 2016; Jorba et al., 2017; Giménez et al., 2017). Since these are commonly used for studying properties of native tissue, comparisons between the pre- and post-decellularization state can be readily adapted.

Decellularization, by definition, seeks to isolate ECM by removal of cellular content and debris that can elicit adverse immune responses. Ensuring sufficient decellularization is critically important before clinical translation as inadequate decellularization, such as with early decellularized heart valves, can elicit severe immune rejection and harm to patients (Simon et al., 2003). Double-stranded DNA content from lyzed nuclei is a common surrogate marker for measuring the extent of decellularization as it is known to stimulate inflammatory responses, such as type I interferon pathways in macrophages (King et al., 2017; Brown et al., 2009). In general, cutoffs of <50 ng/mg dry ECM weight, <200 base pair DNA fragment length, and lack of visible nuclear material with nuclear counterstains, are commonly cited based on empirical observations of minimal adverse host responses from commercial and custom decellularized materials fitting these parameters (Gilbert et al., 2009; Brown et al., 2009; Crapo et al., 2011). However, these thresholds may not correlate with biological significance and specific understanding of the underlying mechanism is needed before the field sets such specifications (see Section 2.2). Furthermore, other cellular debris such as remnant mitochondria and cell membranes can elicit persistent proinflammatory macrophage responses (Londono et al., 2017).

As opposed to evaluating acellularity that has sometimes demonstrated poor prediction of graft acceptance (Kasimir et al., 2006), other optimized methods have focused on specifically targeting sourcing of antigenicity for removal. Several xenogeneic epitopes such as the α-Gal, a carbohydrate structure absent in humans and Old World monkeys, elicit immune rejection responses from anti-α-Gal antibodies. These adverse host responses act as a major immunological barrier for xenografts. For therapeutic applications, decellularization and further processing (i.e., partial enzymatic digestion) have been shown to reduce α-Gal content to minimal quantities along with demonstration of a lack of anti-α-Gal antibody-driven host responses in Old World primate models (Wang et al., 2017b; McPherson et al., 2000; Daly et al., 2009). However, given the repercussions detergents have on ECM preservation, milder stepwise methods have been developed utilizing optimized solvents for solubilization of hydrophilic and lipophilic sources of antigenicity (Wong and Griffiths, 2014). These methods have demonstrated improved preservation of ECM properties such as collagen alignment, elastin content, and mechanical properties, while eliciting similar or improved immunological outcomes such as milder cellular infiltration and lesser fibrous capsule thickness (Wong et al., 2013, 2016). Interestingly, residual antigenicity based on IgG binding from antibovine conditioned rabbit serum on treated bovine-derived scaffolds determined no correlation between the degree of antigen removal and residual nuclei content. This result indicates limitations of DNA content quantification for predicting graft acceptance (Wong et al., 2011). For evaluation, specific antigens within decellularized materials can be immunolabeled for staining or ELISA analysis. Unknown graft-specific antigens can be evaluated by collection and analysis of serum-isolated antibodies in an animal model post-implantation (Sandor et al., 2008). High-throughput methods utilizing serum IgG immunoprecipitation and liquid chromatography tandem mass spectrometry have demonstrated broad coverage and identification of sources of antigenicity from native bovine tissue that could provide rapid antigen identification of tissue-derived materials (Gates et al., 2017).

Lipids are overall undesirable in decellularized tissue as they can interfere with proper decellularization and further scaffold processing (e.g., digestion), and elicit cellular responses uncharacteristic of the tissue of interest. Although decellularization methods remove some content, additional rinsing steps in organic solvent such as isopropyl alcohol are usually needed for complete removal (Ungerleider et al., 2015). These steps are especially important with older human tissue due to higher fat content compared to young adult porcine tissue commonly used in protocols (Sackett et al., 2018; Johnson et al., 2014). Confirmation by histology such as Oil Red or with a quantitative assay such as colorimetric sulfo-phospho-vanillin interaction with lipid content (Cheng, 2011) can assure adequate lipid content removal. Ultimately, understanding of isolated ECM characteristics and higher scrutiny of antigenicity are critical for continued advancement and successful clinical implementation of decellularized materials.

Post-decellularization Processing and Modifications

Milling for ECM Powder and Partial Enzymatic Digestion for Hydrogel Formation

Additional processing can be performed on isolated ECM material based on intended application (see "Applications of Decellularized Tissues"). Following decellularization, isolated ECM can be frozen and lyophilized for characterization and long-term storage. Although useable as its native scaffold, mechanical breakdown of the native architecture into a homogeneous ECM powder provides flexibility for applying material in in vitro and in vivo platforms. ECM powders can be formed with a mortar and pestle following freezing with liquid nitrogen or more uniformly ground by milling lyophilized material (Fig. 1.3.6A.3D). This powder can be directly mixed with a liquid carrier (Fig. 1.3.6A.3E) or alternatively processed into a hydrogel by partial enzymatic digestion (Fig. 1.3.6A.3F). This can be accomplished with pepsin in acidic solution, followed by neutralization and reconstitution to physiological salt and pH conditions (Freytes et al., 2008; Voytik-Harbin et al., 1998). Similar to collagen alone, injection of the digested ECM suspension or incubation at 37°C can cause self-assembly into a nanofibrous hydrogel. Generally, reported times between 24 and 96 h have been sufficient for digesting particles into a homogeneous solution (Saldin et al., 2017). Notably, adjusting parameters such as salt concentration and digestion time has been shown to affect material properties (Johnson et al., 2011) and solubilized protein fragments influencing in vitro cellular responses (Agrawal et al., 2011; Williams et al., 2015b), respectively.

Cross-Linking

Like other biomaterials, cross-linking methods can be utilized to modulate degradation rate and mechanical strength of decellularized ECM. These methods include chemical, natural, and physical agents. Chemical cross-linker glutaraldehyde has been widely used for vascular tissue engineering applications (Chapter 1.2.5; Zhao et al., 2011). As previously mentioned, glutaraldehyde treatment can potentially lead to calcification (see "Tissue Cross-linking" section) resulting in failure of the implanted decellularized tissue (Perrotta et al., 2011; Hussein et al., 2017). Treatment with organic solvents and amino acids can decrease calcification (Park et al., 2017). Another well-known chemical cross-linker genipin forms covalent bonds between free primary amine groups of lysine and

hydroxylysine residues in collagen. A previous study with genipin-cross-linked liver ECM scaffold demonstrated increased tensile strength and elastic modulus compared to glutaraldehyde-treated scaffolds (Gao et al., 2018). Other examples of cross-linking agents include EDC/NHS and transglutaminases. EDC/NHS cross-linking significantly improved compression modulus and reduced degradation of porcine acellular dermal matrix (Li et al., 2013). Transglutaminase is a natural cross-linking enzyme that produces a reaction between glutamine and lysine residues on proteins, resulting in covalent amide bond formation (Williams et al., 2015a). Liver scaffolds cross-linked by transglutaminase showed increased elastic modulus and tensile stress response, decreased porosity, and maintained cell attachment (Takeda and Xu, 2014).

Other cross-linking methods, such as photooxidation, increased acellular blood vessel thermal stability and mechanical strength (Moore, 1998; Lu et al., 2009). Also, gamma and ultraviolet irradiation (UV) have been used, which produce free radicals leading to polymer chain scission and cross-linking (Park et al., 2013). These methods can be combined with chemical agents. Decellularized porcine cornea cross-linked by carbodiimide and gamma irradiation showed increased thermal stability and mechanical strength compared to native tissue (Lin et al., 2017).

Applications of Decellularized ECM

Decellularized tissues in various forms have become commercial products for clinical use (Table 1.3.6A.1) with more

products on the translational pipeline based on promising preclinical results in large animal models and evaluations under way at the clinical trial stage (Table 1.3.6A.2). A summary of decellularized tissue applications is provided below to demonstrate the progression and trends in the field for research and clinical use.

Scaffold-Based Therapies

In vivo implantation of decellularized ECM scaffolds into different tissue sources provides a three-dimensional structure for cellular infiltration and restoration of function to a particular tissue. These biomaterials can be implanted into the same tissue source (orthotopic) or alternative environments (heterotopic). Allogeneic or xenogeneic acellular scaffolds from heart valves, skin, SIS, and bladder among others, are commercially available, while others are in preclinical to clinical development.

Heart valves: Clinical studies with decellularized human valve allografts were developed in the late 1990s, with three options currently available. The widely known option, CryoValve SG, is an acellular pulmonary valve which demonstrated in a clinical trial maintenance of structural integrity and hemodynamic function after 4 years of implantation (Brown et al., 2010; Hawkins et al., 2003a). Two other products have demonstrated positive results in early and midterm studies, but long-term outcomes are still necessary (Cebotari et al., 2011; Sarikouch et al., 2016; da Costa et al., 2010).

Apart from allogeneic valves, xenografts (Fig. 1.3.6A.4A) have been tested in preclinical and clinical stages. SynerGraft, the first developed decellularized porcine valve, was implanted in a sheep model of right ventricular outflow tract reconstruction. Infiltration of fibroblasts toward the leaflet supportive tissue with no evidence of calcification was observed 6 months after implantation (O'Brien MF., 1999). In clinical trials, both positive and negative results have been observed. Negative outcomes included an inflammatory response, possibly due to incomplete decellularization (Simon et al., 2003; Goldstein et al., 2000). A xenogeneic pulmonary valve (Matrix P), was also developed with sodium deoxycholate treatment. In a clinical study, implantation of the scaffold maintained normal structural integrity (Konertz et al., 2011). However, another study resulted in a foreign-body reaction against the xenograft with severe inflammation

and fibrotic tissue (Voges et al., 2013). Controversial results with both xenogeneic valves indicate the need to carefully evaluate biocompatibility in preclinical stages, improve preimplant conditioning, or removal of xenoantigens after the decellularization process.

Skin: Several decellularized skin tissues are already FDA cleared for different applications, such as superficial and deep burns, and ulcers. In 1995, the first acellular human dermal matrix by sodium deoxycholate and freeze-drying decellularization methods, AlloDerm (Fig. 1.3.6A.4B), was developed for full-thickness skin injury (Wainwright, 1995). Over the years, this scaffold has been used for other approaches, such as breast reconstruction and abdominal hernia repair (Breuing and Warren, 2005; Slavin and Lin, 2012; Skovsted Yde et al., 2016; Krishnan et al., 2014). Other acellular human dermis matrices have been developed using different decellularization methods, such as AlloMax, which is treated with hyper/hypotonic solutions and sodium hydroxide (Chauviere et al., 2014; Orenstein et al., 2010; Hinchcliff et al., 2017). GraftJacket, another FDA-cleared commercial product, is used in orthotopic (e.g., chronic wound healing) and heterotopic (e.g., rotator cuff tendon repair) locations (Brigido, 2006) (Derwin KA, 2006). Xenografts include Strattice and Surgimend, derived from porcine and bovine sources, respectively. These scaffolds are used for breast reconstruction, hernia repair, and abdominal and chest wall repair (Begum et al., 2016; Salzberg et al., 2013; Ball et al., 2017).

Other tissues: Different tissues, besides heart valves and skin, have been decellularized for scaffold-based therapies. Acellular porcine SIS is widely used in diverse fields such as gastroenterology, dermatology, orthopedic, and cardiovascular fields. SIS (Surgisis) has been used since 1999 for hernia repair, and different clinical studies have indicated success with this product (Oelschlager et al., 2003; Holcomb et al., 2005; Franklin et al., 2004; Edelman and Hodde, 2006). Another application of SIS includes wound healing of chronic leg ulcers (Oasis) or arterial and venous ulcers (Mostow et al., 2005; Romanelli et al., 2010).

• **Figure 1.3.6A.5** Porcine urinary bladder matrix for wound healing applications. (Modified with permission from Acell.)

Moreover, SIS has been tested in preclinical studies of cardiovascular surgery, such as valve replacement and myocardial repair (Rosen et al., 2005; Fallon et al., 2014; Mosala Nezhad et al., 2016). The variety of preclinical results has supported SIS (CorMatrix) use in numerous clinical studies (Mosala Nezhad et al., 2016; Quarti et al., 2011; Gerdisch MW, 2014). Even though results of SIS application in the cardiovascular field are promising, large-scale and long-term clinical studies are needed to better assess integration in a heterotopic environment. The need for additional evaluations has been especially evident in pediatric applications, as mentioned in the case study.

Chondrofix (Fig. 1.3.6A.4C), a decellularized cadaveric human hyaline cartilage and subchondral bone, was implanted in patients with focal cartilage defects. After 28 months of implantation, allografts led to decreased knee pain with maintenance of subchondral bone (Gomoll, 2013). However, another study indicated the need for reoperation due to structural damage of the graft after 2 years (Farr et al., 2016). As a relatively new option for osteochondral defects, long-term clinical studies are needed to efficiently evaluate applications in the orthotopic scenario.

Acellular porcine urinary bladder (MatriStem) (Fig. 1.3.6A.5) has been tested in clinical studies of deep burns demonstrating reepithelialization and also effective treatment of acute diabetic or venous ulcerations (Kim et al., 2016b; Balland et al., 2016). Hernia repair application has also been assessed in clinical studies involving a large cohort of patients, without postoperative complications (Howell et al., 2018). The porcine urinary bladder was also tested in a pilot clinical study for volumetric muscle loss, where three of the five patients involved had an improved functional capacity of the damaged limb 6 months after the scaffold implantation (Sicari et al., 2014).

Whole Organ Recellularization

To address the critical shortage of donor organs, tissue-engineering approaches developing functional organs from decellularized xenogeneic or allogeneic sources seeded with different cell populations have been investigated. Whole-organ recellularization is a complicated task that takes into consideration three main factors: cell source, cell seeding approach, and a bioreactor. Successful organ regeneration is dependent on complete recellularization of the parenchyma (functional tissue of an organ), vasculature, and supportive structures (Badylak et al., 2011; Scarritt et al., 2015). Furthermore, the method of cellular delivery is important, since fluid shear stress and pressure can affect cell adhesion to the scaffold and proliferation. Finally, a bioreactor is essential for adequate delivery of nutrients to the center of the organ. Besides perfusion, mechanical and electrical cues may be necessary depending on the organ to recellularize.

Over the past years, different organs from various animal sources have been recellularized. In 2008, the field of whole-organ recellularization started when adult rat heart was decellularized and perfused with neonatal rat cardiac or endothelial cells. After 8 days in culture under electrical stimulation and load, the construct started to pump at a rate equivalent to 2% of adult heart function (Ott et al., 2008). After this breakthrough, researchers started to recellularize different organs including kidney, liver, and lungs. In one study, recellularization of kidney scaffold with epithelial and endothelial cells led to urine production in vitro. The construct when orthotopically implanted and connected to native vasculature in the recipient rat, was well perfused, and urine, creatinine, urea, and albumin were produced (Song et al., 2013). Furthermore, decellularized liver matrix seeded with primary rat hepatocytes maintained hepatocyte viability after 2 days in culture. After 8 h of transplantation in rats, hepatocytes maintained their morphology and parenchymal positions (Uygun et al., 2010). Lung scaffolds have been seeded with epithelial and endothelial cells, leading to gas exchange after 5 days in culture. This was also observed 6 h after the construct was implanted and ventilated by the airways and respiratory muscles of recipient rats (Ott et al., 2010). In another study, lung constructs seeded with neonatal rat lung epithelial and endothelial cells replaced lungs of rats and gas exchange was documented during the 45–120 min of implantation (Petersen et al., 2010). Another example includes recellularization of acellular rhesus macaque lung scaffold, done by airway seeding with macaque bone marrow mesenchymal stem cells, and further vascular seeding perfusion with endothelial cells (Bonvillain et al., 2013). From the reproductive system, decellularized porcine uterus repopulated with human endometrial stem cells resulted in a contracted scaffold and organized seeded cells (Campo et al., 2017). Although successful studies have been done in small animal models, several issues with organ transplantation need to be considered (see "Current Challenges and Future Directions of Decellularized Tissues" section).

• **Figure 1.3.6A.6** ECM powder from porcine urinary bladder (MicroMatrix). (Modified with permission from Acell.)

Powder and Injectable Decellularized ECM Therapies

For tissue conditions not requiring volumetric replacement of tissue structures, ECM scaffolds further processed into powder or hydrogel forms can be utilized (see "Milling for ECM Powder and Partial Enzymatic Digestion for Hydrogel Formation"). As volumetric organization in these platforms is broken down, these therapies can be evenly applied onto tissue surfaces or act as space-filling material.

Several ECM powder products that can be applied as a dry powder, hydrated paste, or injectable are commercially available, such as MicroMatrix (ACell) (Fig. 1.3.6A.6) from porcine urinary bladder, micronized AlloDerm (Allergan) from human dermal tissue, Powder Extracellular Matrix (Cook Biotech), and ECM Particulate (CorMatrix) from decellularized SIS. Clinical use has been mainly for enhanced recovery and comfort of slow or nonhealing percutaneous wounds, ulcers, and surgical operations compared to traditional treatment methods (Dorman and Bass, 2016; Rommer et al., 2013; Lecheminant and Field, 2012; Frykberg et al., 2016; Ahmed et al., 2012; Kruper et al., 2013). At the preclinical stage, surgical implantation of ECM powders with carriers has been demonstrated for several tissues including bone (Brown et al., 2012; Peterson et al., 2004) and cardiac (Tabuchi et al., 2015). However, required

invasive surgery for directly applying ECM powders has limited translation compared to less invasive injection delivery.

Application and efficacy of injectable ECM powders have been applied to a wider range of tissue including liver (Nakamura and Ijima, 2013), lung (Manni et al., 2011), bone (Teng et al., 2017; Peterson et al., 2004), and adipose (Wu et al., 2012; Beachley et al., 2015; Gibson et al., 2014; Kokai et al., 2019). In the clinical setting, micronized Alloderm has been applied for facial soft tissue augmentation (Sclafani et al., 2000, 2001) and treating unilateral vocal fold paralysis (Pearl et al., 2002; Milstein et al., 2005; Morgan et al., 2007; Vinson et al., 2010) with beneficial long-term functional outcomes at least up to 1 year postinjection. Based on evaluation for treatment, postmyocardial infarction in small (Zhao et al., 2010) and large animal models (Slaughter et al., 2014; Soucy et al., 2015), ECM Particulate (CorMatrix) has undergone a phase I clinical trial (RESTORE: NCT02139189) delivered in tandem with coronary artery bypass operation for patients with an ejection fraction between 25% and 40%. Several injectable decellularized adipose ECM powders have been evaluated in phase I clinical trials for the treatment of soft tissue defects: Acellularized Adipose Tissue 01 or A3T01 (Aegeria Soft Tissue) (NCT01992315, NCT02817984) and Renuva (NCT02445118), with the latter showing safe implantation and greater than 40% volumetric retention at 16 weeks (Kokai et al., 2019).

Due to the shear thinning properties of enzymatically digested ECM suspension that forms a hydrogel postinjection (Ungerleider et al., 2015), these materials are highly compatible with less invasive delivery methods. The digestion process also renders a hemocompatible material (Seif-Naraghi et al., 2013). For tissues that normally require invasive surgery for treatment, such as the heart, this advantage helps reduce risk and hastens patient recovery from deployment. Many promising results have been produced for ECM hydrogels in preclinical animal models from a variety of different source tissues for orthotopic and heterotopic applications including cerebral, skeletal muscle, tendon, and cardiac applications (Saldin et al., 2017; Spang and Christman, 2018). Potentially due to delivery advantages, the development and preclinical testing of ECM hydrogels across a wide variety of tissues has been gaining interest and could prompt an upcoming wave of clinically applied hydrogel products in the near future.

Generally, ECM hydrogels are still at an early phase of the translation process and are not yet available as a clinical therapy (Spang and Christman, 2018). Currently, VentriGel (Ventrix, Inc.) is the only product to reach the clinical stage. VentriGel made from myocardial matrix of decellularized porcine left ventricular tissue has demonstrated feasibility, safety, and efficacy in both small and large animal models (Singelyn et al., 2009, 2012; Seif-Naraghi et al., 2013). Accompanying mechanistic evaluation by transcriptomic and immunohistochemistry analysis has demonstrated increased arteriogenesis, immune cell infiltration, cardiomyocyte preservation, cardiac tissue development, and oxidative metabolism along with reduced apoptosis, hypertrophy, and fibrosis among a plethora of modulated pathways in matrix versus saline-injected controls (Wassenaar et al., 2016). Evaluation in a phase I trial (NCT02305602) in patients with ejection fraction between 25% and 45% was recently completed, demonstrating safety of an ECM hydrogel in patients for the first time (Traverse et al., 2019).

Aside from advancements testing and translating ECM hydrogels alone, these methods have also been demonstrated as a useful codelivery vehicle with other therapeutic agents for synergistic benefits. Cellular codelivery in hydrogels (Lee et al., 2014; Rao et al., 2017; Yuan et al., 2017) has commonly demonstrated enhanced viability of cellular payload with some improved outcomes for ECM compared to single-component systems. Additional noncovalent interactions with native ECM components such as heparin-binding glycosaminoglycans have been demonstrated to further elevate sustained delivery of exogenously loaded proteins, nucleic acid therapeutics, and exosomes in ECM hydrogels (Hernandez Melissa et al., 2018; Seif-Naraghi et al., 2012; Kwon et al., 2013; Smith et al., 2014) that would typically require additional components or modification for these properties in nondecellularized ECM hydrogel systems (Brouwer et al., 2013; Purcell et al., 2014). Thus, a plethora of options are available to apply these ECM materials and improve efficacy in the clinical setting.

Tissue-Specific In Vitro Models of the Native Microenvironment

Decellularized tissue can be utilized as an in vitro model representative of biophysical, biomechanical, and biochemical cues in a 3D architecture of a native ECM microenvironment. The influence of these environmental signals can help functionally and phenotypically maintain cells difficult to grow on tissue culture plastic or single ECM coating systems such as preventing dedifferentiation postisolation of culture primary esophageal epithelial cells (Ozeki et al., 2006; Bhrany et al., 2006; Hussey et al., 2017). Alterations and influence of the healthy ECM microenvironment can be studied by decellularizing tissue from disease animal models or patient biopsies for assessing disease progression or as a therapeutic screening model such as studying the influence of ECM on human breast cancer progression and efficacy of therapeutics against those cues (Liu et al., 2019)

ECM processed into a powder or an enzymatically digested suspension can be readily utilized for 2D coatings of cell adhesion surfaces (DeQuach et al., 2010; Shakouri-Motlagh et al., 2017; Lee et al., 2014; Zhang and Dong, 2015), resuspended as a soluble form in cell culture solution or formed into a 3D ECM hydrogel scaffold (Gaetani et al., 2018; Kim et al., 2016a; Wolf et al., 2014). Although processed forms lose 3D architecture, organization, and mechanical properties representative of the native tissue, batching from different tissue samples improves compositional consistency, and implementation in these different forms provides a flexible platform more readily incorporated into existing in vitro model systems. Similar to the scaffold form, cues from processed ECM can aid in maintenance of

cell behavior, viability, and function of primary isolated cell cultures such as enhancing insulin release from cultured pancreatic islets that are normally difficult to maintain in vitro (Chaimov et al., 2017). Culture on these ECM materials has also been shown to promote enhanced differentiation of stem and progenitor cells toward tissue-specific lineages such as heart, nerve, and immune cell populations (Lee et al., 2014; Rao et al., 2017; DeQuach et al., 2011; Wolf et al., 2012). Mechanistic study of therapeutics can also be improved by utilizing diseased tissue-derived ECM. Mesenchymal stem cell in in vitro culture on infarcted cardiac tissue-derived ECM demonstrated regressed expression of cardiac lineage markers while expression of prosurvival cytokine was elevated compared to healthy cardiac ECM, supporting cellular therapy efficacy by a paracrine mechanism (Sullivan et al., 2014). For the hydrogel form, cellular responses are elicited by eluted soluble fragments and hydrogel fractions. Variations of secreted cytokines from macrophages incubated with different hydrogel fractions made from urinary bladder have been observed (Slivka et al., 2014).

Aside from utilizing decellularized ECM alone, incorporation with other materials and in in vitro systems recapitulating additional properties of the native tissue environment can enhance representation of the healthy and diseased microenvironment. These allow study of how multiple environmental variables influence tissue development, disease progression, and screening of therapeutic efficacy. Incorporation of fetal versus adult brain ECM into an in vitro 3D model of cortical brain tissue with a silk and collagen I base scaffold enhanced neural network formation and neural firing function of seeded cortical neurons with fetal ECM compared to adult or collagen alone. These results support that the fetal ECM aids in early growth and development, differentiation, and organization of the cortical network (Sood et al., 2016). More specific organization of decellularized ECM for 3D cell culture can be achieved by combining with bio-ink printing platforms either alone (Jang et al., 2017a) or onto mechanically supportive synthetic (Pati et al., 2014) or naturally derived filler material (Bejleri et al., 2018) allowing for multilayered cell-laden tissue analogues. Utilizing photoinitiated cross-linking of the ECM allows further control of the local mechanical properties with these bioprinting platforms (Jang et al., 2016; Grover et al., 2014). Mechanical properties can be bulk or regionally controlled for mimicking different tissue conditions such as emulating heterogeneous stiffness profiles in healthy versus cirrhotic liver with photocross-linked decellularized liver ECM (Ma et al., 2018). Ultimately, isolation of the native decellularized ECM and flexibility implementing these materials redefined our general capabilities to represent tissue-specific properties in vitro.

Current Challenges and Future Directions for Decellularized Tissues

Despite several decellularized tissues being commercially available, there are still challenges involving optimization and variability of the decellularization process. The need for a standard technique is required, especially for scaling-up production for clinical translation. Another crucial factor to consider is minimizing sources of immunogenicity, especially for treating demographics with abnormal immune responses such as pediatric patients. Decellularization protocols are being developed to specifically address these issues (Iop et al., 2014; Gallo et al., 2012). Pursuing improvements and more standardized use of animal models that better represent the human immune response and aspects of the targeted patient population can also prevent limited efficacy and unexpected safety issues at the clinical stage (Wang et al., 2017a; Mortell et al., 2006).

Along with optimizing methods, elevating mechanistic understanding of material properties supporting proregenerative cellular responses will aid future improvements in decellularized tissue-based therapies. Although commonly used adult porcine tissue provides abundant quantity and convenience utilizing commercial waste, whether this is an ideal source material is unknown. Mass spectrometry and transcriptomic analysis have suggested ECM components and properties from younger tissue may support greater tissue repair. For example, the neonatal mouse heart has a short regenerative window postgestation that is lost with aging. Transiently abundant agrin protein (Bassat et al., 2017) and lesser cross-linking (Notari et al., 2018) found in neonatal mouse heart ECM were determined to elicit repair in adult cardiac tissue postinjury and prolong the regenerative capability during the neonatal stages, respectively. Alternatively, decellularized myocardial matrix hydrogels from zebrafish hearts, which can fully regenerate 20% amputated cardiac tissue volume, elicited greater cardiac function, lesser negative remodeling, and increased number of cycling cardiomyocytes in infarcted mouse hearts compared with murine-derived hydrogels (Chen et al., 2016). Although translation feasibility from these sources is limited by tissue yield, isolating underlying contributors to tissue regeneration could allow adoption into other platforms.

Whole-organ recellularization in the clinical stage is still likely a long pathway. Further studies should include long-term graft function in healthy and diseased animal models. Before implantation, there are some challenges that still need to be optimized. Recellularization protocols would need to be refined to organ size, species, and donor characteristics (Song and Ott, 2011). Moreover, a durable vascular network is one of the major hurdles (Soto-Gutierrez et al., 2012) as incomplete reendothelialized vasculature is at risk for acute thrombosis because of exposed ECM. Furthermore, the immune response following implantation can lead to scar tissue formation, further inhibiting vascularization (Badylak et al., 2011). In summary, whole-organ recellularization is a promising field to decrease the number of patients with end-stage failure, however, the mentioned issues need to be addressed before clinical translation can be considered with recellularized constructs.

CASE STUDY: CONSIDERATIONS APPLYING DECELLULARIZED SCAFFOLDS AT INFANCY VERSUS ADULTS

Appropriate scaffolds for valve or myocardial wall repair should be bio- and hemocompatible, provide mechanical support while being resorbed with surrounding tissue, and not calcify. One option is CorMatrix ECM, a decellularized porcine small intestinal submucosa (SIS) extracellular matrix (ECM) sheet scaffold. Products with CorMatrix ECM initially received a European CE mark in 2010 and were later FDA cleared as devices for vascular repair, pericardial closure, and tissue reconstruction. While there have not been large randomized controlled clinical trials, CorMatrix ECM has demonstrated some favorable outcomes in adult cardiovascular surgical procedures based on case reports and reviews of vascular (Szczeklik et al., 2015), valvular (Gerdisch et al., 2014), pericardial (Stelly and Stelly, 2013), and myocardial wall repair (Holubec et al., 2015; Yanagawa et al., 2014). For example, CorMatrix ECM was implanted in 19 adults for mitral valve replacement. During the 10.9-months mean follow-up, no evidence of calcifications or development of stenosis was observed with partial vascularization of the graft and without valve-related complications in 17 recipients. Two patients experienced complications with limited scaffold resorption, though these patients had distinct complicating medical histories for treatment of other conditions such as cancer (Gerdisch et al., 2014).

More mixed results have been observed in pediatric applications when utilized for congenital cardiac defect surgical reconstruction. While positive outcomes in explanted scaffolds from pediatric patients have been reported showing reabsorption and replacement with collagen, reendothelialization, and no evidence of calcification (Scholl et al., 2010), histological evaluation of some explanted CorMatrix material collected due to complications or reoperations has shown cases of chronic inflammation and limited material resorption (Witt et al., 2013; Zaidi et al., 2014; Rosario-Quinones et al., 2015; Wong et al., 2016; Padalino et al., 2015). In one study, negative outcomes occurred in 9 of 47 recipients (0.1–14.5 years old), where the longest follow-up was approximately 9 months (Zaidi et al., 2014). In all explanted samples, a mild to severe inflammatory response was observed from macrophage, lymphocyte, and eosinophil infiltration. Mild calcification with neointima formation at the scaffold surface was also visualized, without scaffold reabsorption. Another evaluation in 25 recipients (5 days to 57 years old), six infant recipients required reoperation with evidence of prolonged inflammatory response, hypersensitivity reaction, and fibrosis in explants (Rosario-Quinones et al., 2015). In a study of infantile intracardiac repair (4–8 months), 10 of 12 CorMatrix patches explanted at a median of 21 months postimplantation had calcification, fibrosis, and chronic inflammation in the scaffold (Nelson et al., 2016). While extensive preclinical research supports the biocompatibility of these scaffolds, the contrasting outcomes and number of pediatric cases experiencing complications compared to adult recipients suggests that further considerations are required for pediatric applications.

One reason for differences in the outcomes between the adult and pediatric populations could be related to the immune modulation in infants and young children (Nelson et al., 2016). For immune tolerance of maternal alloantigens, an antiinflammatory, immune-suppressed state is maintained in infants for several months postgestation (Simon et al., 2015). This state is caused by the high percentage of T-cell-independent B1 cells secreting IL-10 and TGF-β promoting differentiation of T cells toward the regulatory T-cell phenotype (Hannet et al., 1992; Mold et al., 2010). Although an immune suppressed state could be considered ideal for safe uptake of a biomaterial implant, studies have demonstrated the importance of activation and transitioning between proinflammatory and proremodeling states of macrophages and T cells for biomaterial-induced tissue repair and associated tissue remodeling responses (Nassiri et al., 2015). Furthermore, the transient immune-tolerant state at infancy has been shown to not reliably prevent rejection of xenogeneic grafts (Mattis et al., 2014). As decellularization quality batch variability has been observed in some CorMatrix scaffolds (Wong et al., 2016), xenogeneic antigens could elicit a progressive humoral response in the developing immune system, leading to later graft rejection. These issues could also limit efficacy in senior patients or patients with medical histories that hinder normal activity of their immune system (Gerdisch et al., 2014). These issues, coupled with potential genetic deviations with congenital tissue diseases, support heightened caution and scrutiny when applying these materials in infant patients.

Conclusion

Progress in tissue processing has immense promise to address the increasing need for available donor tissue and to create new standards of therapy for tissue diseases with decellularized ECM materials. With the extensive research being performed, improvements in preservation of tissue and whole-organ recellularization have potential to minimize human donor tissue waste and overcome shortages by expanding resources with xenogeneic tissue sources, respectively. Application and advancement of decellularized ECM treatments can further reduce the patient population awaiting transplant by mitigating negative outcomes and promoting tissue repair. With further understanding of complex diseases and tissue repair processes, an increased impact of these processed tissues is expected on the scientific community and medical practice.

Questions

1. What are the issues with classical cryopreservation (freezing) on tissue preservation? How are these issues addressed with vitrification? What limitations still exist with tissue preservation despite minimizing structural damage to tissue at low temperatures?
   a. Classical cryopreservation causes immobilization of solute components by freezing of water and formation of ice crystals causing extracellular tearing, cell membrane lysis, and segregation of solute molecules, leading to a toxically high concentration of solute molecules due to displacement from organized crystal structure.
   b. Vitrification creates a high-viscosity, glass state due to the relatively high concentration of cryoprotectant and rapid freezing leading to immobilization of solute components faster than ice crystal formation can take place.
   c. Despite improvements in reaching the "frozen" state, standard methods cause uneven thawing throughout large volumes of tissue, causing similar issues with classical cryopreservation as different regions regain mobility of solute components. The cellular response during these freezing and thawing processes also can cause pathological responses that limit the actual restoration of the tissue, however, this requires further evaluation.
2. What is the purpose of tissue cross-linking and cross-linking for decellularized materials? Why does glutaraldehyde still have issues regarding durability and biocompatibility? Give an example of a chemical cross-linking method together with the mechanism of action.
   a. Tissue cross-linking decreases the rate of enzymatic digestion by the host cells and delays the hyper-acute and acute immune response by masking antigens. For decellularized ECM, besides modulating the degradation rate, cross-linking also tailors the mechanical properties of the material.
   b. Incomplete binding of glutaraldehyde to the collagen network leads to the presence of cytotoxic aldehyde groups that might be involved in long-term calcification as observed in bioprosthetic heart valves.
   c. An example of a chemical cross-linker is carbodiimide coupled with N-hydroxysulfosuccinimide. These agents cross-link nonspecifically all proteins by linking the amine and the carboxyl groups by amide bonds.
3. Why is DNA commonly utilized as a surrogate marker of decellularization quality? What are the limitations of this approach? How do methods of antigen removal address some of these limitations?
   a. DNA is commonly measured as a remnant of cellular content because it has been linked to the activation of inflammatory mechanisms.
   b. A limitation of this method is that DNA is not the only source of antigenicity that could elicit an inflammatory response for in vivo applications as other remnant cellular components and especially xenogeneic epitopes can elicit immune rejection responses.
   c. Antigen removal focuses specifically on assessing content during the decellularization that interacts with antibodies that could elicit immune responses of engrafted tissue-derived materials, thus being a more direct measure of content that could stimulate an immune rejection response.
4. Give an example of three commercially available ECM-based products. Mention the tissue source, together with the application.
   a. AlloDerm is an acellular human dermal matrix used for full-thickness skin injury, breast reconstruction, and abdominal hernia repair. Oasis is a porcine small intestinal submucosa matrix applied in chronic leg ulcers, myocardial repair, and arterial and venous grafting. MatriStem is an acellular porcine urinary bladder matrix used for deep burns, and acute diabetic or venous ulcerations.
5. What is an advantage of injectable ECM particulate and ECM hydrogels as therapies?
   a. Injectable therapies can be delivered through less invasive or minimally invasive methods, which can improve the recovery times and safety of the procedure. For hydrogels, in particular, their shear thinning properties allow them to be delivered by catheter methods, allowing delivery to organs that require highly invasive and risky surgeries such as the heart.
6. What current medical issues do tissue-processing methods seek to address? How do these methods address limitations of the standard practices in the medical field?
   a. Tissue-processing methods seek to improve the resources and treatments for patients with chronic tissue injuries and diseases, especially ones that can only be addressed by eventual organ transplant.
   b. Tissue-processing methods address the limitations of current medical technology in a variety of ways. These methods hope to improve the preservation of donated organ tissue, expand the available sources of organs used for transplant with xenogeneic-derived substitutes, and develop alternative treatments that can be utilized to promote repair for damaged and diseased tissue in patients.

Introduction

The fields of bioengineering and regenerative medicine aim to develop new strategies to treat or replace failing organs. While ongoing pathological changes of the extracellular matrix (ECM) may contribute to the failing of a tissue or organ, specific ECM proteins could be the key to a successful treatment, potentially supporting a higher regenerative capacity or overcoming limitations of cell therapy approaches.

ECM proteins or naturally occurring materials, such as alginates or chitosan, can offer several advantages for bioengineering and regenerative medicine applications in terms of biocompatibility, since the surrounding biological environment can recognize and metabolically process implanted substances through established pathways (Shin et al., 2003). A unique advantage of naturally-derived materials is that through either enzymatic or hydrolytic degradation the host can successfully clear and metabolize the implanted substance (Prestwich and Atzet, 2012). While this may not be desirable in permanent and long-term implants such as hip replacements, it is extremely advantageous when timed biological resorption is desired, i.e., in delivery vehicles for drugs or therapeutic cells. ECM proteins and natural materials can be chemically modified and cross-linked to match the degradation rate to a particular biological application (Augst et al., 2006; Badylak and Gilbert, 2008; Prestwich and Atzet, 2012).

One frequent concern about ECM proteins derived from animals and natural materials is the immunogenic response that can occur following implantation (Prestwich and Atzet, 2012). This response results from the fact that the implanted materials, although similar to the endogenous host ECM component, may not be identical, and thus contain antigenic determinants (Prestwich and Atzet, 2012). This issue is mainly common among animal-based ECM proteins. The immunogenic effect can be reduced by either chemical modification or through sourcing of the ECM material (Badylak and Gilbert, 2008).

Chemical modification and cross-linking are common methods for altering mechanical properties such as elasticity and tensile strength of natural materials that are often not appropriate for dynamic physiologic environments (Prestwich and Atzet, 2012). However, the complex structures of natural materials can complicate technical modifications that are simple to perform in synthetic polymers (Prestwich and Atzet, 2012). Nonetheless, numerous research studies have demonstrated the successful modification and purification of natural-based materials (Prestwich and Atzet, 2012).

Another common issue arising with ECM proteins is the lot-to-lot variability in molecular structure that can occur due to, for example, animal sourcing (Prestwich and Atzet, 2012). But variability arises not only due to species-to-species variation, but also from tissue-to-tissue variation, which can complicate processing and quantification of the materials. As a complex mixture of various molecules arranged

in a three-dimensional (3D) manner, the ECM features the fundament for cell anchorage and migration as well as regulatory functions for all types of cells (Votteler et al., 2010). The ECM's constitutions can be divided into three kinds of classes: (1) proteins with primarily structural functions such as collagens and elastic fibers, (2) proteoglycanes (PGs) or glycosaminoglycanes (GAGs), which are first of all responsible for regulatory processes, and (3) matricellular proteins. The structure and function of a tissue depends on the relative proportion of these constituent molecules. Those tissues that have to withstand large tensional forces tend to be particularly rich in fibrillar collagens and elastic fibers, while tissues that are exposed to compressive forces usually contain high levels of PGs and GAGs (Votteler et al., 2010). Although most of the ECM components are well known, the precise composition of this mixture of molecules varies from tissue to tissue and remains underinvestigated. However, in recent years it has been acknowledged that the 3D architecture of the ECM is an important driver of cell modulation, as it regulates signal transduction mechanisms, which in turn can impact ECM remodeling (Votteler et al., 2010). Understanding the spatial distribution of ECM components within tissues and organs often provides insight into their function and basic mechanisms of action. A detailed analysis of the miscellaneous elements of the ECM is of great value in gaining structural and diagnostic information, particularly with regard to bioengineering efforts.

The following sections will discuss common types of ECM proteins as well as natural-based biomaterials. We will conclude this chapter highlighting different strategies to produce recombinant human ECM proteins and manufacturing approaches that utilize ECM proteins and natural materials.

Collagens

Collagens are the most abundant and ubiquitous ECM proteins in mammals, which are not only critically important for the biomechanical stability of tissues, but are also intimately involved in cell adhesion and migration during growth, differentiation, morphogenesis, and wound healing (Schenke-Layland, 2008; Votteler et al., 2010). To date, various types of collagens (more than 28) have been identified, each with a unique biological function (Hulmes, 2008) (Table 1.3.6B.1).

Although both fibrillar and nonfibrillar collagens are found in mammalian tissues, the fibril-forming collagens (types I, II, III, V, XI, XXIV, and XXVII) account for the majority of the body's collagen mass (Leitinger and Hohenester, 2007; Hulmes, 2008; Schenke-Layland, 2008). Each fibrillar collagen molecule consists of three polypeptide chains, called α-chains. Molecules can be homotrimeric, consisting of three identical α-chains, or heterotypic, consisting of up to three genetically distinct α-chains (Hulmes, 2008). Individual α-chains are identified by the following nomenclature: $\alpha_n(N)$, where N is the Roman numeral indicating collagen type and n is the number of the α-chain (Hulmes, 2008). Thus the chain composition of collagen II is $[\alpha_1(II)]_3$, while that of collagen type I (ColI), a heterotrimer with two identical α_1-chains and a third distinct α_2-chain, is $[\alpha_1(I)]_2\alpha_2(I)$ (Hulmes, 2008). The common characteristic of the classical fibrillar collagens is a long central triple-helical region in each α-chain, consisting of a continuous $(Gly\text{-}X\text{-}Y)_n$ repeat, where n is 337–343 (depending on the collagen type). All fibrillar collagens are synthesized in the form of soluble precursor molecules, called procollagens, with large N- and C-terminal propeptide domains (Hulmes, 2008). The C-propeptides are removed during the later stages of biosynthesis, usually by specific metalloproteinases, leaving short C-telopeptides (Hulmes, 2008). The extent of N-terminal processing depends on the collagen type (Hulmes, 2008).

TABLE 1.3.6B.1 Collagen Types

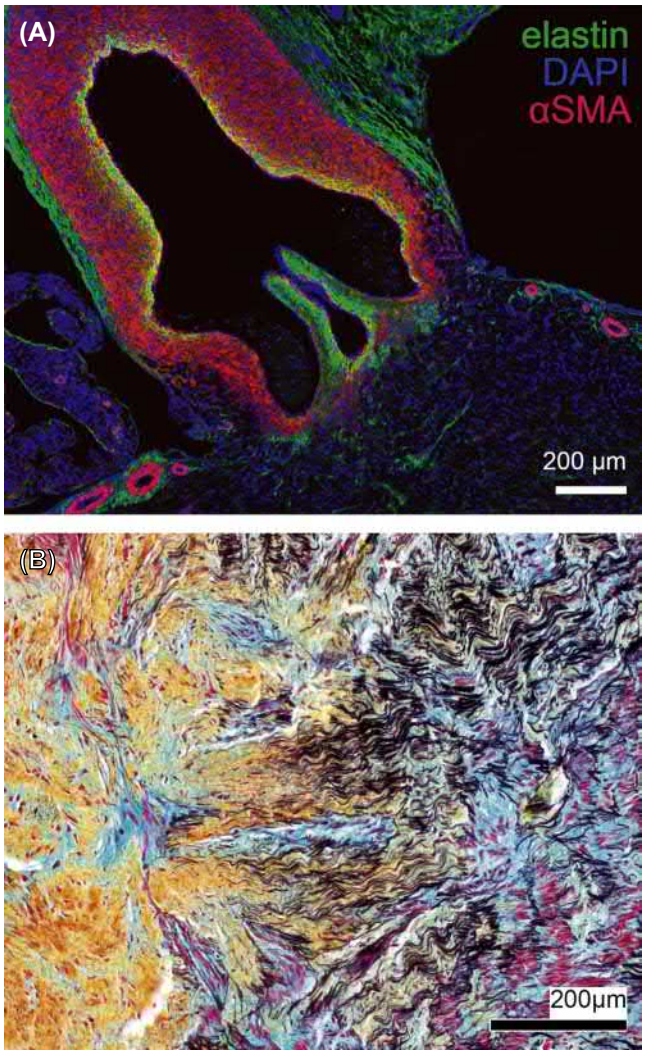
Subfamily	Types
Fibrillar collagens	I, II, III, V, XI, XXIV, and XXVII
Fibril-associated collagens	IX, XII, XIV, XVI, XIX, XX, XXI, and XXII
Beaded filament-forming collagens	VI
Basement-membrane (BM) and BM-associated collagens	IV, VII, XV, and XVIII
Short-chain collagens	VIII and X; inner ear-specific or saccular collagen
Transmembrane collagens	XXVI and XXVIII

Collagen biosynthesis is a highly complex process, involving numerous intra- and extracellular steps, all of which then contribute to the structure and biomechanical properties of the collagen fibrils. While there are several types of collagen, the fibrils all share the characteristic triple-helical structure, but have variations in the length of the nonhelical and helical sections, variations in the number of carbohydrates attached to the helical fraction, and the formation of covalent cross-links (Stenzel et al., 1974; Hulmes, 2008).

There are four types of collagen that are mainly focused on in bioengineering applications: fibrillar ColI is commonly found in skin, bone, and tendons, while type II (ColII) is mainly synthesized in cartilage (Votteler et al., 2010). Type III collagen (ColIII) is prevalent in vascular structures (i.e., blood vessel walls), and can also be found in skin and the peritoneum. The nonfibrillar collagen type IV (ColIV) is a crucial element within the basement membrane underlying epithelial cells (Votteler et al., 2010). The small ColIV molecules link also to GAGs with much larger structural proteins such as ColI and thus contribute to the gel properties of the ECM (Votteler et al., 2010). ColIV is unique in that it is largely nonhelical and does not form fibrils.

Gelatin is an irreversibly denatured and hydrolyzed form of collagen that is commonly used in pharmaceuticals, cosmetics, and foods. Most medical-grade collagens and gelatin are obtained from closely regulated bovine and porcine tissue. However, human collagens can be obtained by recombinant methodology (see section "Manufacturing Approaches Utilizing Natural Materials" in this chapter), isolation from tissues such as lung and placenta, or from human cell culture (Lee et al., 2001).

Collagens, in most cases ColI, are used as a biomaterial because of their widespread abundance in nature and ease of modification (Stenzel et al., 1974; Stone et al., 1997; Friess, 1998). Collagens are composed of ~20 amino acids, each providing pendant side groups available for chemical modifications (White et al., 1973; Hulmes, 2008). The prevalence of hydroxyl, amine, and carboxylic acid groups allows simple cross-linking between and within collagen units (Prestwich and Atzet, 2012). Cross-linking collagen can also decelerate the degradation of implanted materials, and is thought to reduce to some extent the immunogenicity in xenografted collagen materials (Nimni et al., 1987; Prestwich and Atzet, 2012). Exposure to glutaraldehyde produces collagens with firm covalent cross-links and elastic behavior (Prestwich and Atzet, 2012). Numerous commercial products have been developed from collagen-based technologies. CosmoDerm (Allergan) is, for example, a human collagen-based implant generated and purified from human fibroblast cell culture. ColI is the major component of this material with some presence of ColIII, as determined by Western blot analysis (Prestwich and Atzet, 2012). Zyderm (Allergan) is based on bovine-derived ColI. Both products, CosmoDerm and Zyderm, are chemically cross-linked by treatment with glutaraldehyde (Prestwich and Atzet, 2012). Gelfoam (Pfizer) is an absorbable, water-soluble, nonelastic, and porous sterile compressed sponge produced from denatured ColI from porcine skin. It is used for compression of wounds and in combination with human thrombin as a hemostat (Prestwich and Atzet, 2012).



• **Figure 1.3.6B.1** (A) Fluorescence image of a human 9-week outflow-tract heart valve. Tropoelastin/elastin protein expression (green) is seen in the valve leaflets and the entire outflow tract vasculature. (B) Bright-field image of an adult porcine aortic vessel section stained with Movat's pentachrome to visualize collagens (yellow) and elastic fibers (black), as well muscle tissue (red), proteoglycans, and glycosaminoglycans (green–blue). *DAPI*, 4′,6-Diamidino-2-phenylindole; *SMA*, smooth muscle actin.

Elastin, Elastic Fibers, and Elastin-Like Peptides

Elastic fibers provide the essential recoil for all tissues that are exposed to constantly repeated strain, such as blood vessels or heart valve leaflets (Fig. 1.3.6B.1) (Votteler et al., 2013). They are also abundantly expressed in lung tissue, the eye, ligaments, and skin; all organs that commonly stretch and relax (Geutjes et al., 2006; Daamen et al., 2007; Vindin et al., 2019).

The processes underlying elastic fiber formation are highly complex and require the interplay of various molecules. To date, the mechanisms that drive elastic fiber formation, termed "elastogenesis," are, although well explored, not very well understood. They are currently the subject of intense research by many groups. It is well known that elastic fibers consist of various ECM proteins such as microfibrillar proteins (fibrillins), linking proteins (fibulins, elastin microfibril interfacers), microfibril-associated glycoproteins, soluble factors (transforming growth factor beta), and the core protein elastin (Sherratt, 2009; Wagenseil and Mecham, 2007, 2009; Wise and Weiss, 2009; Hubmacher et al., 2014). Due to its extremely long half-life (e.g., elastin turnover in human lung is approximately 74 years (Shapiro et al., 1991)), elastin is believed to remain functional, under normal physiological conditions, during a human lifetime. For the assembly of elastic fibers, specifically for the assembly of fibrillins and consequently of microfibrils, a fibronectin network is also needed (Sabatier et al., 2009). It is known that microfibrils provide a microenvironment that controls tropoelastin/elastin arrangement and cross-linking processes (Kielty et al., 2002).

Although there have been many attempts to engineer elastic fibers in human tissues, the in vitro generation of elastic

fibers represents a major bottleneck in bioengineering. Neonatal or adult rat vascular smooth muscle cells and neonatal human dermal fibroblasts are routinely used to synthesize tropoelastin in vitro, showing elastin deposition in two-dimensional cell cultures (Hinderer et al., 2015). Hinderer et al. used a customized bioreactor, combined with a 3D hybrid electrospun fibrillar polymer scaffold, to induce an elastic fiber-containing network, including elastogenesis-associated proteins (Hinderer et al., 2015). However, there have been no reports of the generation of fully functional human-based elastic fibers in 3D tissue-engineered constructs.

A different approach is the utilization of tropoelastin as biomaterial to engineer elastic tissues in vitro. The ability of tropoelastin to self-assemble has driven investigations into utilizing coacervation to facilitate the fabrication of tropoelastin-based materials such as hydrogels and electrospun scaffolds for tissue repair (Yeo et al., 2015; Vindin et al., 2019). The introduction of the recombinant technology to produce synthetic tropoelastin (see also section "Manufacturing Approaches Utilizing Natural Materials" in this chapter) helped to provide scalable host overexpression systems to meet the demands of industrial applications. In the development of these systems, gene optimization is, however, critically important. This was exemplified by poor yields in early implementations of an *Escherichia coli* overexpression system, due to rare bacterial codons populating up to 35% of the native human tropoelastin gene (Indik et al., 1990). By engineering a synthetic gene highly optimized for bacterial expression, significantly enhanced protein yields of multigram quantities were obtainable for biomaterial fabrication (Martin et al., 1995).

Elastin-like peptides (ELPs) have been synthetically produced (Urry et al., 2002; McHale et al., 2005). These polypeptides are composed of the highly repetitive amino acid sequences found in elastin. Physical properties of the ELPs can be manipulated based on amino acid sequence and resulting hydrophobicity. The polypeptides can coacervate and then be cross-linked by gamma irradiation. Researchers have produced nonwoven fabrics and fibers by electrospinning ELPs (Huang et al., 2000).

Proteoglycans and Glycosaminoglycans

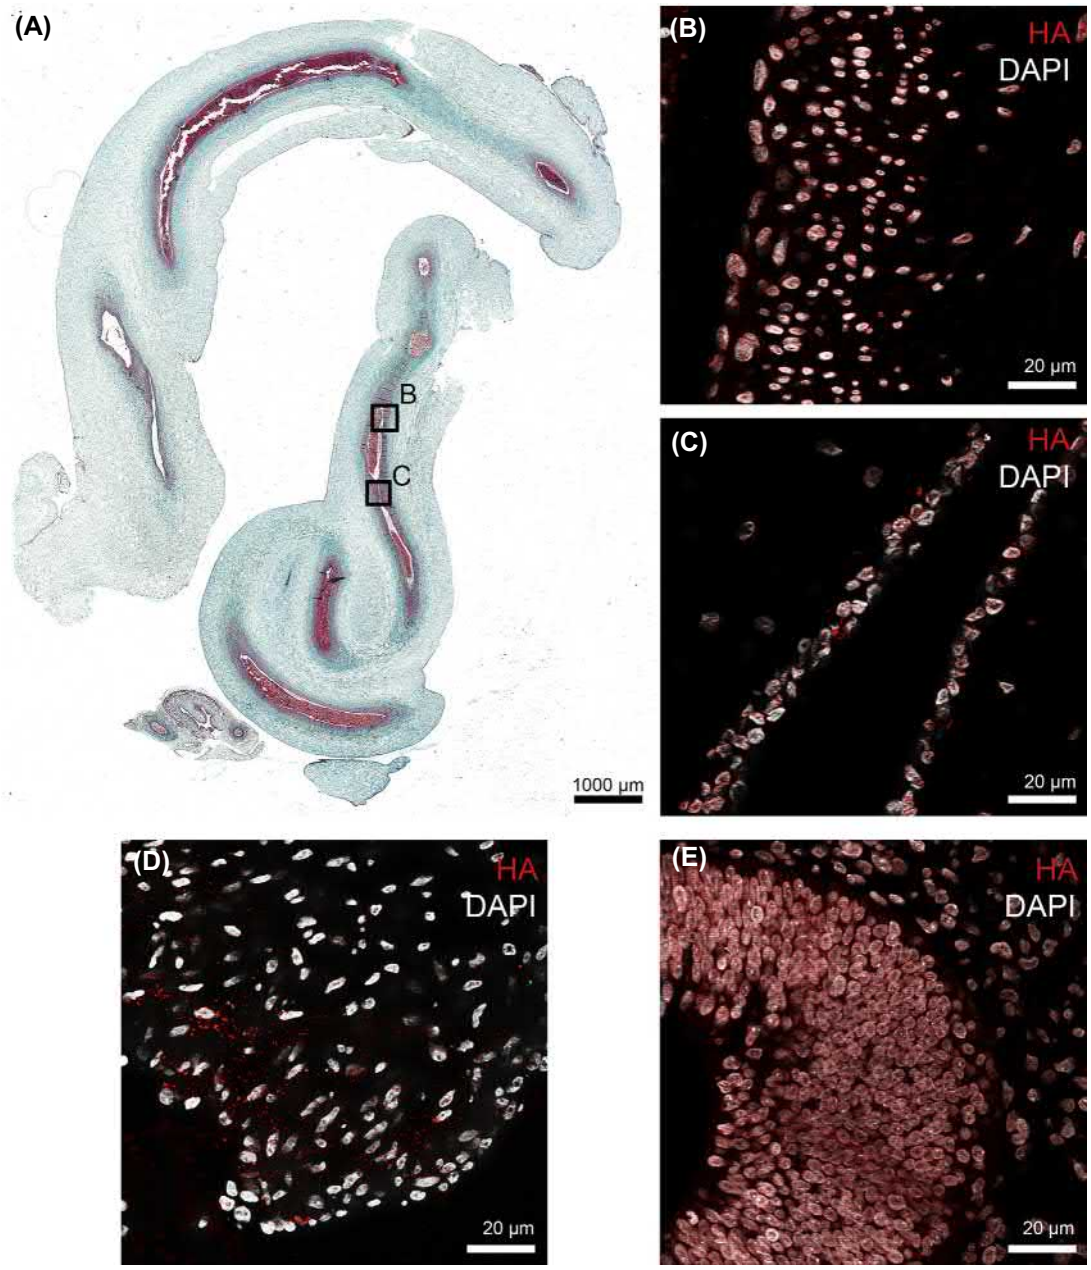
In humans, PGs are the first ECM elements, emerging in the early developing embryo (Fig. 1.3.6B.2). Therefore they are supposed to be the most critical factors of regulatory mechanism for normal cell function and tissue development (Votteler et al., 2010). PGs persist in core protein and covalently attached sulfated GAGs, including chondroitin sulfate (CS), heparan sulfate (HS), and hyaluronic acid (HA). Within the ECM, they offer a huge water-holding and growth factor-binding capacity and have a significant impact on cell adhesion, migration, and differentiation through the regulation of their various protein partners (Badylak et al., 2008).

GAGs are a family of polysaccharides that can generally be described as an alternating copolymer, which are found in all animal tissues. The repeat units of GAGs consist of a

• **Figure 1.3.6B.2** Bright-field image of a 4-week embryo stained with Movat's pentachrome. Proteoglycans and glycosaminoglycans are depicted in green–blue.

hexamine unit (glucosamine or galactosamine) and a sugar (galactose, glucuronic acid, or iduronic acid) (Prestwich and Atzet, 2012). GAGs are found on all cell surfaces and in the ECM, and they are well preserved among species (Hildebrandt, 2002; Prestwich and Kuo, 2008; Prestwich and Atzet, 2012). The molecular weights of GAGs generally range from 5 to 5000 kDa (Prestwich and Atzet, 2012). There are several specific GAGs used as biomaterials, including heparin, HS, keratan sulfate, dermatan sulfate, CS, and HA.

Heparin is a highly sulfated GAG and is widely used as an anticoagulant (Breckwoldt et al., 1991; van der Giessen et al., 1998; Hildebrandt, 2002). Due to the sulfation levels it is very strongly negatively charged. Pharmaceutical-grade heparin is routinely derived from bovine or porcine mucosal tissues. Heparin is chemically related to HS and is composed of variably sulfated disaccharides. The predominant saccharide units are D-glucosamine and uronic acid (either D-glucuronic acid or L-iduronic acid) with sulfation of some hydroxyl groups (Prestwich and Atzet, 2012). Due to the strong negative charge, heparin has been found to bind to growth factors, such as vascular endothelial growth factor and basic fibroblast growth factor, and stabilize them in vivo, thus regulating their release (Peattie et al., 2008). Growth factor release is dependent on the strength of association with heparin, and can vary depending on the growth factor and environment from days to weeks (Peattie et al., 2008). Heparin was one of the first biological molecules to be covalently immobilized to biomaterials (Hoffman et al., 1972; Schmer, 1972; Basmadjian and Sefton, 1983), and



• **Figure 1.3.6B.3** (A) Human embryonic (10-week) umbilical cord section stained with Movat's pentachrome. Proteoglycans and glycosaminoglycans are depicted in green–blue. Blood vessels and embryonic blood cells are shown in dark red. (B, C) Fluorescence images of hyaluronic acid (HA)-stained human umbilical cord tissue. HA can also be found in (D) 15-week embryonic heart muscle and (E) 5-week embryonic eye tissue. (B–E) Cells are shown in white (4′,6-diamidino-2-phenylindole [DAPI]).

has since been used extensively for coating in catheters, stents, and other medical devices (Breckwoldt et al., 1991; van der Giessen et al., 1998; Cauda et al., 2008; Jiang et al., 2009; FDA TyCo, 2010).

CS is a negatively charged GAG that is composed of repeating glucuronic acid and *N*-acetylgalactosamine units. Most disaccharide units contain a single sulfate at C-4 or C-6 hydroxyl groups, as well as a carboxyl group that can be chemically modified (Yuan et al., 2008; Baldwin and Kiick, 2010). CS is a major component of cartilage tissue with a huge capacity to absorb water, which is crucial for the compressive strength of that tissue. CS is commonly attached to proteoglycans as a structural protein or it can be found on cell surfaces or basement membranes where it functions as a receptor. Commercial CS is often sourced and purified from shark or whale cartilage, or it is harvested from bovine or porcine tissues (Baldwin and Kiick, 2010).

HA is found in the ECM of all tissues of the body, and is particularly abundant in umbilical cords, as well as embryonic hearts, the eye, and cartilage (Laurent, 1989) (Fig. 1.3.6B.3). HA is the only nonsulfated glycosaminoglycan, and consists of repeating disaccharide units of *N*-acetylglucosamine and glucuronic acid. In addition to being unsulfated, HA is unique among GAGs in that it exists in

much higher molecular weights (50–6000 kDa), is secreted by cells, and (with a few exceptions) does not occur as a proteoglycan, that is, bound to a protein core (Prestwich and Kuo, 2008; Prestwich and Atzet, 2012). HA has been extensively studied as a biomaterial, in part due to these and other unique properties (Shu et al., 2002, 2004, 2006). HA occurs primarily as the sodium salt under physiological conditions; collectively, HA, sodium HA, and other HA salts are often referred to as hyaluronan (Prestwich and Atzet, 2012). There exist three major commercial sources of HA: a product that was isolated (1) from rooster combs (>2000 kDa HA), (2) from bacterial fermentation (50–100 kDa HA), and (3) HA oligosaccharides that are produced enzymatically (ranging from only a few disaccharide units up to 20 kDa) (DeAngelis et al., 2003; Prestwich and Atzet, 2012). HA forms lubricious and viscoelastic solutions that can protect, for example, eye tissues during ophthalmic surgeries, provide viscosupplementation in joints, reduce postsurgical adhesions, and can also help to deliver drugs in vivo (Kuo, 2006; Prestwich and Atzet, 2012). However, a rather short residence time in vivo and its poor mechanical properties led to many chemical modifications of HA (Shu and Prestwich, 2004; Allison and Grande-Allen, 2006). In the past two decades, HA-based medical devices and coatings have addressed many clinical needs with different levels of success. A detailed overview of monolithic and living HA as well as the applications of HA in bioengineering and regenerative medicine applications are provided in Prestwich and Atzet (2012). Moreover, the chemistry and biology of HA is exhaustively reviewed on the Glycoforum website (http://glycoforum.gr.jp/science/hyaluronan/).

Alginates

Alginates constitute a family of linear anionic polysaccharides isolated from coastal brown algae species (commonly known as kelp) such as *Laminaria hyperborean* (Augst et al., 2006; Prestwich and Atzet, 2012). Alginates are composed of (1,4)-linked β-D-mannuronic acid (M) and α-L-guluronic acid (G) residues in homopolymer blocks of either similar or strictly alternating sections (i.e., MMMMM, GGGGG, MGMGMG) (Rowley et al., 1999). The relative amounts of the blocks are dependent on the origin of the alginate (Prestwich and Atzet, 2012). Due to axial links, G blocks are stiffer than M blocks and alternating sequences in turn increase the solubility of the alginate (Prestwich and Atzet, 2012). The molecular weight of alginates can vary between 50 kDa and 100,000 kDa (Prestwich and Atzet, 2012). Alginate hydrogels can be formed by various cross-linking methods. One common technique is to use a divalent cation (Ca^{2+} or Ba^{2+}) to form ionic bonds between the carboxylic groups of neighboring strands, thereby inducing chain–chain associations (Prestwich and Atzet, 2012). Alginate can also be cross-linked by partial oxidation of the poly(guluronate), followed by reaction with adipic dihydrazide to form covalent cross-links (Prestwich and Atzet, 2012). A third cross-linking strategy uses polyethylene glycol diamines to covalently link alginate chains (Prestwich and Atzet, 2012). Gel stiffness and elasticity vary with composition and cross-linking method. The stiffness of divalent cation cross-linked alginate increases with the following trends in composition: MG < MM < GG, whereas elasticity increases following GG < MM < MG (Prestwich and Atzet, 2012). Thus the M:G ratio, cross-linking method, and molecular weight can all be used to tune mechanical properties of alginate gels (Prestwich and Atzet, 2012).

Because alginate is foreign to mammalian cells, alginate materials are not naturally broken down enzymatically after implantation in vivo. As a result they have a poorly controlled in vivo degradation. When the divalent cations are exchanged with Na^+ ions, ionically cross-linked alginate typically undergoes slow uncontrolled dissolution at neutral pH (i.e., greater than 3 months) (Mi et al., 2002a; FDA PhytaCare 510(k), 2010; FDA HemCon 510(k), 2010; Prestwich and Atzet, 2012). Degradation kinetics of covalently cross-linked alginate generally depends on the type and density of cross-linker (Mi et al., 2002b). However, there are strategies to adjust degradation kinetics by modifying polymer molecular weight, composition (M:G), and partial oxidation.

Another unique property of alginate is that it is relatively biologically inert. Cells do not naturally adhere to alginate, which has fostered investigations into the attachment of ECM proteins and peptide sequences to hydrogels (Prestwich and Atzet, 2012). Adhesion proteins such as laminins, fibronectin, and collagens have all been coupled to alginate, as well as the integrin-binding, fibronectin-derived, cell adhesive peptide arginine–glycine–aspartic acid and its derivatives (FDA PhytaCare 510(k), 2010; FDA Collamend 510(k), 2010; Prestwich and Atzet, 2012). These modifications have led to significant improvements in cellular attachment to alginate materials.

Specifically tailored alginate hydrogels have numerous proposed uses, including bulking agents, drug delivery vehicles, and scaffolds for regenerative medicine (Prestwich and Atzet, 2012). Alginate hydrogels have also been clinically investigated as a carrier for transplanted chondrocytes to treat intrinsic sphincter disease, and as a delivery vehicle for mineralization-promoting proteins (Prestwich and Atzet, 2012). Alginate-based biomaterials have been approved by the Food and Drug Administration (FDA) for topical use in wound healing. The PhytaCare Alginate Hydrogel and the Silverlon Calcium Alginate Dressing products both have 510(k) clearance as barrier wound dressings that provide a microbial barrier for partial to full thickness wounds, including ulcers, graft sites, surgical wounds, and burns (Prestwich and Atzet, 2012).

Chitosan

Chitosan is a polycationic copolymer of *N*-acetyl-glucosamine and *N*-glucosamine, and is generally obtained by alkaline deacetylation of chitin, a linear homopolymer of *N*-acetyl-glucosamine (Prestwich and Atzet, 2012). Chitin

is structurally related to glycosaminoglycans, but lacks the uronic acid groups. It is the primary component in fungi cell walls, and the exoskeleton of crustaceans such as shrimp, crab, and lobster (Khor and Lim, 2003; Prestwich and Atzet, 2012). When the degree of deacetylation (conversion to *N*-glucosamine) is greater than 50%, the biopolymer is termed chitosan (Prestwich and Atzet, 2012). The biopolymer is soluble in dilute acidic solutions, such as acetic acid or hydrochloric acid, and as a result the amino groups become protonated (Jiang et al., 2008). Chitosan hydrogels can be formed by entangled networks, ionic cross-links/polyelectrolyte complexes, or by covalent cross-linking (Mi et al., 2002b; Berger et al., 2004). Once dissolved, entangled networks of chitosan can gel by increasing the pH or extruding the solution into a nonsolvent. Entangled networks have limited use due to a lack of mechanical strength and a tendency to dissolve (Prestwich and Atzet, 2012). Due to the cationic nature of chitosan, combination with a negatively charged polymer, such as chondroitin sulfate or hyaluronan, will result in an ionic-bound network (Prestwich and Atzet, 2012). Covalently cross-linked hydrogels can be prepared by reaction with various difunctional molecules such as glutaraldehyde, poly (ethylene glycol), dialdehyde diethyl acetal, or genipin (Dal Pozzo et al., 2000). Chitosan is metabolized by human enzymes such as lysozyme, and thus can be considered biodegradable. Degradation rates depend, however, on the type of hydrogel network, and specifically for covalent networks, the type and density of cross-linker (Freier et al., 2005a). As with alginate, much research has explored the conjugation of biomolecules to chitosan, by either ionic, adsorption, or covalent modification of ECM proteins and peptide sequences to modify cellular response (Suh and Matthew, 2000; Ho et al., 2005). Chitosan provides multiple hydroxyl and amino functional sites for chemical modification opportunities (Berger et al., 2005). Chitosan-based hydrogels have been researched and developed for applications in drug and growth factor delivery, scaffold-based tissue regeneration, and wound dressings (Rao and Sharma, 1997; VandeVord et al., 2002; Mi et al., 2003; Freier et al., 2005b). Chitosan-based biomaterials have also been approved by the FDA for topical use in wound healing and as hemostats. Scion Cardio-Vascular, Inc. developed and markets a soft absorbent pad called the Clo-Sur P.A.D as a noninvasive topical approach to hemostasis based on chitosan and its absorbent properties (Prestwich and Atzet, 2012). This product has been cleared as a Class III medical device by the FDA. Other devices with FDA 510(k) clearance are Aquanova's superabsorbent dressing for wounds such as ulcers, and Celox's granulated chitosan for hemostasis (Prestwich and Atzet, 2012).

Fibrin

Fibrin is a naturally occurring biodegradable matrix that can be produced via polymerization of fibrinogen and thrombin to form a mesh network (Ahmed et al., 2008). Fibrinogen is a glycoprotein synthesized by the liver and is soluble in the bloodstream (Linnes et al., 2007). Thrombin, also produced in the liver and found in the bloodstream, initiates end-to-end polymerization of the soluble fibrinogen to form long strands that precipitate to form a fibrin mesh (Prestwich and Atzet, 2012). This polymerization occurs naturally at a wound site and contributes, in conjunction with platelets, to form a clot. In vivo, fibrin gels are degraded by the proteolytic enzyme plasmin.

Fibrin gels often do not possess the required mechanical strength for some physically dynamic environments. To overcome this, researchers have combined various natural or synthetic polymers, such as collagen or polyglactin, to provide stronger gels (Eyrich et al., 2007; Dare et al., 2009). Using fibrin-based gels, 3D mitral valve constructs were produced as an experimental platform to serve as a test system to study mitral valve cellular phenotype behavior (Liu et al., 2018). Commercially available fibrin sealants are used to control bleeding and speed wound healing. Fibrinogen can be isolated from animal plasma, including human plasma; thus autologous scaffolds for tissue engineering applications can be generated from a patient's own blood (Prestwich and Atzet, 2012).

Manufacturing Approaches Utilizing Natural Materials

Human Recombinant ECM Protein Production

For the safety and efficacy of a high-quality human-based protein product like an injectable hydrogel with defined composition and protein concentrations, several points must be taken into account. For safe clinical application, the identity of the ECM proteins should be ideally human. Protein sequences among different species may show high homology to the human sequence, but even slight differences might be detected and trigger a response from the immune system of a patient (Courtman et al., 2001; Schernthaner, 1993; Meyer et al., 1988). With regard to a possible protein extraction from human tissue, it should be noted that these tissues are rare, of varying origin and quality, and with uncertain infection background. Also, the purification of a specific protein from a tissue with complex protein composition can require harsh methods (Nandi et al., 1987). These can damage the protein and impair or abolish its natural activity. Therefore the recombinant production of a protein of interest is much preferred compared to its extraction from human tissue. Progress in genetics allowed a better understanding of protein production and the possibilities of genetic manipulation (Urlaub et al., 1983; Seth et al., 2006; Korke et al., 2002). One of the most important accomplishments of this development is recombinant protein production in high-yield host cell lines (Seth et al., 2006; Korke et al., 2002). The recombinant production of protein products and therapeutics is an important branch of the pharmaceutical industry, which achieves turnovers measured in the billions worldwide. Compared to protein extractions from tissues, recombinant protein production has the advantage

of granting the secured availability of the human protein of interest in a reproducible high quality (Wurm, 2004). To generate high-quality protein products, the recombinant production of the human ECM proteins of interest by a safe host cell line under defined conditions and in defined media is preferable to other options. The careful selection of the host cell line, transfection, clone selection, production, and purification method needs to be based on the requirements for recombinant human ECM protein production under good manufacturing practice-translatable conditions.

For proteins to be synthesized in biologically active forms, they need to be properly folded and posttranslationally modified. There are more than 200 different posttranslational protein modifications possible in mammalian cells. Glycosylation is one of the most common and important posttranslational modifications (Palomares et al., 2004; Bhatia and Mukhopadhyay, 1999). When glycans are attached to asparagine residues on the core protein this is defined as *N*-linked glycosylation and when glycans are attached to serine or threonine residues as *O*-linked glycosylation (Bhatia and Mukhopadhyay, 1999). This posttranslational modification cannot be done in microbial hosts like *E. coli* because these organisms lack the required machinery to synthesize the appropriate mammalian glycoforms (Korke et al., 2002; Palomares et al., 2004; Zhu et al., 2007). Many ECM proteins carry complex glycosylations that are important for activities such as growth factor sequestering and can enable interactions with cells or other ECM components. Therefore an adequate host with the required enzymes for posttranslational modification of human proteins needs to be chosen.

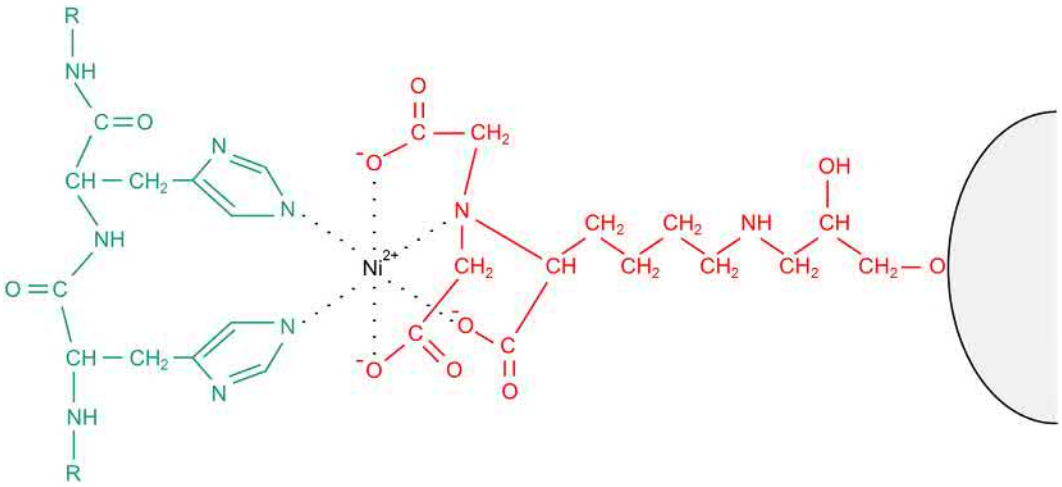
Chinese hamster ovary (CHO) cells are the most commonly used cell line for the production of recombinant protein therapeutics in the pharmaceutical industry (Wurm, 2004; Omasa et al., 2010). CHO cells are robust protein expression hosts that are easy to maintain, which have the ability to adapt to suspension cultures (Sinacore et al., 2000). Suspension culture results in enhanced cell density and cell productivity levels compared to cultures employing adherent cells and therefore is the most common cell culture format for recombinant protein production with CHO cells (Wurm, 2004). Using a mutant CHO cell line deficient in the dihydrofolate reductase (DHFR) enzyme, an improved selection of stable clones and coamplification of the gene of interest can be achieved with rising methotrexate (MTX) levels (Urlaub and Chasin, 1980; Kellems, 1991).

The increased number of copies of the gene of interest in the host genome due to coamplification with the DHFR gene results in a higher productivity of the production clone. The DHFR enzyme catalyzes the reaction of dihydrofolate to tetrahydrofolate, thereby playing a central role in the synthesis of this nucleic acid precursor in all organisms and eventually for DNA replication and cell growth. MTX is a potent competitive inhibitor of the DHFR enzyme, with a 1000-fold higher affinity to DHFR than folate. Making use of this coamplification system, specific productivity levels are expected to be highly increased (Wurm et al., 1986, 2004). For a further increase of product expression, codon adaptation can be applied to the gene sequence of ECM proteins (Zhou et al., 2004). The genetic code is degenerated, which means that many amino acids are encoded by more than one triplet codon. The concept of codon adaptation is based on the usage of the most frequently used triplet code for an amino acid, resulting in an optimized gene sequence, matching the codon usage of the rodent host while still encoding the same human protein (Ikemura, 1981). This is how codon adaptation can bypass predictable bottlenecks in transfer (tRNA) availability for a certain codon in the host cell line. Additional to permanent recombinant protein production, an inducible production of ECM proteins can be beneficial. This is the case if the permanent amplified recombinant protein production causes a metabolic burden to the host cell, leading, for example, to a reduced cell proliferation (Gu et al., 1992). Undesired inhibition of host cell proliferation during the clone selection phase could also be caused by the biological effects of the protein of interest (Yamaguchi and Ruoslahti, 1988). Therefore instead of conventionally designed plasmids for permanent protein production, the inducible production system uses plasmids with the protein of interest under the transcriptional control of an inducible promoter (Gossen et al., 1995). For this system, it is necessary to stably transfect the host cells with a plasmid for the permanent production of an activator protein (Gossen et al., 1995; Urlinger et al., 2000). Subsequently, this stable activator clone is transfected with the plasmid for inducible production of the ECM protein of interest. In this plasmid an inducible promoter controls the transcription of the gene of interest, and can only be activated by the permanently produced activator ECM protein in the presence of doxycycline (Gossen et al., 1995; Urlinger et al., 2000).

Purification of Recombinant ECM Proteins

For easier protein purification without the need for a lysis step as well as intact protein activity, recombinant ECM proteins should be secreted to the culture media by the host cells, just like these ECM proteins are secreted into the interstitial space in the human body (Sheehan and O'Sullivan, 2004). For secretion purposes, the ECM protein's natural secretion peptide needs to be included in the ECM gene sequence in the production plasmid. Incomplete protein secretion of the recombinant ECM proteins could cause protein aggregate formation in the host cell, impairing its metabolism as well as the protein purification and protein activity (Sheehan and O'Sullivan, 2004). Protein purification of secreted proteins from the culture media leads to higher yields with maintained protein activity as no cell lysis or chemical extraction of the protein-containing cell compartment and refolding of the protein to bioactive conformation needs to be performed (Mukhopadhyay, 1997; Sheehan and O'Sullivan, 2004).

Affinity chromatography is one of the most efficient and selective chromatographic protein purification methods



• **Figure 1.3.6B.4** A protein with a polyhistidine tag (in green) is bound to a nickel ion (Ni^{2+}). The nickel ion is immobilized to a solid support (sepharose bead) by the chelating agent nitrilotriacetic acid (in red) and a linker (in red).

(Zhu et al., 2007). Several small affinity tags are widely used as an efficient tool for recombinant protein purification, histidine tags being one of the most known and also favored (Yip and Hutchens, 1994; Hochuli et al., 1987). The main step in the purification of a secreted, histidine-tagged protein is based on a specific type of affinity chromatography, the so-called immobilized metal affinity chromatography (IMAC) (Porath et al., 1975). In this case the natural affinity of the amino acid histidine to immobilized nickel ions on an affinity chromatography column is used for the protein purification (Hochuli et al., 1987; Yip et al., 1989). A nickel ion-charged sepharose bead matrix ensures a high binding capacity for histidine-tagged proteins (Hochuli et al., 1987). The molecular interaction, which is the basis of this affinity chromatography, is depicted in Fig. 1.3.6B.4.

Reproducible IMAC purification with defined equilibration, wash and elution buffers, constant flow rates through the affinity chromatography column, and monitoring of important measurement data can be accomplished with a fast protein liquid chromatography system (Sheehan and O'Sullivan, 2004). Monitoring and recording of flow rate, conductivity, pressure, and absorption at 280 and 256 nm provide an informative basis for the different sections of the purification process. Automated elution fraction collection and subsequent desalting and buffer exchange, concentration, wash, and sterile filtration of the protein solution result in a high-quality pure protein product that can be stored until its use for biomedical applications such as 3D bioprinting or electrospinning at −80°C.

3D Bioprinting

3D scaffolds can either be produced by laser-based, printer-based, or nozzle-based printing, whereas the printer-based method is suitable for printing cells (Hinderer et al., 2016). Compared to printing, bioprinting includes the addition of cells, growth factors, and other functional elements (Murphy and Atala, 2014). It has been demonstrated that ECM proteins are suitable for generating 3D bioprinted scaffolds. Collagens (Chang et al., 2012), fibrin (Cui and Boland, 2009), and methacrylated gelatin (Hoch et al., 2013) have been used in bioprinting applications. Hoch et al. introduced living chondrocytes to an in-house manufactured gelatin solution to create an ink for bioprinting. In their study, the authors showed that the printed chondrocytes exhibited excellent viability, concluding that this method is suitable for generating ECM-based cell carriers for application in cartilage tissue engineering (Hoch et al., 2013; Hinderer et al., 2016). Due to the layer-by-layer deposition of the material, complex and well-defined 3D structures, such as whole organs, can be realized. Sun et al. developed a printing and coating method termed "Patterning on Topography" (PoT) that enables the layering of proteins such as fibronectin, laminin, collagen type IV, and other ECM proteins onto printed geometric surfaces ranging from smooth to very topographically complex surfaces with high fidelity (Hinderer et al., 2016). In this method, thermally sensitive poly(*N*-isopropylacrylamide) are spin coated onto glass coverslips and then sandwiched with ECM proteins that have been microcontact printed with a polydimethylsiloxane stamp. The sandwiched layers are dipped in distilled water and allowed to cool to room temperature (Hinderer et al., 2016). This allows the transfer of the printed ECM protein layer onto the printed topography layer, where the ECM adheres via hydrophobic interactions, resulting in a highly defined ECM-layered surface that can be used for cell culture or potentially on implant surfaces. In this work, the printed ECM was used to elucidate how competing physical and chemical microenvironment cues influence cardiomyocyte behavior (Hinderer et al., 2016). Joo et al. performed similar work where their group used PoT to investigate the effects of ECM patterns on the migration and differentiation of adult neural stem cells (Joo et al., 2015; Hinderer et al., 2016). Using humidified microcontact printing, Ricoult et al. printed ECM proteins onto smooth surfaces without the need of harsh chemicals that are typically involved in

this process, thus protecting the proteins from denaturalization (Ricoult et al., 2014; Hinderer et al., 2016). They created vascularized printed topographies with nanometer resolution as a proof of principle for the possibility of the solvent-assisted printing of proteins and nanoparticles. Further options and current applications of 3D bioprinting in regenerative medicine as well as current challenges in the field, including improvement of resolution, generation of more adequate printable biomaterials, and upscaling to clinical relevant sizes, have been intensively reviewed by Murphy and Atala (Murphy and Atala, 2014).

Electrospinning of ECM Proteins and Natural Materials

Electrospinning is an attractive method to generate fibrous and porous matrices with a high surface area for regenerative medicine applications. Varying matrix properties, such as fiber and pore sizes, enable the control of cellular responses, including migration, proliferation, and progenitor cell differentiation (Hinderer et al., 2016). The basic experimental set-up for electrospinning includes a syringe that is connected to a pump, as well as a conductive flat or rotating electrode (=collector), and a high-voltage power supply. A polymer solution is pumped through the syringe and forms a droplet on the needle tip. By applying high voltage, the droplet adopts a conical shape, and as soon as the electrical field strength exceeds the surface tension, a thin fiber develops. Due to equal charges, instabilities occur and the fiber travels in spinning motions to the collector, the solvent evaporates, and a solid fibrous network is generated. Depending on the collector shape, different scaffold types can be obtained. Therefore it is possible to spin flat sheets, tubes, or even the shape of a heart valve (Hinderer et al., 2016). Today, there are various methods described to electrospin synthetic polymers from different solvents (Hinderer et al., 2014, 2016). One of the first examples of electrospinning ECM proteins was performed by the Chaikof group where they spun a 1 wt% solution of type I collagen with polyethylene oxide to create a collagen mesh (Huang et al., 2001). Fourteen years after the first ECM scaffolds were spun, groups have electrospun natural decellularized ECM (Wen et al., 2014), or ECM components such as collagen blends, HA, or proteoglycans (Hinderer et al., 2016). Rao et al. used coaxial electrospinning to create a brain white matter in vitro model to study the migration of malignant brain tumors. They tested HA, collagens, and Matrigel, an extract of the Engelbreth-Holm-Swarm mouse tumor, in the outer shell of the nanofibers to analyze the effects of different proteins on cell migration (Rao et al., 2013). Electrospun scaffolds can be layered using multiple methods. For example, a positively charged chitosan and negatively charged ColI were used to create a layered scaffold to promote wound healing (Huang et al., 2015). Although electrospinning is a simple and cost-effective method to generate 3D fiber-containing materials, due to the need of high electrical fields and harsh solvents, it is quite challenging to maintain a physiological protein function. Although there are a few publications focusing on functional electrospinning of ECM molecules (Hinderer et al., 2012), a clinical translation has not yet been demonstrated.

Summary

Regenerative strategies such as stem cell-based therapies and tissue engineering applications are being developed with the aim of replacing, remodeling, regenerating, or supporting damaged tissues and organs. When aiming for ultimately clinical applications, in addition to, or instead of, a careful cell type selection, the design of appropriate 3D scaffolds is essential for the generation of bioinspired replacement tissues. Such scaffolds are composed of degradable or nondegradable biomaterials. The development of effective and efficient drug carrier systems is also highly relevant for novel therapeutic treatment strategies. ECM and natural materials have a great potential to be utilized as scaffolds for bioengineering and regenerative medicine. The native ECM is a heterogeneous network of soluble and fibrous proteins, PGs, and GAGs, which is maintained by both covalent and noncovalent interactions. Recapitulating the composition and structure, and moreover the native function of the ECM, is a highly challenging task to bioengineers and biochemists. This said, researchers have worked successfully over the past decades on many novel approaches either to produce and further manufacture ECM proteins and natural materials, or to harness the knowledge obtained from studies focusing on the ECM. This has enabled them to mimic the native function of the ECM using ECM-like materials supporting cell attachment, growth, and proliferation as well as differentiation. The fundamental role of such natural materials is to enhance the natural biological repair processes mediated by endogenous cells. However, no technology will reach patients and physicians unless it is commercialized. Upscaling of the laboratory-grade processes is often a hurdle. Advanced process development, such as the introduction of technologies that allows recombinant protein production, has and will further push great ideas to the market.
