Introduction

The chapter "A History of Biomaterials" at the start of this book documents the development and design of indwelling materials for medical and dental purposes. The primary design criteria in the choice of materials were pragmatic and based on the necessary mechanical properties required to fashion a functional device. Orthopedic implants require strong materials for load bearing, articulating surfaces such as joints require durability and resistance to wear, stents and shunts require flexibility and patency, and sutures require a high tensile strength, yet must also be flexible enough for intricate manipulation.

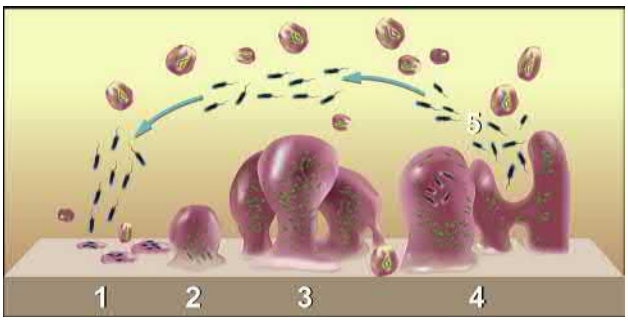
Indwelling devices, however, increase the risk of infection. Catheter-associated urinary tract infection (CAUTI), the most common health care-associated infection, accounted for nearly 40% of all nosocomial infections worldwide (Hooton et al., 2010). Prolonged catheter use is the primary risk factor for developing CAUTI (www.cdc.gov/hai/ca_uti/uti.html). Additionally, the incidence of prosthetic joint (hip and knee) infections (PJIs) and cardiovascular implantable device (CID) infections is increasing dramatically (Xu et al., 2017). CIDs include cardiovascular implantable electronic devices and ventricular assist devices, and implantation is increasing with an aging population. Although estimates vary with the types of devices, host factors and underlying diseases, infection rates generally increase with duration.

While for some procedures, such as orthopedic joint arthroplasty, surgical-site infection rates are low (1%–2%) (Kurtz et al., 2012), the ever-growing number of patients undergoing these procedures translates to large numbers of infection each year. By 2020, estimates suggest that there will be 70,000 cases of infection in the United States alone (Kurtz et al., 2012). Infection of artificial joints is especially devastating, since oral or intravenous antibiotic therapy frequently fails to resolve the infection, leaving the only course of action to surgical debridement, or partial or total revision. The formation of microbial biofilms on these devices contributes significantly to device-related surgical site infections rendering these infections extremely difficult to treat with conventional topical or systemic antibiotic therapy.

Bacterial Biofilms

What Are Biofilms and Why Are They Problematic?

Bacterial biofilms are communities of bacteria that attach and subsequently grow on surfaces of abiotic materials as well as host tissues (Hall-Stoodley and Stoodley, 2009) (Fig. 2.2.8.1). Biofilms also exist as aggregates in fluid or mucus



• **Figure 2.2.8.1** Key processes in biofilm development. (1) Initial attachment of single cells and cell aggregates in the overlying fluid. (2) Initiation of microcolony formation where production of extracellular polymeric substances (EPS) more firmly adheres cells to the surface. (3) Early development of biofilm clusters by clonal expansion (mixed or single species. (4) Mature biofilm. (5) Dispersion of single cells and detachment of biofilm aggregates containing cells and EPS. (Redrawn from Stoodley, P., Sauer, K., Davies, D.G., Costerton, J.W., 2002. Biofilms as complex differentiated communities. Annu. Rev. Microbiol. 56, 187–209.)

layers adjacent to tissues (Dastgheyb et al., 2017). Once attached, bacteria embed themselves in a highly hydrated and protective material termed "extracellular polymeric substances" (EPS). While the EPS matrix consists of bacterially produced polymers, such as extracellular DNA (eDNA), polysaccharides, lipids, proteins (Flemming and Wingender, 2010), host materials can also be incorporated into the EPS. Numerous in vitro and ex vivo studies show that both Gram-negative and -positive pathogens can form biofilms on commonly used medical materials and devices such as surgical sutures and meshes (Engelsman et al., 2007), orthopedic implants and catheters (Jacobsen et al., 2008; Machado et al., 2009), and on host tissues (Hall-Stoodley et al., 2006; Malone et al., 2017a).

The Biofilm Microenvironment

Importantly, biofilms can modify their local environment (Benoit and Koo, 2016) largely because transport through the biofilm EPS is diffusion limited. Nutrients, such as oxygen, are consumed by bacterial cells respiring at the periphery of the biofilm more rapidly than they are able to diffuse into the biofilm. Similarly, acid fermentation deeper within biofilm structures can lead to anaerobic and acidic conditions at the base of the biofilm.

Antibiotic and Antimicrobial Tolerance of Bacteria in Biofilms

Bacteria in biofilms are more resistant to environmental stresses such as dehydration, metal toxicity, and ultraviolet (UV) light exposure than free-floating planktonic bacteria. These strategies, which likely evolved for survival in the natural environment, facilitate survival against attempts to eradicate them with modern materials, antibiotics, and antimicrobial agents. While the exact nature of biofilm tolerance is not fully understood, the most common mechanisms involve (1) bacteria in the interior of the biofilm enter a dormant state due to nutrient depletion (Fux et al., 2004), (2) reaction of antimicrobial agents with the EPS through binding and/or degradation (Anderl et al., 2000), and (3) the development of recalcitrant populations, such as slow growing small colony variants or "persister" cells (Lewis, 2005). These mechanisms are referred to as "tolerance," which is distinct from "resistance," a genetically heritable trait. Recalcitrance to antibiotics and the multifactorial nature of biofilm development requires multitargeted strategies for control (Koo et al., 2017).

Biofilms and the Immune Response

Once formed, biofilms are difficult to eradicate by host immune effectors, including oxidative stress and low pH. Foreign materials alone may also suppress the efficacy of host immunity. Biofilm defense mechanisms include EPS matrix production, which protects bacteria within the biofilm from phagocytes due in part to physical size and viscoelastic properties (Davis-Fields et al., 2019), depending on the biofilm species and age (Guenther et al., 2009). The EPS matrix also reduces the ability of antibodies to penetrate the biofilm (De Beer et al., 1997). Thus biofilm formation facilitates evasion of host immune effectors, and many biofilm-associated infections (cystic fibrosis lung infection, chronic otitis media, gingivitis, and PJI) are associated with chronic inflammation (Hoiby et al., 2015). Paradoxically, such an inflammatory response fails to eradicate the biofilm but contributes to the pathology by damaging host tissue. In some infections, however, biofilms evade the immune system by eliciting a muted inflammatory response (Le et al., 2018). Growing evidence suggests that low-virulence organisms, such as *Staphylococcus epidermidis* and *Cutibacterium acnes*, survive in biofilms as "subclinical" infections.

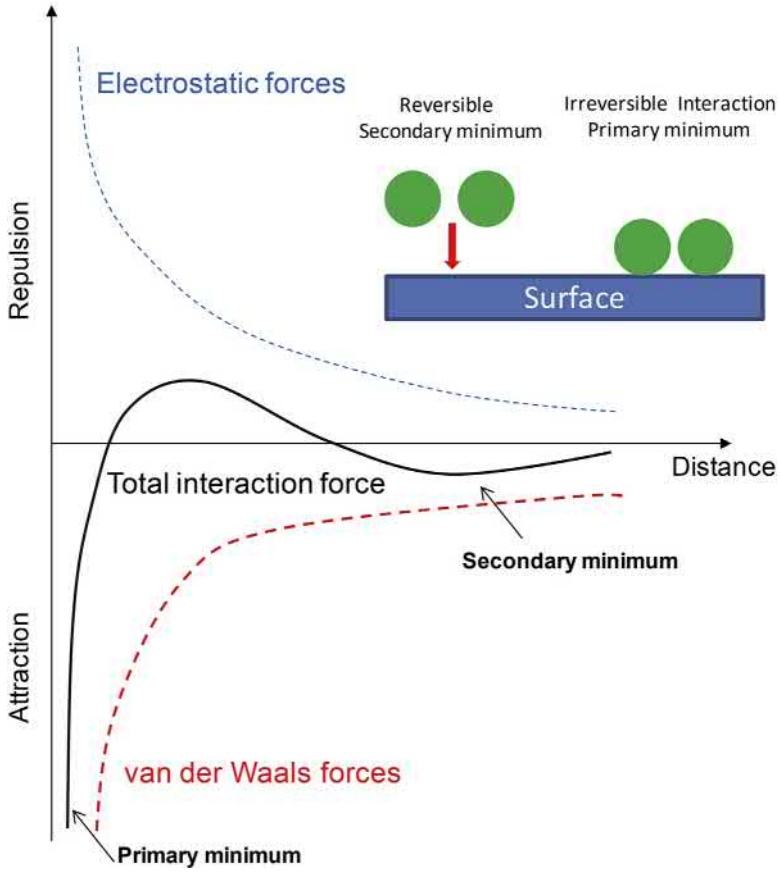
Bacterial Adhesion

Since bacteria become much more difficult to control once they have formed a biofilm, the ideal antibiofilm surface would prevent attachment in the first place. Such a surface would have surface properties that were inherently nonadherent to bacteria, yet were biocompatible.

The Process of Bacterial Adhesion to Surfaces

Bacterial adhesion is a process occurring in integrated phases, the first of which involves bacteria approaching and interacting with the biomaterial surface by long-range, nonspecific interactions like van der Waals or gravitational forces. Once in proximity to the surface (<5 nm), short-range interactions, such as hydrogen bonding and hydrophobic, ionic, and dipole interactions, can be established between the biomaterial surface and the bacterial cell.

Two approaches have been proposed to understand the forces acting between biomaterial surface and bacterial cell during the adhesion process: (1) Derjaguin, Landau,



• **Figure 2.2.8.2** The Derjaguin, Landau, Verwey, Overbeek theory prediction of bacterial cell adhesion (*green spheres*) on a flat surface.

Verwey, Overbeek (DLVO) theory and (2) the thermodynamic model. In both models, bacterial cells are considered abiotic colloid particles even if recent reports of rapid aggregation of staphylococci in synovial fluid (Dastgheyb et al., 2015) suggest that initial interactions of some species with surfaces might not be in the form of single cells, as commonly depicted in conceptual models, but might occur as aggregates of cells. These "protobiofilm" aggregates, which form rapidly through adhesive processes rather than growth, are tolerant to antibiotics and may provide protection even before bacterial proliferation and EPS production occurs on the surface.

DLVO Theory

DLVO theory considers that microorganisms approaching a surface are attracted or repelled depending on the resultant net interaction force deriving from the sum of van der Waals interactions (generally attractive) and Coulomb electrostatic interactions generated from the electrical double layer of the cell and the substratum (generally repulsive) as the driving force in bacterial adhesion (Van Loosdrecht et al., 1990) (Fig. 2.2.8.2).

DLVO theory has been shown to have limited application in the study of bacterial adhesion. Indeed, direct observations of planktonic bacteria using electron microscopy showed that planktonic bacterial cells are not smooth-surfaced colloid particles (Fux et al., 2005). Rather, the entire surface of single bacterial cells is covered by protein appendages (i.e., flagella and pili) projecting as much as 2–6 μm from the cell, and a structured matrix of hydrophobic extracellular polymeric substances (EPS). This external "glycocalyx" is anchored to the polysaccharide O-antigen fibers that project from the lipopolysaccharide of the outer membrane of Gram-negative bacteria, and polysaccharide teichoic acid fibers that project from the cell wall of Gram-positive cells, such that the actual surface of planktonic bacterial cells capable of interacting with a surface consists of a 0.2–0.4-μm-thick layer of protein and polysaccharide fibers.

Thermodynamic Model

The thermodynamic model (Morra and Cassinelli, 1997) takes into account different types of cell/biomaterial interactions (e.g., van der Waals, ionic, and dipole interactions), which are expressed in terms of Gibbs free energy (G) through the determination of the surface tension of adhering bacterial cells, the surface, and the suspending liquid medium, according to:

$$\Delta G^{adh} = \gamma_{bs} + \gamma_{bl} + \gamma_{sl} \qquad \textbf{(2.2.8.1)}$$

where ΔG^{adh} is the free energy of adhesion, γ_{bs} is the bacterium–substratum interfacial tension, γ_{bl} is the

bacterium–liquid interfacial tension, and γ_{sl} is the substratum–liquid interfacial tension. It is possible to obtain experimental data for the various interfacial tensions involving solid surfaces by the use of Young's equation:

$$\gamma_{sv} - \gamma_{sl} = \gamma_{lv} \cos\theta \qquad (2.2.8.2)$$

where γ_{sv}, γ_{sl}, and γ_{lv} are, respectively, the surface tension (or surface free energy) of solid substratum S and vapor phase V, solid substratum S and the liquid L, and the liquid L and vapor phase V; θ is the contact angle of the liquid on the solid (Fig. 2.2.8.3).

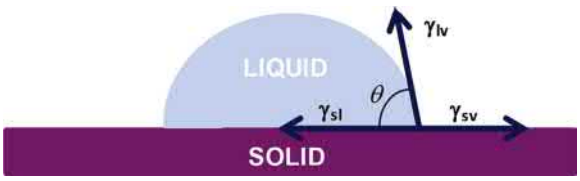
By thermodynamic consideration (Neumann et al., 1974), an equation state relation for the substrate and the liquid surface tension (γ_{sl}) has been formulated where γ_{sl} depends on γ_{lv} and γ_{sv}:

$$\gamma_{sl} = \frac{\left[(\gamma_{sv})^{0.5} - (\gamma_{lv})^{0.5}\right]^2}{1 - 0.015\,(\gamma_{sv}\gamma_{lv})^{0.5}} \qquad (2.2.8.3)$$

Combined with Young's equation this gives:

$$\cos\theta = \frac{(0.015\,\gamma_{sv} - 2)\,(\gamma_{sv}\gamma_{lv})^{0.5} + \gamma_{lv}}{\gamma_{lv}\left[0.015\,(\gamma_{sv}\gamma_{lv})^{0.5} - 1\right]} \qquad (2.2.8.4)$$

which allows the determination of the unknown surface tension of the surface–vapor, γ_{sv}, through contact angle measurements and liquid–vapor surface tensions (γ_{lv}) data. Therefore for a specific liquid–surface couple, for which γ_{lv} and γ_{sv} are known, determination of the surface tension of the bacterial species (γ_{bv}) can be used to predict the extent of adhesion. Adhesion will be favored if the process itself causes a decrease in the interfacial free energy ΔG^{adh}. In this regard, two distinct situations are possible: (1) the surface tension of the bacterium is greater than that of the suspending medium ($\gamma_{lv} < \gamma_{bv}$), in this case ΔG^{adh} decreases with increasing γ_{sv} (bacterial adhesion is favored onto hydrophilic surfaces), or (2) the surface tension of a bacterium is lower than that of the suspending medium ($\gamma_{lv} > \gamma_{bv}$), in which case ΔG^{adh} decreases with decreasing γ_{sv}. This thermodynamic approach was validated by studying the adhesion of bacterial strains onto various polymer surfaces with different concentrations of dimethylsulfoxide to vary liquid surface tension. The surface tension of various bacterial species was determined by evaluating the contact angle on layers of cells (Absolom et al., 1983). While this model describes only the equilibrium of adhesion and cannot be used to describe the kinetics, it helps illustrate why surface hydrophobicity generally induces the adhesion of bacteria, while surface hydration has the opposite effect.



• **Figure 2.2.8.3** Representation of the contact angle (θ) of the Young's equation.

Influence of Material Properties on Bacterial Adhesion

The biomaterial physicochemical properties have been shown to affect bacterial adhesion (Fig. 2.2.8.4). A combination of charge, roughness, hydrophobicity/hydrophilicity, and mechanical properties of the substratum surface may either encourage or discourage bacterial adhesion (Song et al., 2015).

Surface Free Energy (Wettability)

The surface free energy values and contact angles of common polymeric biomaterials are shown in Table 2.2.8.1. Material surfaces are classified as hydrophilic if the contact angle (θ) is less than 90 degrees and hydrophobic when higher than 90 degrees. The wetting features of materials depend on surface chemical compositions. Fluorinated compounds like polytetrafluoroethylene are the most hydrophobic, while oxygenated compounds like polyethyleneoxide are the most hydrophilic. In general, bacterial adhesion is more pronounced on hydrophobic surfaces. However, recent studies have shown that *superhydrophobic* (contact angles higher than 150 degrees) and *superhydrophilic* (very low contact angles) surfaces can both prevent biofilm formation. Although none of the currently used biomaterials exhibits extreme wetting features (Table 2.2.8.1), superhydrophobicity or superhydrophilicity can be obtained by combining surface composition with surface topography and roughness (Feng et al., 2002). Indeed, for rough surfaces the contact angle is described by the Wenzel equation:

$$\cos\theta^* = r\cos\theta$$

where θ^* is the apparent contact angle, θ is the intrinsic contact angle, and r is the roughness factor defined as the

• **Figure 2.2.8.4** Schematic illustration of the main material properties (wettability, surface charge, roughness, and topography) affecting bacterial adhesion.

ratio between actual and projected surface. This equation predicts an increase in apparent contact angle (increase in hydrophobicity) for rougher hydrophobic materials and the opposite behavior for hydrophilic materials.

Various mechanisms have been described to explain the resistance of superhydrophobic and superhydrophilic surfaces to bacterial fouling. Superhydrophilic surfaces are antifouling due to the formation of a dense layer of water (*water layer theory*) that weakens the interaction between bacterium and substrate. In contrast, superhydrophobic surfaces prevent wetting due to air trapped in the surface features (Zhang et al., 2012). According to the Cassie model, water droplets cannot penetrate into the surface roughness grooves and thus sit atop the surface protrusions (Fig. 2.2.8.5).

Consequently, the adhesion force between water droplets and material surface weakens and water droplets readily roll off providing easy-to-clean properties, i.e., the "lotus leaf effect."

Roughness

Generally, an increase in surface roughness promotes bacterial adhesion, since bacteria have a larger surface available and are protected from shear forces (Boyd et al., 2002). Specifically, a small increase in surface roughness increases bacterial adhesion, while a large increase may decrease or have no effect as found for polymethyl methacrylate (PMMA) surfaces in which a small increase in the arithmetic average roughness (Ra = 0.04–1.24 μm) promoted bacterial adhesion while higher Ra values (Ra = 1.86–7.89 μm) had the opposite behavior (Taylor et al., 1998). However, the roughness threshold values will depend on the material, bacterial strain, and culture conditions, making it difficult to predict the extent of bacterial adhesion just on the basis of material roughness.

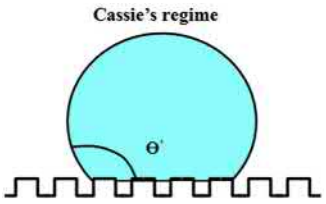
Environment Factors Influence Bacterial Adhesion

Bacterial adhesion is multifactorial, affected by bacterial density, flow conditions, and organic conditioning layers. Flow conditions are known to influence the extent of bacterial adhesion (Thomen et al., 2017), biofilm structure (Stoodley et al., 1998), and quorum sensing (QS) communication (Stoodley, 2016). *Escherichia coli* adhesion was studied under different shear stresses by a microfluidic system that allowed control of hydrodynamic conditions and real-time monitoring of biofilm development. A threshold value of shear stress was reported for biofilm settlement, where a shear stress of 10 MPa inhibited biofilm formation (Thomen et al., 2017). In addition, the shear stress values favoring bacterial attachment were significantly lower than those needed to cause bacterial detachment, suggesting that stronger interactions between the bacterium and the surface are established after initial adhesion (Ming et al., 1998).

A bioorganic conditioning layer on the material surface can also affect bacterial adhesion mediated via ligand/receptor interactions. Indeed, many bacterial strains like staphylococci can express multiple adhesins for host proteins and matrix polymers (Liesenborghs et al., 2018). Therefore the deposition of such molecules onto the biomaterial surface after implantation, which occurs as a typical foreign body reaction (FBR), can mask underlying surface properties and significantly affect bacterial adhesion. Interestingly, the effects of some surface device features, such as charge, roughness, and hydrophobicity, on FBR are similar to those reported for bacterial adhesion processes (Klopfleisch and Jung, 2017), suggesting it may be possible to develop a biomaterial well tolerated by the host and at the same time be resistant to bacterial adhesion.

TABLE 2.2.8.1 Surface Free Energy of Main Polymeric Biomaterials

Material	Surface Free Energy (20°C) (Dynes/cm)	Contact Angle (Degrees)	Notes
Water	72.8	–	
Polyethylene	27	93	Hydrophobic
Polypropylene	28	95	Hydrophobic
Polyvinyl chloride	27	103	Hydrophobic
Polydimethylsiloxane	20	114	Very Hydrophobic
Polytetrafluoroethylene	16	119	Very Hydrophobic
Polyethyleneterephthalate	43	75	Hydrophilic
Polyurethane	38	85	Hydrophilic
Polycarbonate	46	75	Hydrophilic
Polymethylmethacrylate	37	65	Very Hydrophilic
Polyethyleneoxide	43	63	Very Hydrophilic



• **Figure 2.2.8.5** Cassie model for rough surfaces.

Device-Related Infection

Medical and surgical practices rely on an increasing array of biomedical implants and tens of millions are implanted each year. Intravenous catheters, prosthetic heart valves, joint prostheses, orthopedic fixation hardware, peritoneal dialysis catheters, cardiac pacemakers, cerebrospinal fluid shunts, and endotracheal tubes save millions of lives, but all carry the risk of device-related infection, which is generally the first or second most common complication. Many types of catheters and fluid management devices, such as central venous catheters (CVCs), dialysis catheters, ventilators, neurosurgical shunts, and drains, are commonly associated with infection (Rolighed Thomsen et al., 2010). In the United States in 2002 surgical site infection accounted for 20% (244,000) of all healthcare-associated infections outside the ICU (Klevens et al., 2007). Although difficult to dissect exact numbers, many of these were likely associated with a foreign body. The same study reported that 36% of these infections (424,060) were urinary tract infections (UTIs) and the Centers for Disease Control reported that CAUTI accounts for 75% of UTIs (www.cdc.gov/hai/ca_uti/uti.html). Additionally, 250,000 catheter-related bloodstream infections occurred in the United States in 2002 (Daniels and Frei, 2013). In orthopedics, up to 70,000 cases of hip and knee arthroplasty infection are estimated by 2020, with hospital costs expected to reach $1.62 billion (Kurtz et al., 2012).

Major Medical Devices, Materials, and Pathogens

There is a clear correlation between implanted devices and risk of surgical site infection. Any time the protective skin barrier is breached, the possibility exists of introducing bacterial pathogens by air or being drawn in during surgical incision. As early as 1956, Elek showed the inherent propensity of indwelling medical devices to serve as a source of microbial attachment and chronic infection (Elek, 1956). While an injection of 7.5×10^6 *Staphylococcus aureus* into the dermis of healthy volunteers was required to establish an infection (which uneventfully resolved), a 1 cm length of nondissolvable silk suture required only 100–10,0000 cells to develop "severe local abscesses that required draining and vigorous antibiotic treatment" to resolve, illustrating that the presence of a foreign material could decrease the infectious dose by 500- to 10,000-fold. Table 2.2.8.2 lists some of the leading medical devices associated with biofilm infection as well as the material and common pathogens.

Evidence for Biofilms on Devices

Biofilm-associated infections are difficult to detect by conventional blood culture (Tzeng et al., 2015). Most clinical studies of biofilm infections on medical devices therefore rely on the recovery of bacteria from the device (Trampuz and Widmer, 2006), or the culture of strains positive for biofilm formation without directly showing aggregated bacteria (Arciola et al., 2006). Confocal microscopy can analyze hydrated specimens and is compatible with a wide range of fluorescent labeling techniques, including nucleic acid viability staining, antibody labeling, and fluorescent in situ hybridization probes to identify specific bacterial species that directly show viable aggregated bacteria on the device. Figs. 2.2.8.6 and 2.2.8.7 are ex vivo examples of biofilms growing on retrieved components from revision orthopedic surgery from a chronic infection. Typically, biofilms on retrieved implants are more heterogeneous than those grown in vitro and show small aggregates of cells. A combination of confocal microscopy, polymerase chain reaction (PCR), and quantitative reverse transcription PCR (RT-qPCR) provide the most robust evidence for the presence of active bacterial biofilms on implant materials (Nucci et al., 2005, Stoodley et al., 2010).

Control of Biofilm Formation

Control strategies can be divided into three main classes (Fig. 2.2.8.8): (1) antimicrobial approaches, (2) antifouling approaches, and (3) approaches that affect biofilm architecture. Antimicrobial approaches rely on biomaterials that kill microorganisms in proximity to or contacting the surface. Antifouling materials instead repel microbes by either physical or chemical modalities. Biomaterials affecting biofilm architecture do not necessarily kill microbes or prevent adhesion but rather target biofilm virulence.

Antimicrobial Approaches: Biomaterials With Antimicrobial Properties

The design of novel antimicrobial biomaterials is the major focus in preventing biofilm-associated medical device-related infections (Francolini et al., 2017; Koo et al., 2017). Most biomaterials in this category either display or release bioactive molecules, while others promote cell lysis by exposing functional groups that effectively interact with bacteria cell membranes.

Biomaterials Releasing Bioactive Molecules

A common approach in preventing biofilm formation entails surface modification with antibacterial agents, such as antibiotics, metal ions, and nitric oxide. These active compounds are applied to the biomaterial surface by different strategies, namely: (1) physical adsorption (Piozzi et al., 2004); (2) impregnation inside the biomaterial (Donelli

(2016)

et al., 2006); (3) complexation (Francolini et al., 2013); and (4) conjugation (Woo et al., 2002). Physical adsorption is the simplest strategy applicable to many drugs but can suffer from uncontrolled release and short-term device durability. While drug complexation or conjugation may better control drug release, this approach requires a functionalization step to introduce chemical groups capable of binding the selected drugs. Drug-releasing approaches have been applied to different kinds of devices, including orthopedic implants, CVCs, and urinary catheters.

Antibiotics

In orthopedic applications, antibiotics are either impregnated in bone cements (usually PMMA) used for prosthesis fixation or adsorbed onto the titanium (Ti) surface of the prosthesis in cementless prostheses. A number of antibiotic-loaded (A-L) acrylic bone cements and spacers have been developed to prevent or treat PJIs (Table 2.2.8.3). Notably in the United States, the Food and Drug Administration approved the use of A-L cements only in the second stage of a two-stage total joint revision, while in Europe they are

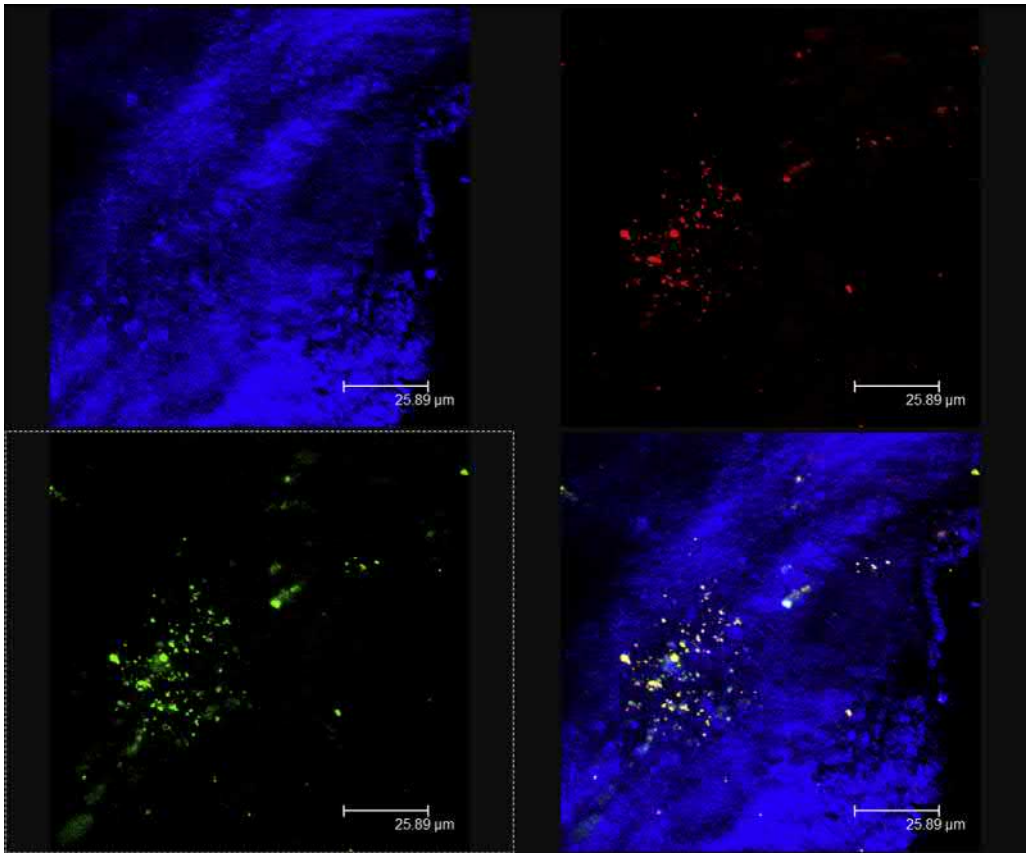
approved also for use in primary total joint arthroplasty. Gentamicin is the most common drug for bone cement impregnation and a large number of gentamicin-loaded cements are available. Gentamicin is also combined with other antibiotics such as vancomycin.

In cementless prostheses, an alternative approach involves coating the implant surface with biodegradable materials that release antibiotic in a controlled fashion. In these systems, the kinetics of antibiotic release strictly follows the kinetics of coating biodegradation. The biodegradable polylactic-*co*-glycolic acid (PLGA) copolymer (Aviv et al., 2007) and poly(D,L-lactide) (PDLLA) polymer (Vester et al., 2010) have been intensively used as coatings for Ti implants to deliver gentamicin. These systems significantly reduced infection rate and improved patient recovery. More recently, mesoporous materials, such as hydroxyapatite, due to their ability to promote osteogenesis, have been used alone or in combination with antimicrobial agents as coatings for dental and bone implants (Oliveira et al., 2017).

For CVCs, antimicrobial-CVCs coated with chlorhexidine/silver sulfadiazine (CH/SS) or minocycline-rifampin (M/R) were first approved for clinical trials in the mid-1990s. The in vivo efficacy of such CVCs was compared in a recent Cochrane analysis (Chong et al., 2017) and indicated that M/R-CVCs reduced catheter colonization more robustly than CH-/SS-CVCs. Both types of antimicrobial-CVCs, however, improved outcomes of catheter-related bloodstream infections. Notably, the routine use of M/R-CVCs in ICUs does not appear to increase antibiotic resistance (Turnbull et al., 2018). Rifampicin-miconazole-coated CVCs were developed to counteract CVC colonization by *Candida* spp. and showed reduced colonization with respect to uncoated CVCs (5% vs. 36%) over 7 days (Yucel et al., 2004). M/R were also adsorbed to silicone urinary catheters, but lacked antimicrobial efficacy against *E. coli* and *Pseudomonas aeruginosa* (Singha et al., 2017). In contrast, the adsorption of rifampin, sparfloxacin, and triclosan onto urinary catheters provided long-term broad-spectrum antibiofilm activity against *Proteus mirabilis*, *S. aureus*, and *E. coli*. The antibiotic-coated Nitrofural-impregnated Foley catheter has been shown to be an effective urinary catheter in preventing biofilm formation compared to silver alloy-coated catheters (Johnson et al., 2012).

Silver

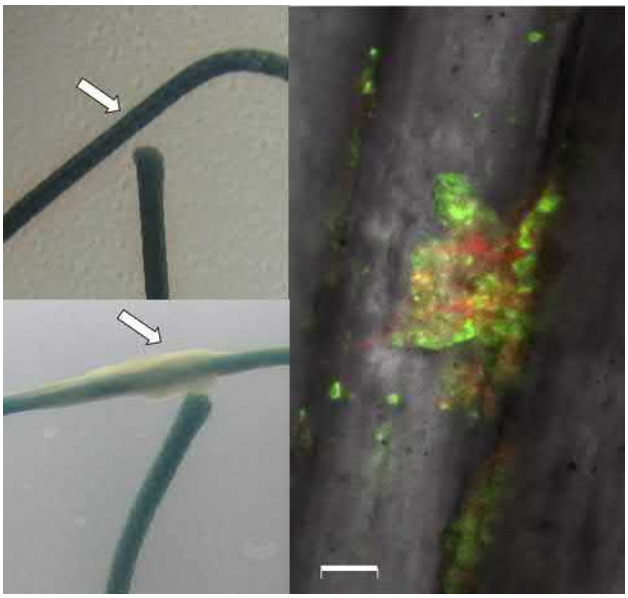
Silver (Ag) has raised much interest because of its long-lasting antimicrobial effect against Gram-positive and -negative bacteria, fungi, protozoa, and certain viruses. The active



• **Figure 2.2.8.6** Biofilm attached to orthopedic screws from a nonunion fracture case. The screw surface with associated invested tissue is blue imaged by reflected confocal microscopy. Staphylococci were stained red by fluorescent in situ hybridization using the Sau probe. All bacteria were stained green with the Eub338 probe. The overlay (*bottom right*) shows that the biofilm consisted primarily of staphylococci with other types of cocci. Scale bar = 25 µm.

form of silver (Ag^+) accumulates at the cellular membrane and leads to membrane perforation (Brett, 2006). In addition to directly damaging cell membranes, Ag^+ appears to be able to interact with essential cell enzymes blocking electron transport chain function and promoting the generation of reactive oxygen species. Ag ions can be released from different formulations, including Ag salts, Ag oxide, metallic Ag, Ag alloy, or Ag nanoparticles. Ag nanoparticles are the most active form exerting antimicrobial activity at 10-fold lower concentrations than Ag ions (Lok et al., 2006).

Silver has been loaded into PLGA coatings for Ti implants and reduced the survival of either methicillin-resistant *Staphylococcus aureus* (MRSA) or *P. aeruginosa* in a rabbit orthopedic implant infection model (Zeng et al., 2019). Three types of silver-CVCs have also been developed: (1) CH/SS, (2) silver-containing zeolites (AgIon technology), and (3) silver, platinum, and carbon black polyurethane (PU) catheters (oligon catheter). While the CH/SS-coated CVCs improved the outcomes of catheter-related bloodstream infections, their efficacy in vivo was lower than M/R-CVCs (Chong et al., 2017), presumably due to low activity of silver against Gram-positive bacteria. Also a metaanalysis found the efficacy of the other two types of silver-CVCs to be limited (Chen et al., 2014), raising questions about the utility of Ag.



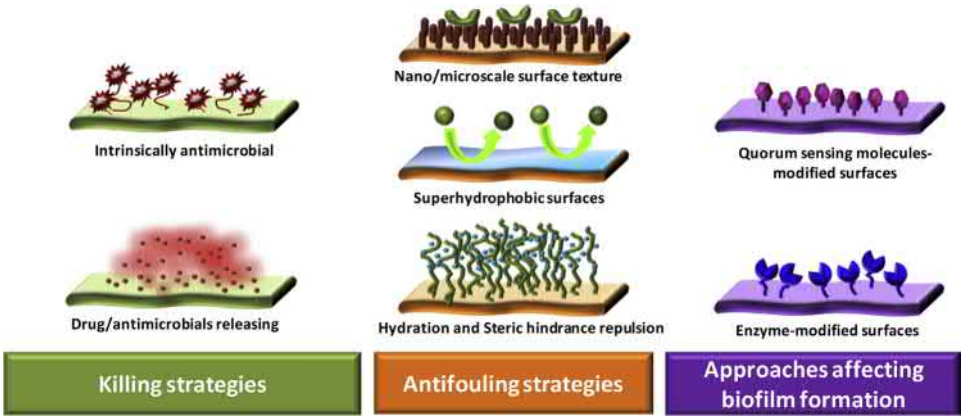
• **Figure 2.2.8.7** Biofilm aggregated attached to a braided permanent surgical suture associated with a knee arthroplasty revision (Swearingen et al., 2016). *Left panels*: Outgrowth of biofilm (*white arrow*) after 2 days from a section of the suture that was placed in nutrient agar immediately after explantation. No visual indication of biofilm presence was on the suture before incubation (*top left*, *white arrow*). *Right panel*: Confocal microscopy of biofilm on a suture from the same case. Bacterial cocci stained red with the nucleic acid probe Syto59 and surrounding EPS stained green with a lectin that labels poly-*N*-acetyl glucosamine, an EPS polymer of staphylococcal biofilms. PCR confirmed *Staphylococcus aureus*. Scale bar = 5 μm.

Silver is also commonly used for urinary catheters (Johnson et al., 2012). Most clinical trials are focused on Ag alloy coatings due to poor solubility of silver salts. Generally, Ag alloy-coated urinary catheters were more effective in reducing CAUTI than Ag oxide-based coatings (Davenport and Keeley, 2005), but less effective than antimicrobial nitrofural coatings (Pickard et al., 2012).

Silver is successfully used in wound-dressing materials. In a recent Cochrane systematic review analyzing dressings and topical agents for treating venous leg ulcers, silver dressings were among the most highly ranked treatments. Silver dressings increased healing of venous leg ulcers (Norman et al., 2018), and silver-treated polyethylene mesh or nylon hydrophobic materials exhibited prolonged efficacy with sustained Ag release compared to hydrophilic dressings (Kostenko et al., 2010), illustrating how material properties may influence the efficacy of an antimicrobial agent.

Low-Dose Nitric Oxide

While low-dose nitric oxide (NO) was first shown to modulate c-di-GMP levels in *P. aeruginosa*, which in turn led to biofilm dispersal, biofilm dispersal has subsequently been shown with multiple types of bacteria (Barraud et al., 2015). Since gaseous NO is highly labile, NO donors in a material are stabilized to selectively deliver NO. Nitroxides (sterically hindered NO analogs) that exert biological responses via NO-mimetic properties are being evaluated to address stability (De La Fuente-Núñez et al., 2013).



• **Figure 2.2.8.8** Approaches to control bacterial adhesion and biofilm formation onto biomaterials.

TABLE 2.2.8.3 Examples of Antibiotic Releasing Devices

Device	Product Type	Antibiotic
Orthopedic prosthesis	Bone cements	Gentamicin
		Tobramycin
		Gentamicin + Vancomycin
		Gentamicin and clindamycin
		Erythromycin and colistin
	Prosthesis coatings	PLGA + Gentamicin
		PDLLA + Gentamicin
		HA + gentamicin, tobramycin, vancomycin, or doxycycline
Central venous catheters	Catheter coatings (both the internal and external surfaces are coated with antibiotics)	Minocycline and rifampin- central venous catheter
		Rifampin and miconazone-central venous catheter
Urinary catheters	Catheter coatings	Minocycline-rifampin silicone catheters
		rifampin, sparfloxacin, and triclosan
		Nitrofural

HA, Hydroxyapatite; *PDLLA*, poly(D,L-lactide); *PLGA*, polylactic-*co*-glycolic acid.

For example, carboxy-TEMPO induced *P. aeruginosa* and *E. coli* biofilm dispersal similar to NO as well as reduced biofilm tolerance to ciprofloxacin. Carboxy-TEMPO failed, however, to disperse MRSA biofilms, indicating that NO activity may be restricted to certain bacteria. Other strategies under development combine antibiotic activity with a donor compound (e.g., antibiotic–nitroxide conjugates), or target QS alongside NO pathway fimbrolide–NO donor hybrids (Kutty et al., 2013).

Intrinsically Bioactive Biomaterials: Cationic Materials

Many research groups have recently focused on intrinsically biocidal polymers because of their long lifetime and low propensity to induce antibiotic resistance (Munoz-Bonilla and Fernandez-Garcia, 2012). The best studied macromolecular biocides are cationic polymers with a net positive charge either in the backbone or side chain. Cationic polymers bind to the negatively charged components of the microbial cell membrane promoting membrane disassembly and leakage or lysis. Cationic polymers are extracted from natural sources or synthesized in the lab.

Natural Cationic Polymers

Chitosan. Chitosan is a polysaccharide composed of randomly distributed *N*-acetylglucosamine and D-glucosamine having low toxicity toward mammalian cells (Kumar et al., 2004) and antibacterial activity against many Gram-positive and -negative bacteria (Rabea et al., 2003). Chitosan can be processed to obtain a variety of products, including hydrogels, membranes, fibers, and coatings. In addition, its reactive functional groups can be functionalized to improve polymer solubility (Stepnova et al., 2007) and antimicrobial activity (Amato et al., 2018). Chitosan is largely employed in wound dressings, drug formulations, and tissue engineering (Rajoka et al., 2019).

Covalent grafting of chitosan to Ti and Ti alloys was shown to prevent *S. aureus* biofilm formation (Tan et al., 2011). Similarly, chitosan covalently attached to various polymer surfaces (Popelka et al., 2012; Wang et al., 2012a) conferred plastics with antimicrobial properties against *E. coli*, *S. aureus*, and *P. mirabilis.*

Chitosan has also been combined with anionic polymers, such as heparin, hyaluronic acid, and alginate, to obtain antimicrobial self-assembled multilayered films. Chitosan/κ-carrageenan films displayed better antiadhesive properties against enterococci than pure chitosan (Bratskaya et al., 2007). Chitosan/lentinan multilayered coatings on PU surfaces significantly inhibited *P. aeruginosa* (Wang et al., 2012b). Finally, hyaluronic acid/chitosan polyelectrolyte multilayers were successfully developed onto Ti-6Al -4V alloys for orthopedic applications (Valverde et al., 2019).

Antimicrobial Peptides. Antimicrobial peptides (AMPs) are produced as part of the first line of defense in innate immunity system. Typical AMPs are small cationic peptides (10–50 amino acids) with amphiphilic features to optimally interact with bacterial membranes. As polycations, AMPs interact with negatively charged moieties of cells and then cross or produce pores in the outer membrane or cell wall of bacteria. Several AMP antibiofilm mechanisms have been described, including: (1) degradation of the biofilm matrix; (2) interference with bacterial cell signaling systems; and (3) downregulation of genes responsible for biofilm formation (Yasir et al., 2018). Several

studies have focused on functionalization of biomaterials with AMPs. Self-assembling AMPs layered onto nanotubular titanium surfaces coated with calcium phosphate reduced the adhesion of *E. coli* and *S. mutans* with respect to control surface in vitro (Yazici et al., 2019). The AMP tachyplesin I (Tac), first linked to the polyhydroxyalkanoate granule-associated protein (PhaP) and further immobilized on poly(3-hydroxybutyrate-*co*-3-hydroxyvalerate) films via hydrophobic interaction, resulted in a coated film significantly inhibiting the growth of *E. coli*, *P. aeruginosa*, *S. aureus*, and *Bacillus cereus* in vitro and accelerating wound healing in a deep-wound mouse model (Xue et al., 2018). Temporin-SHa, a small hydrophobic and low cationic AMP, covalently immobilized on modified gold surfaces and displayed antibacterial activity (from 80% to 90% killing efficiency) of Gram-positive *Listeria ivanovii* (Oger et al., 2019). Finally, Moussa et al. (Moussa et al., 2019) synthesized an amphipathic antimicrobial peptide (GL13K) for usage in dental resin composite restorations to prevent dental caries (Moussa et al., 2019).

Synthetic Cationic Polymers

Polyethylenimine (PEI) represents one of the most investigated synthetic cationic polymers. PEI is a hyperbranched cationic polymer with a high density of positive charges, with activity against a number of Gram-positive and -negative bacteria and fungi (Barros et al., 2015). Due to cytotoxicity concerns, PEI derivatives with lower toxicity have been developed with even higher antimicrobial activity (Pasquier et al., 2008). For instance, the derivative *N*,*N*-dodecyl,methyl-PEI has been applied to several surfaces, including glass (Haldar et al., 2007), titanium, and stainless steel for orthopedic applications (Schaer et al., 2012). Bromohexane-alkylated PEI chains linked to the surface of ureteral stents exhibited a brush-like structure with activity against multiple bacterial species without cytotoxic effects (Gultekinoglu et al., 2015). Similarly, quaternized polyethylenimine methacrylate applied to the surfaces of cylindrical catheters and cross-linked to obtain a stable, nonleachable coating achieved a 2-log reduction in MRSA growth and 94.51% reduction in vancomycin-resistant *Enterococcus faecalis* in a mouse catheter model (Zhou et al., 2017).

Other synthetic antimicrobial cationic materials include cationic PUs (Grapski and Cooper, 2001), cationic silicones (Gottenbos et al., 2002), and cationic acrylic polymers (Francolini et al., 2013).

Antifouling Approaches: Biomaterials That Repel Microbes

Antifouling materials effectively repel microbes, thereby impairing bacterial adhesion and biofilm formation. Different types of materials show antifouling properties and are classified as: (1) hydrophilic polymers; (2) superhydrophobic materials; and (3) materials with nano/microscale surface texture.

Hydrophilic Materials Based on Polyethylene Glycol

Polyethylene glycol (PEG) is the most relevant antifouling polymer in biomedical devices. PEG antifouling properties are thought to be related to surface hydration and steric hindrance effects (Chen et al., 2010). PEG chains linked to a material surface assume a brush-like configuration at the water/surface interface, limiting the approach to the surface by bacteria. Compression of the highly hydrated layer of PEG chains is unfavorable because it would involve a reduction in PEG chain mobility and removal of water molecules. Surface packing density and polymer chain length can be used to control PEG antifouling properties (Roosjen et al., 2004). PEG-functionalized PUs were developed by PEG introduction either in the polymer backbone (Corneillie et al., 1998) or polymer side chain (Francolini et al., 2019). Auto-oxidization in the presence of oxygen, metal ions, and enzymes able to oxidize PEG hydroxyl groups, however, may limit long-term effectiveness.

Superhydrophobic Materials

Since the discovery of the "lotus leaf effect," research efforts have focused on developing superhydrophobic surfaces due to their unique self-cleaning and bacterial fouling-resistant properties (Zhang et al., 2012). Superhydrophobic materials can be obtained by combining hydrophobic moieties with proper micro/nanoscale topography. For example, superhydrophobic paper was obtained by deposition of fluorinated silica particles on cellulose surfaces with positive effects on *E. coli* adhesion reduction (Yang and Deng, 2008). Functionalization with fluoroalkyl silane of TiO_2 nanotubes formed in situ reduced *S. aureus* adhesion onto Ti surfaces (Tang et al., 2011). Antifouling Ti surfaces were also obtained by the formation of self-organized nanostructures (superhydrophobic lotus-like Ti), which dramatically increased the contact angle and prevented *P. aeruginosa* but not *S. aureus* adhesion, suggesting that the type of bacteria affects adhesion to nanostructured surfaces (Fadeeva et al., 2011).

Materials With Nano/Microscale Surface Texture

Physical methods are used to fabricate nano/microstructured surfaces (Jaggessar et al., 2017). Lithography or hydrothermal treatments permit nanostructured bioinspired geometries, including cicada wing, dragonfly wing, and Gecko skin patterns. Each of these structures has a specific geometry and peculiar nanodimensions, which affect selective interaction with Gram-negative and -positive bacteria (Jaggessar et al., 2017).

For soft polymeric materials, surface texture is usually obtained by applying various types of lithography, i.e., soft, nanoimprint, deep UV, electron beam, or X-ray lithography. Soft lithography is a polymer replication method that allows the transfer of micro- and nanostructures onto polymer surfaces by molding (Qin et al., 2010). Soft lithography applied to plastic surfaces (polystyrene, polycarbonate,

and polyethylene) and cast into a shrink-induced rough polydimethylsiloxane mold resulted in rough materials with large ~150-degree contact angles (Freschauf et al., 2012). The materials further exhibited a sliding angle (the angle between the substrate surface and the horizontal plane where a liquid drop slides off the surface by gravity) below 20 degrees, significantly lower than that of flat surfaces (~90 degrees), which significantly reduced *E. coli* adhesion.

For metallic surfaces (i.e., orthopedic implants), surface topographies can be obtained by hydrothermal treatment, a reaction carried out in the presence of water under high temperature and pressure. Hydrothermal treatment at 225°C of Ti implants resulted in a novel nanoflower topography without cytotoxicity, yet showed antimicrobial activity against *S. aureus* (Vishnu et al., 2019). Titanium surfaces with homogeneous spike-like structures prepared by hydrothermal reaction showed robust bactericidal activity against *E. coli* (Lorenzetti et al., 2015).

Biomaterials Affecting Biofilm Architecture

While failing to prevent microbial adhesion, some modified materials can affect biofilm architecture. Such materials can expose enzymes or QS molecules that modify biofilm structure and enhance biofilm removal by either physical methods or antibiotic treatments.

Biomaterials Modified With QS-Quenching Enzymes

Bacterial cell–cell communication in biofilms is regulated by the secretion of signaling molecules and concentration gradients of specific molecules in the local biofilm environment. Several QS signals have been identified (Jiang et al., 2019), including: (1) *N*-acyl-homoserine lactones (AHLs), (2) lipids, and (3) cyclic or linear peptides. Recently, QS-quenching enzymes have been isolated and AHL-lactonases and AHL-acylases affect biofilm architecture. The AHL lactonase AiiA, isolated from *Bacillus* and deposited on gold nanoparticles, reduced biofilm thickness of multidrug-resistant *Proteus* (Vinoj et al., 2015), while acylase-functionalized biomedical PUs reduced biofilm *P. aeruginosa* (Grover et al., 2016). A combination of acylase and esterases immobilized on medical plastics resulted in a 2-log reduction in *P. aeruginosa* biofilm formation on enzyme-treated silicone (Kisch et al., 2014). Silicone urinary catheters coated with a stable coating of alternating layers of acylase and the cationic polymer PEI also reduced *P. aeruginosa* biofilm formation in vitro (Ivanova et al., 2015).

Furanones produced by plants can inhibit bacterial adhesion and biofilm formation by interfering with QS pathways, including the AHL-regulatory system in Gram-negative bacteria and the alternative AI-2 signaling system in both Gram-negative and -positive bacteria (DE Nys et al., 2006). The benzofuranone usnic acid, when attached to PUs, was shown to kill adherent *S. aureus* cells and affect *P. aeruginosa* biofilm structure (Francolini et al., 2004). In contrast, the brominated furanone furanone-3 applied to a polyvinyl chloride surface was ineffective against *S. aureus* biofilm (Yujie et al., 2013), but inhibited *E. coli* biofilms (Lianhua et al., 2013). Adsorbed 3-(1-bromohexyl)-5-dibromomethylene-2(5H)-furanone onto various biomaterials reduced *S. epidermidis* adhesion and EPS production (Baveja et al., 2004). Dichloro-5-hydroxy-2(5H)-furanone incorporated onto succinimidyl-functionalized polyvinylpyrrolidone and linked onto PU surfaces enhanced hydrophilicity and increased antibacterial activity against *S. aureus*, *S. epidermidis*, and *P. aeruginosa* (Xie et al., 2018). Finally, halogenated 4-bromo-5-(bromomethylene)-2(5H)-furanone embedded in biodegradable polylactide nanoparticles and applied to Ti implants resulted in localized inhibition of *S. aureus* throughout a 60-day study period, long enough to prevent implant-related infections in both the early and intermediate stages of device implantation (Cheng et al., 2015).

Biofilm Matrix-Degrading Enzymes

Two enzymes, dispersin-B (a poly-*N*-acetylglucosamine [*p*NAG] degrading enzyme) and DNase I (eDNA-degrading thermonuclease) can degrade pNAG or eDNA in the biofilm EPS matrix. Dispersin-B was isolated from the periodontopathogen *Aggregatibacter actinomycetemcomitans* and was shown to disperse preformed biofilms of multiple types of bacteria (Itoh et al., 2005). Layered hydrogels based on cross-linked poly(allylamine hydrochloride) and poly(methacrylic acid) loaded with dispersin-B prevented biofilm formation by *S. epidermidis* (Pavlukhina et al., 2012). Dispersin-B was also adsorbed onto PUs and inhibited *S. epidermidis* biofilm formation as well as exerting synergism with the antibiotic cefamandole nafate (Donelli et al., 2007).

DNase has also been adsorbed to materials and studied for its ability to affect biofilm formation by several pathogens. A DNaseI-functionalized PMMA coating was developed by using dopamine as linker (Swartjes et al., 2013). The resulting coating delayed *S. aureus* and *P. aeruginosa* biofilm formation. Using dopamine as an intermediate DNase I was also immobilized on a titanium surface, where it modified wettability of Ti substrate, increased its hydrophilicity, and inhibited *S. mutans* and *S. aureus* adhesion and biofilm formation over 24 h (Ye et al., 2017). Finally, Foley urinary catheters coated with DNase were able to restrict *P. aeruginosa* biofilm formation for up to 5 days (Ghanwate et al., 2014).

Methods for Testing Antibacterial and Antifouling Properties of Biomaterials

While thousands of strategies have been discussed in the literature for antibiofilm purposes, few have yet to make it to commercialization. One issue is that success in vitro and even small animal models are often not good predictors of therapeutic success in humans. A recent metaanalysis showed that the observed magnitude of biofilm killing in vitro was more dependent on the experimental setup than the active agents themselves (Stewart and Parker, 2019). While conventional

minimum inhibitory and biocidal concentration assays are generally good predictors of antibiotic efficacy against a broad range of bacterial species and antibiotics in acute infections, a comparable generic test for biofilms is lacking. This is due to the complexity of the biofilm–implant environment, the diversity of biofilm phenotypes, and the diverse nature of therapeutic strategies. The need for standard methods has been recognized (Coenye et al., 2018; Malone et al., 2017b) and EPA standard methods EPA MLB SOP MB-19, "Growing a Biofilm using the CDC Biofilm Reactor," and EPA MLB SOP MB-20, "Single Tube Method for Determining the Efficacy of Disinfectants against Bacterial Biofilms," are now available. At least a 6-log reduction in colony forming units (CFUs) per CDC Biofilm Reactor coupon (~1 cm^2) is recognized as a criterion for demonstrating probable efficacy. An important consideration, however, is that the method of removing cells from the surface (usually scraping, sonication, and/or vortexing) prior to enumerating CFUs must itself be validated. While these standards are being adopted as guidelines by regulatory agencies the log reduction required to clear a biofilm infection clinically is unclear and is likely highly contextual. Ideally, a reproducible low-cost, simple test could be designed with broad predictive value for many types of devices.

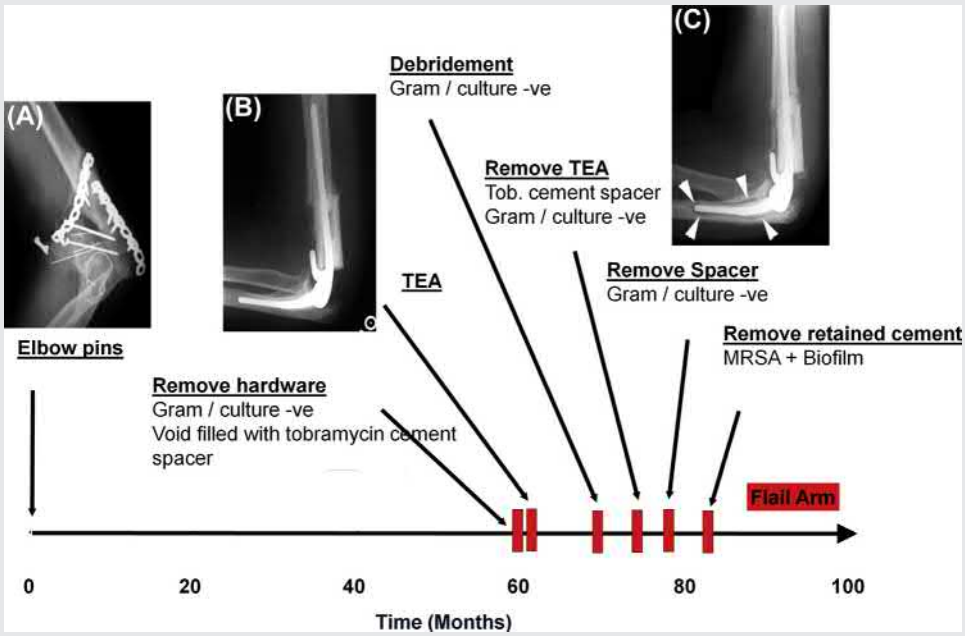
CASE STUDY I: CLINICAL EXAMPLE OF DIFFICULTY IN DIAGNOSING AND TREATING A DEVICE-RELATED BIOFILM INFECTION

Internal metal plates and screws for fixing fractures and the first total joint arthroplasty were performed on knees and hips in the 1890s. Various materials were used and the implants fixed in place by screws and cements formulated from plaster of Paris, resins, and other additives. Early issues included corrosion, lack of mechanical strength, surface wear, osteolysis in response to shed wear particles, and infection. With improvements in materials and implant design, many of the mechanical issues have been resolved; however, infection remains a major complication. Here we present a case timeline illustrating issues with diagnosing and treating an orthopedic infection. The patient was a laborer who had fallen and shattered his elbow, which was subsequently repaired with internal fixation. Five years of discomfort and radiographic evidence of hardware failure led to the decision to perform a total elbow arthroplasty. There was no direct evidence of infection but a two-stage revision was performed to ensure the elbow was infection free prior to implantation. Eight months later the elbow was debrided due to pain. The patient then went through three other operations over 2 years and at each stage there was no direct evidence of bacterial infection by culture or clinical microscopy. Finally, a piece of retained tobramycin-loaded PMMA cement was recovered and examined in a research lab by confocal microscopy and PCR. Live biofilm was found on the cement, despite multiple courses of antibiotics. The infection then resolved but the patient was left with a flail arm.

Learning Points

1. Despite multiple surgeries at great discomfort and cost the only way that the biofilm infection was resolved was removal of the foreign body.
2. Bacterial infection was suspected, but not definitively diagnosed, until the final surgery.
3. Even antibiotic-loaded cement was susceptible to biofilm although it is not known whether the antibiotics had eluted to below therapeutic levels prior to biofilm formation.

Stoodley et al. (2008). "Direct demonstration of viable *Staphylococcus aureus* biofilms in an infected total joint arthroplasty: a case report." The Journal of Bone and Joint Surgery. American volume. 90(8):1751.



CASE STUDY II: SILVER ALLOY COATED URINARY CATHETERS

What Problem Was Addressed?

A 65–70-year-old woman suffering from neurogenic bladder disorder had been permanently catheterized with an indwelling catheter via the suprapubic route since 2006. Soon after, she experienced frequent symptomatic catheter-associated urinary tract infections (0.5–1 CAUTIs/month) requiring antibiotics (0.3–1 antibiotic treatments/month). CAUTIs recurred despite several prevention approaches, including prophylactic antibiotics and bladder rinsing with chlorhexidine.

Interventions

In 2009, the patient started using a silicone catheter, which is less prone to infection and hypersensitivity reactions than latex. In 2011, the patient changed to a silicone catheter coated with phosphate silver ion technology incorporated in a hydrogel coating. In 2013, a silver alloy (gold, silver, and palladium) and hydrogel-coated BIP Foley Catheter was inserted.

Catheters' Performance

While using control catheters, the patient experienced symptomatic CAUTIs requiring antibiotics almost every month for 4 years. The silver-coated catheter had some positive effects. The patient was free from CAUTI for a short period but the symptoms reoccurred after 3 months. After 1 month with the silver alloy Foley catheter, the patient remained free of symptomatic CAUTIs and antibiotic treatment for the following 2.5 years, despite bacteriuria. The coating was stable, with no significant metal release into urine. The same levels of metals were found on both 1 month-used and unused catheters.

Learning Points

1. In long-term catheterization, coated catheters should be preferred to control catheters.
2. The coating technology affects performance of silver-coated catheters. Silver ion technology is less efficacious than silver alloy in long-term catheterization.
3. A nonreleasing mechanism of action ensures coating durability and is safe for patients.

Magnusson, B., et al., 2019. Long-term use of noble metal alloy coated urinary catheters reduces recurrent CAUTI and decreases proinflammatory markers. Ther. Adv. Urol. 11. https://doi.org/10.1177/1756287219854915.

Conclusions

Indwelling medical devices are increasingly used in patient management, whether temporarily for fluids exchange in the case of catheters, or as permanent implants to repair loss of function in the case of orthopedic joints, and cardiovascular stents to stabilize electrical function, or to monitor blood chemistry. Devices will also continue to become more complex in both function and materials. Vexingly, despite advancements in infection control, the rates of surgical site infections have not dropped. Of further concern is the increasing threat of antimicrobial resistance. Infection control engineered into medical devices therefore represents an important strategy to combat infection. A challenge to biomaterials engineers and surface scientists is to develop materials for manufacturing devices that are functional, biocompatible, resistant to infection, and do not promote the development of resistant microbes. While 100% biofilm-proof surfaces remain elusive, more research to better understand biofilm biology may lead to breakthroughs in therapeutic strategies. This formidable challenge offers great rewards with the potential to improve the quality of life of millions of people.

Chapter Questions

1. What are the main stages in bacterial biofilm formation and give examples of how three of these stages may require different approaches with respect to biofilm control?
2. What are three features of bacteria when they are growing as biofilms that make them much more difficult to kill than when they are growing rapidly as a planktonic culture?
3. Classify the different strategies of biofilm control on the basis of their effects on bacterial cells.
4. Given the following three types of medical devices (urinary catheters, orthopedic implants, and CVCs), identify and list materials used for fabrication of the device.
5. Explain how material surface texture (roughness, topography) affects bacterial adhesion.
6. List three antibiotics used for medical device coating to prevent device-related infections. What are three main challenges with coating strategies?

2.3.1 How Well Will It Work? Introduction to Testing Biomaterials

BUDDY D. RATNER

Bioengineering and Chemical Engineering, Director of University of Washington Engineered Biomaterials (UWEB), Seattle, WA, United States

When an engineer designs a suspension bridge over a river, he or she will start with a precise engineering drawing and then, based on well-established mathematical models, assess the strength of materials and corrosion resistance needed to ensure the structure will stand for some anticipated lifetime, e.g., 100 years. The strength of materials and corrosion resistance are compiled in widely accepted handbooks containing data obtained through rigorous testing. The engineer can confidently design the bridge from computer models and handbook data. The bridge will stand and function appropriately for 100 years. Moreover, such a bridge manufactured according to a given set of design criteria and specifications should perform approximately the same whether it crosses a river in Seattle, Birmingham, or Boston.

Now, consider an engineer who sets out to design a heart assist device or a hip prosthesis. This engineer will find the basic mechanical property data relevant to the materials used in handbooks, but little on specific biointeractions, biodurability, and the implications of these biological reactions for the ultimate performance of the complex device. Because of the limited amounts of validated and qualified data on how a given material will perform in the challenging in vivo environment, biomaterials scientists devise tests to observe the performance of materials (and devices) and assess potential biointeractions. These tests are often (but not always) focused on the mechanics and biology relevant to the specific application (orthopedic, cardiovascular, urological, etc.), and they do not consider the potential for different circumstances and possibly different biomaterials–tissue interactions in different patients. This section of the textbook focuses on useful tools and ideas for testing biomaterials.

After this introduction, the section leads off with a chapter titled "The Concept and Assessment of Biocompatibility" (Chapter 2.3.2). Biocompatibility is possibly the most central concept in understanding biomaterials, and you cannot test for biocompatibility until you understand what it is. Chapter 2.3.3 ("In Vitro Assessment of Cell and Tissue Compatibility") and Chapter 2.3.4 ("In Vivo Assessment of Tissue Compatibility") provide fine overviews of thinking circa early 21st century on testing for biocompatibility, primarily focused on toxicology (in vitro) and the foreign-body reaction (in vivo), and parallel the thinking by most national regulatory agencies (for example, the US Food and Drug Administration). So, why do we need a chapter on the concept of biocompatibility? There are new developments that will probably change the definition of biocompatibility. For example, Chapter 2.3.2 discusses a material (with no toxic leachables) fabricated as a solid film that heals with the classic foreign-body reaction, and the same material fabricated as a precise, porous structure that heals in a vascularized, afibrotic manner. Today's definitions and regulatory climate are not structured to appreciate the significance of these differences. Furthermore, there are other strategies to shift the healing of today's "biocompatible" biomaterials to a more tissue-integrated, vascularized reconstruction. In this fourth edition of the *Biomaterials Science* textbook, we introduce the issues and concerns stimulating new thinking on biocompatibility in Chapter 2.3.2. Chapter 2.2.2 ("Inflammation, Wound Healing, and the Foreign-Body Response") provides essential background to understand the material in Chapters 2.3.2, 2.3.3, and 2.3.4.

Chapter 2.3.5, "Evaluation of Blood–Materials Interactions," looks at another face of the biological reaction to synthetic materials. Millions of medical devices are interfaced

with the bloodstream each year. The reaction of blood with biomaterials is strikingly different from the reactions seen in soft tissue and bone in both kinetics (rapid) and outcomes (clot). Although blood compatibility assessment goes back to the 1930s, to this day we have no widely accepted list of biomaterials that are blood compatible. Indeed, there is little agreement about the structural/chemical/molecular characteristics of a material that engender blood compatibility. Why this lack of clarity and consensus? Chapter 2.3.5 introduces the issues in blood compatibility assessment (the nature of blood, the impact of flow, and the nature of the biomaterial), and illustrates how simple assessment schemes can lead to erroneous conclusions. Accepted blood compatibility tests are introduced but, more importantly, the chapter provides guidelines for drawing conclusions from the results of these tests. Some thoughts on which materials might be blood compatible are offered in this chapter.

Chapter 2.3.6 addresses the use of animals in biomaterials and medical device research. Animal implants (in vivo assessment) are usually required for preclinical testing of medical devices. Without animal testing, it is less likely that the research we perform will transition from laboratory bench to patient. The use of animals in testing is fraught with ethical issues—respect for the animal lives to be sacrificed and minimization of pain to the animal (see Chapter 3.1.11). Also, a key issue is how significant are the results obtained in animals for understanding the performance of the medical device in humans? Humans are different genetically, biochemically, and biomechanically from animals. Also, humans are different genetically, biochemically, and biomechanically from each other. Can predictive models be developed? The answer is, in most cases, "yes," but with some forethought and planning. Without careful consideration and understanding of specific animal models, animal lives will be sacrificed and research funds wasted, since the results obtained may not be useful for the human device. The biomechanics issue is particularly challenging. Almost any orthopedic device (spine, joints) will be subjected to different mechanical forces in the skeletal system of an animal walking on four legs versus an upright, bipedal human. Other considerations are: (1) should we go directly from in vitro testing to testing in human subjects, and (2) what about developing devices for veterinary use (for example, about 5000 intraocular lenses are implanted in dogs each year)? Biomaterials researchers are largely dependent on animal models, and understanding them is essential— Chapter 2.3.6 provides an introduction to the regulatory, ethical, and practical implementation issues associated with common animal models used in the biomaterials community.

2.3.2

The Concept and Assessment of Biocompatibility

BUDDY D. RATNER[1], FREDERICK J. SCHOEN[2]

[1]Bioengineering and Chemical Engineering, Director of University of Washington Engineered Biomaterials (UWEB), Seattle, WA, United States

[2]Department of Pathology/Brigham and Women's Hospital and Harvard Medical School, Boston, MA, United States

What do we mean when we say a biomaterial is biocompatible?

- Is biocompatibility simply a binary "yes" or "no," or is there a continuum of biocompatibilities ranging from "good" to "bad?"
- How can we measure biocompatibility?
- How do we improve or enhance the biocompatibility of a biomaterial?

The *idea* of biocompatibility is central to what makes a material a biomaterial. Also, new developments and concepts in cell biology are shifting thinking about biocompatibility, and this chapter offers an opportunity of a glimpse into the future of biocompatible biomaterials.

> Biocompatibility is so central to what makes a material a biomaterial, that a focused discussion of the subject is justified.

This chapter clarifies some of the issues in biocompatibility, and also raises questions that will likely impact the field in the coming years. In contrast to empirical approaches and practical considerations focused solely about the safety of implanted devices (for example, toxicology, the state of the art today), modern cell and molecular biology ideas may give us a useful "theory of biocompatibility" with quantifiable parameters, testable hypotheses, and validated engineering rules.

Biocompatibility Today

We start with an overview of the state of the art in biocompatibility today, i.e., in the first quintile of the 21st century.

A definition for biocompatibility, widely used in the biomaterials/medical device community, is:

> *"the ability of a material to perform with an appropriate host response in a specific application (Williams, 1987; Zhang and Williams, 2019).*

This definition, though accurate and quite useful in the design, development, and application of biomaterials in medicine, nevertheless offers no insights into the mechanisms of biocompatibility, how to test the biocompatibility of a material or how to optimize or enhance the biocompatibility of a material to improve clinical outcomes. This section of the textbook will expand the definition and explore the philosophical and scientific ideas surrounding biocompatibility.

Specific concepts impacting biocompatibility are elaborated upon in Chapters 2.2.2, 2.3.3 and 2.3.4. Biocompatibility can be assessed using in vitro and in vivo assays. Although a variety of direct chemical and physical interactions may also be important, measurement of the consequences of leachable or secreted substances from biomaterials to cells in culture is the primary goal of in vitro biocompatibility assays. For example, cell proliferation inhibition or cell death are negative outcomes in such assays, and we assume that they would reflect characteristics of materials that are not biocompatible. The in vivo (implantation) response to a "biocompatible" biomaterial is generally described as a mild inflammatory reaction, which, after some 3–6 weeks, resolves itself into a thin fibrous capsule (essentially scar), to a large extent a consequence of the tissue trauma of implantation. Moreover, there may be an ongoing low-level *chronic* inflammatory response, characterized by a limited number of macrophages present at the implant surface even years after implantation, but the reaction site is relatively

quiescent, and with no other indication of adverse local or systemic response. Additionally, the presence of some multinucleated foreign-body giant cells (FBGCs) at the biomaterial–tissue interface is common and of no significant consequence, but a high density of macrophages and many FBGCs suggests that the biomaterial is exerting a persistent inflammatory stimulus. The composite reaction is termed the "foreign-body reaction," or FBR.

Four factors impact that which we refer to as "biocompatibility." These are:

1. Toxicology (the measurement and study of the effects of material leaching from biomaterials) (Chapters 2.3.3 and 3.1.3).
2. Reactions related to products from extrinsic microbiologic organisms colonizing the biomaterial (for example, endotoxin contamination; see Chapters 2.2.8 and 3.1.4).
3. Mechanical effects such as rubbing, irritation, compression, stress concentrations caused by high aspect ratio shapes, corners and modulus mismatch, and mechanical failure. Closely related are size-related effects, for example, if the implant is much larger than a macrophage, comparable in size to a macrophage, and capable of being phagocytosed, or much smaller than a macrophage, i.e., nano-size.
4. A broad range of interactions with the surrounding environment, including proteins, other soluble molecules and ions in extracellular fluid and blood, live microorganisms, and cells, inducing cell–biomaterial interactions (and tissue–biomaterial interactions) that might affect and, indeed, in some cases dominate longer term in vivo outcomes.

Four factors impact that which we refer to as "biocompatibility." These are:

- toxicology
- extrinsic organisms
- mechanical effects
- various biological interactions with the environment, including cell–biomaterial interactions.

Points 1, 2, and 3, above, are well understood, and often applied in the design of biocompatible biomaterials—we understand the principles, have the ability to measure their impact, and we can design devices using clearly defined principles to achieve good outcomes. Point 4 is less well-developed and concerns are expanded upon below, and in other chapters in this textbook. It is important to understand that in contrast to living organ transplants, biomaterials are not generally "rejected." The process of tissue or whole-organ rejection denotes an inflammatory process that results from a specific immune response (i.e., a response to defined antigens by antibodies and antigen-specific T cells), and which synthetic biomaterials typically do not generate. In the FBR (as discussed below), the nature of the reaction is largely dependent on the chemical and physical characteristics of the implant and is a nonspecific (or "innate") immune response.

Toxicology

Polymeric materials often contain extractable components, such as unreacted monomer, oligomers, initiator fragments, stabilizers, and other processing additives. Metals, glasses, and ceramics can release ions and other processing components. The type of reaction that will be considered from a toxicology standpoint is if these substances are released and negatively impact cells (in vitro) or adjacent tissues (in vivo), or if they affect an organism systemically. Biomaterials science, standards organizations, and allied fields have developed reliable methods to measure and identify leachates, and also sensitive and standardized methods to look at the reaction of tissues and cells to these leached substances. These methods are summarized in Chapter 2.3.3. The ISO 10993 standards provide many specific, defined tests for toxicity associated with leachables.

The Products of Extrinsic Organisms Colonizing the Biomaterial

Bacteria (whether viable or not) and their cell wall components are intense inflammatory activators. Fungi such as *Candida* are also inflammatory activators (Kojic and Darouiche, 2004). In the case of implants that are contaminated with fungi, bacteria, or bacterial cell-wall endotoxin (lipopolysaccharide), an intense and usually long-term biological reaction is seen, characterized by large numbers of white blood cells (mostly polymorphonuclear leukocytes [aka neutrophils] and macrophages, collectively called "pus") in the vicinity of the implant. In humans, this reaction would be described by the patient as producing pain, redness, and heat. This response to the contaminated implant can lead to exceptionally thick foreign-body capsules. High concentrations of inflammatory cells (including FBGCs) and thick, dense foreign-body capsules are characteristics of poor biocompatibility. Such extreme reactions to devices with contaminating organisms have been documented with breast implants (Pajkos et al., 2003), and other implant devices. This is distinct from *infection* with live microbiologic organisms, such as bacteria or fungi, in which the organisms may multiply and cause ongoing local tissue destruction and potentially systemic effects. Although infection with live organisms shares some morphologic features with, and can occasionally look like, "poor biocompatibility," the *acute* inflammatory reaction induced by active infection is generally dominated by neutrophils and morphologically distinct from FBR. Infection is generally not regarded as a biocompatibility issue, but rather owing to ineffective sterilization, intraoperative contamination, or seeding by microorganisms during in vivo function (see Chapter 3.1.4).

Mechanical Effects

If an implant is rubbing, abrading, or moving in contact with tissue, or has sharp corners, undesirable reactions that

are superficially classified as "nonbiocompatible" will be observed, irrespective of the material composition. Mechanical mismatch between a hard biomaterial and a soft tissue can lead to damage or irritation to the soft tissue. Cell and tissue responses to mechanical forces are well-known and usually quite significant (Stamenović; Ingber, 2009; Janson and Putnam, 2015; Kumar et al., 2017; Vining and Mooney, 2017; Murray, 2017). An excellent example of the mechanical effect on in vivo bioreaction was seen in 1976, when scientists implanted in rat muscle medical-grade "biocompatible" materials having circular, triangular, and pentagonal shapes (Matlaga et al., 1976). The degree of reaction increased in the order: circle (lowest reaction), pentagon, triangle. The effect was attributed to micromotion associated with the acute angle of the triangle leading to the greatest tissue irritation (induced by stress concentration). In general, it is the role of the implant designer to ensure that the device does not excessively rub or irritate tissue (rounded edges are better than sharp edges, for example). Wherever possible, a surgeon places and anchors a device into an implant site in a manner that minimizes rubbing and irritation.

Cell–Biomaterial Interactions

This topic dominates the literature in biomaterials science (see Chapter 2.1.3). It has been clear since the mid-19th century that living cells interact and attach to different materials in different ways, and the nature of that interaction may have immense influence on gene expression and thereby cell fate, including attachment, migration, spreading, proliferation, differentiation, activation, secretion, and detachment. It is also well established that an adsorbed protein film always precedes cell interaction with surfaces, and the nature of the protein layer directs and modulates the cell response (see Chapter 2.1.2). Since inflammatory cells, such as neutrophils and macrophages, "interrogate" implanted materials shortly after implantation, and since different surfaces interact in different ways with proteins and cells, we would expect the biomaterial to impact the cell-driven in vivo reaction. However, let's examine this conclusion. In vitro, profound differences are seen in cell interactions between different materials. For example, a poly(2-hydroxyethyl methacrylate) (polyHEMA) hydrogel will not permit macrophages to adhere in cell culture, while a tissue culture polystyrene (TCPS) surface readily allows those same cells to adhere. Yet, if the polyHEMA and TCPS are implanted in vivo, both will heal similarly with an avascular, collagenous foreign-body capsule (again, both resulting from the dominant effect of healing of a surgical wound). In fact, all "biocompatible" materials, be they hydrophilic, hydrophobic, metallic, polymeric, or ceramic, will heal similarly with a classic (and largely quiescent) foreign-body reaction (FBR) if there are: (1) no leachables; (2) no products from extrinsic organisms; and (3) no mechanical irritation. The explanation for this striking difference between in vitro bioreaction and in vivo bioreaction has yet to be elucidated, but does highlight the multicell complexity of the in vivo environment, in comparison to the relatively simple environment with one cell type in vitro.

Two additional phenomena are important in modulating the biomaterial–tissue interaction: (1) frustrated phagocytosis; and (2) cytokine release. Macrophages are functionally differentiated to engulf and digest foreign material, in a process called *phagocytosis* (literally, cell eating). Phagocytosis occurs after the adsorbed proteins on the foreign body interact with receptor proteins that are on the surface of the macrophage. The macrophage then stretches itself around the foreign body and, if possible, engulfs it. This traps the foreign particle in a compartment called a lysosome, into which the macrophage secretes a battery of chemicals that attempt to degrade the foreign material. Frustrated phagocytosis is the term used to describe the situation when the macrophage is incapable of "eating" a piece of biomaterial much larger than its size and certainly cannot engulf a macroscopic implant. In this situation the lysosomes (which may be in contact with the foreign material but open to the surroundings) may release their contents into (and themselves may be highly irritating to) the adjacent tissues, causing local tissue damage and inflammation. Moreover, to address a large surface, a macrophage can fuse with other macrophages to form multinucleated FBGCs, whose quantity is often used as a marker of the activity (i.e., aggressiveness) of the FBR (i.e., more FBGC indicative of less biocompatibility). Macrophages also release cytokines (diffusible signaling proteins) in response to biomaterials (Bonfield et al., 1992). Cytokines can be considered as proinflammatory (e.g., IL-1, TNF-α) or antiinflammatory (e.g., IL-4, IL-10) (Kim and Nair, 2019). A measurement of the cytokine shower from an implanted biomaterial may offer insights into its biocompatibility. The neutrophil and the macrophage, both cell types seen in the early phases of the reaction to implanted biomaterials, are considered elements of the innate immunity system. There is now evidence suggesting that T cells, usually thought of as components of the adaptive immune system, are also part of the reaction to biomaterials, particularly when proregenerative healing is noted (Sadtler et al. 2016).

For biodegradable materials used as implants, there are a few additional considerations. Most biodegradable materials degrade sufficiently slowly that a low-level FBR is observed. When the implanted degradable material ultimately disappears, the foreign-body capsule may largely recede. The magnitude of the FBR may be impacted by reaction to the low-molecular-weight degradation products. For example, consider poly(lactic glycolic acid) (PLGA). Though the degradation products are lactic acid and glycolic acid, metabolic molecules always seen in normal physiology, if the degradation is rapid, the high, local acid concentration could damage tissue and trigger an intensified FBR.

Summary of Ideas to This Point

Important points about biocompatibility as we understand it today are:

1. The biological reaction we call biocompatibility is negatively impacted by leachables, products of extrinsic organism surface contamination, and micromotion.
2. As long as leachables, extrinsic organism surface contamination, and micromotion are not impacting the reaction, all materials will give an approximately similar bioreaction in vivo, referred to as the "normal" (i.e., expected, low-level) FBR, composed of a thin fibrous capsule and minimal ongoing inflammation.
3. When the foreign body capsule is thin and the reaction site, after approximately 1 month or longer, is relatively quiescent, this is an acceptable (and indeed, usually unavoidable) FBR and we call the implant "biocompatible (or inert)."
4. Inert biomaterials lead to the reaction described in point 3 (above), and thus are called "biocompatible."
5. The favorable long-term interface between a biomaterial and the surrounding tissues in most medical devices is characterized by a thin, dense, collagenous capsule that isolates the biomaterial implant from the body, and has a minimal, if any, inflammatory component.

New Developments Are Changing the Paradigm of Biocompatibility

Although millions of devices made of biocompatible biomaterials are implanted in humans every year, largely with successful outcomes, there are concerns with the way some implants heal (the FBR), and the fibrous capsule can cause defects in implant performance. For example, a dense fibrous capsule can inhibit diffusion of analytes to implanted sensors, interfere with release of drugs from implanted controlled drug release devices, and enhance the resistance of an electrical path, thereby blocking communication with tissues for implanted electrodes. Capsular contraction is a problem for some devices, such as breast implants, where the contraction of the fibrous capsule (i.e., not an unexpected consequence, since all scars contract) distorts the soft implant, tending to make it spherical. Moreover, a lack of vascularity near the implant–tissue interface can slow the body's response to, and treatment of, an infection adjacent to a medical device. Certainly, the fibrous capsule associated with the FBR can create surgical problems for device removal and revision. In many cases, vascularized, integrated tissue (more resembling normal tissue structure) would be preferable to an avascular, dense capsule.

The potential for vascularized, nonfibrotic healing is now being realized. Such reconstructive healing can be achieved with extracellular matrix (ECM) components or with inert biomaterials with engineered porosity.

Decellularized ECM derived from a number of tissues, for example, small intestinal submucosa (SIS), has been found to heal into the body with little or no fibrosis, excellent vascularity, and general tissue reconstruction (Badylak, 2007). SIS and other decellularized ECMs have been used in millions of human surgeries, largely with good results. If the SIS is cross-linked, it will heal in a proinflammatory manner, with a capsule and a classical FBR. The excellent healing of SIS is attributed to the ability of macrophages to degrade the ECM to bioactive peptides that actively promote healing. Importantly, the ECM structure is heavily infused with macrophages in the early stage of healing, and those macrophages have been shown to be in a phenotype (also referred to as a polarization) conducive to healing (called M2), in contrast to the proinflammatory, fibrotic phenotype (designated M1) (Mantovani, 2006; Badylak et al., 2008; Murray, 2017). There are also suggestions that soluble ECMs derived from neonatal cell culture might be used as coating for implants to aid in healing and integration (Naughton and Kellar, 2008).

Certain porous synthetic biomaterials will also heal in a minimally fibrotic, angiogenic fashion. Observations on the special characteristics of the healing of porous structures in the body go back to the early 1970s (Karp et al., 1973; Klawitter et al., 1976). Many studies demonstrate the importance of pore characteristics to biocompatibility and implant healing (Brauker et al., 1995; Golden et al., 1990). The concern with all these studies was that the materials used had a broad distribution of pore sizes, making it difficult to ascertain the effect on healing of a specific pore size. A method was developed to make materials with a single, consistent pore size, based on using solvent-soluble microspheres as templates to create uniform, interconnected pores. When such materials were implanted subcutaneously, it was noted that when pores were in the size range 30–40 microns, vascularized healing and reconstruction with little fibrosis were observed (Marshall et al., 2004; Madden et al., 2010). Also, these materials were heavily infused with macrophages during healing, and many of the macrophages were in the M2 phenotype (Madden et al., 2010; Sussman et al., 2014). These same materials with 30–40-micron pores healed well in skin percutaneous sites (with dermal and epidermal reconstruction) (Fukano et al., 2010), heart muscle, and other tissues. A further discussion of porous materials can be found in Chapter 1.4.7.

Other strategies have recently been described to manipulate the FBR and the healing response. Implanted spheres of sizes around 1.5 mm have demonstrated reduced FBR (Veiseh et al., 2015). Certain triazole analogs have also been observed to inhibit the FBR (Vegas et al., 2016). Exceptionally nonfouling zwitterionic gels will heal in with no capsule and good local vascularity (Zhang, 2013). Other strategies for modulating the FBR have involved the surface display of important proteins that steer the macrophage to a pro-healing state and delivery of cytokines (i.e., toward the M2 phenotype).

With relevance to biocompatibility, consider differences engendered solely as a result of physical factors. A synthetic hydrogel is fabricated as a solid slab or as a porous structure with 30–40-micron interconnected pores. The chemical compositions of both are identical. Also, they have similar mechanical properties, no leachables, and no endotoxin or bacteria. Yet one heals in a capsule with the classic FBR,

while the other heals in a vascularized, reconstructed manner with little fibrosis. It seems challenging to use the word "biocompatible" for both, given the sharp differences in in vivo biological reaction, despite identical chemistries.

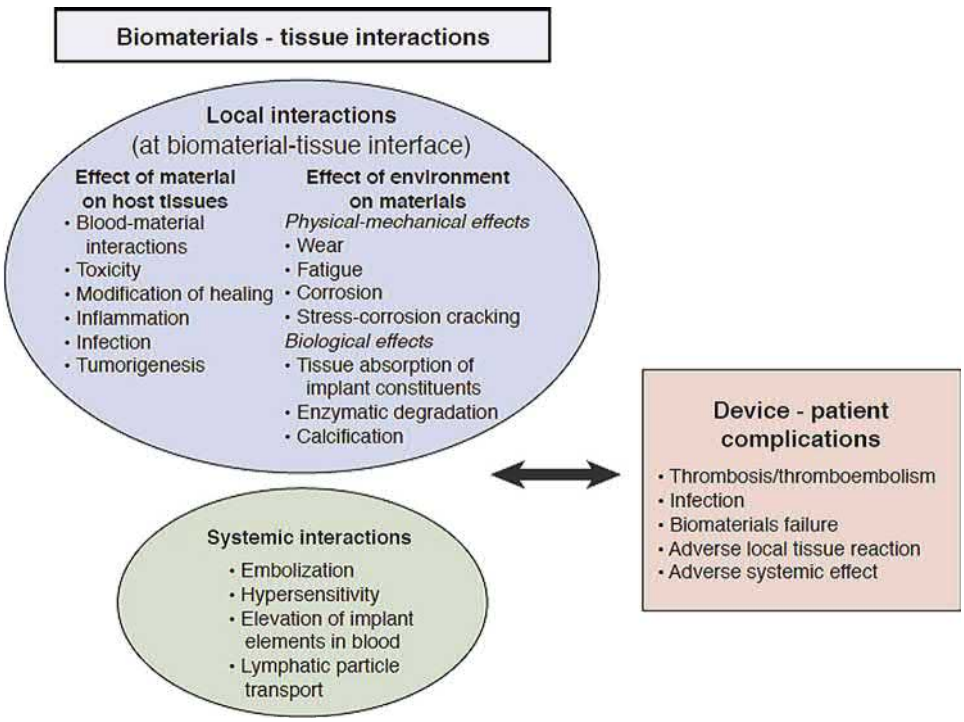
A "biocompatible" material is fabricated as a porous structure or a solid slab. The porous structure heals in an avascular, proangiogenic manner. The solid slab is encapsulated with the classic FBR. How can we use the word "biocompatible" for two such different bioreactions?

Clinical Significance of Biocompatibility

Most implants serve their recipients well for extended periods by alleviating the conditions for which they were implanted. However, some implants and extracorporeal devices ultimately develop complications (i.e., adverse interactions of the patient with the device or vice versa) which constitute device failure, and thereby may cause harm to or death of the patient. Complications generally result from biomaterial–tissue interactions. Moreover, complications are costly, both to patient outcomes (mortality and morbidity) and to the healthcare budget.

Complications of biomaterials and medical devices result largely as a consequence of biomaterial–tissue interactions, which all implants have with the environment into which they are placed. Although specific issues related to inflammatory mechanisms were discussed in detail above, not all complications that might be considered problems with "biocompatibility' are primarily inflammatory. The broader view includes a wide range of effects of both the implant on the host tissues and the host on the implant (Fig. 2.3.2.1) including specific immunological reactions, systemic effects, blood–material interactions, tumor formation, and infection (discussed in Chapters 2.2.2, 2.2.5, 2.2.7, 2.2.8 and 2.3.5 respectively). To a great extent, these interactions arise from qualitative or quantitative alterations of physiological (normal) processes (e.g., inflammation, blood coagulation, etc.) comprising host defense mechanisms that function to protect an organism from deleterious external threats (such as bacteria and other microbiologic organisms, injury, and foreign materials).

Moreover, systemic and remote "biocompatibility" effects can occur. For example, biomaterial-related systemic toxicity and hypersensitivity reaction (through lymphatics and the bloodstream) in animals and patients with either stainless steel or cobalt-based orthopedic total joint replacement components, where elevations of metallic content occur in tissue (at both local and remote sites) and in serum and urine. Transport of particulates over large distances by macrophages to surround and damage the bone of a metal-on-metal hip joint to cause prosthetic joint loosening owing to "osteolysis" (Ebramzadeh et al., 2011; Gibon et al., 2017) or transport to regional lymph nodes and to the lungs and liver can occur. As a consequence, an enlarged, hard axillary lymph node in a woman who received a silicone-gel breast



• **Figure 2.3.2.1** Biomaterials–tissue interactions. (Reproduced from Schoen, F.J., Padera, R.F., 2012. Cardiovascular Pathology. In: *Cardiac Surgery in the Adult,* fourth ed., Cohn, L.H., Edmunds, L.H. (Eds.), McGraw-Hill, pp. 95–148.)

prosthesis for reconstruction following mastectomy for a carcinoma can be misdiagnosed as tumor (Hausner et al., 1978) and prosthetic hip joint or heart valve failure may lead to particulate matter in the liver (Peoc'h, 1996). "Metal allergy" is well recognized and is frequently associated in women with the use of cheap, high-nickel alloy costume jewelry or earrings, and can also occur in association with metallic implants (Hallab et al., 2001). By themselves, metal ions lack the structural complexity required to challenge the immune system. However, when combined with proteins, such as those available in the skin, connective tissues, and blood, a wide variety of metals induce immune responses, and this can have clinical effects. Cobalt, chromium, and nickel are included in this category, with nickel perhaps the most potent; at least 10% of a normal population will be sensitive by skin test to one or more of these metals, at some threshold level.

Conclusions

Since the introduction of "modern" biomaterials to medical practice in the late 1940s and early 1950s, we have seen an evolution in sophistication and functionality (Williams, 2008). *First-generation* biomaterials were simply inert (e.g., titanium, Teflon, polyethylene). *Second-generation* biomaterials (1970, 1980s) interacted with and changed the biological environment in a controlled manner. Such materials might be engineered for biodegradability, poly(lactic acid) for example, or engineered to integrate into bone and induce bone healing, such as bioactive glasses, or to induce a controlled thrombotic deposit, such as a textured polymer surface on the internal surface of a left ventricular assist device. *Third-generation* biomaterials (1990+) biospecifically orchestrate biological processes, and can direct regeneration and restore functionality, and/or respond to the environment in a proactive manner to favorably influence a tissue reaction. Examples include engineered extracellular matrices (Lutolf and Hubbell, 2005), sphere templated biomaterials (Madden et al., 2010), SIS (Badylak, 2007), "smart" biomaterials (Reyes et al., 2007) and resorbable materials that may induce regeneration solely by harnessing the power of endogenous cells and mechanical signals (Hoerstrup et al., 2000; Wissing et al., 2017). Also, consider the published debate on the effectiveness of biomaterials guided by specific peptide signals (Williams, 2011). As biomaterials evolve, so too must the definition of biocompatibility.

Thus, the way we define biocompatibility may change over the next few years and beyond. Examples that challenge the present paradigm of biocompatibility are published, and materials that show unique healing are being applied in clinical medicine. Recent clarification on the diversity of macrophage phenotypes and understanding of resident tissue stem cell pools in the body may permit engineered "biocompatibility," with control of the extent, rate, and speed of integration. These new developments strengthen the science of biocompatibility, and bring biomaterials and tissue engineering closer together. Precision control of biocompatibility can lead to new biomaterials-based therapies with profound advantages for patients.

For now, the medical device regulatory agencies subscribe almost exclusively to the definition of biocompatibility that we have been using since the first functionally successful implants in the 1950s. In learning the subject of biomaterials, it is important that one appreciates the accepted standards for biomaterials; standards that are used by the $300 billion plus medical device industry worldwide and standards that impact millions of patients (see Chapter 3.1.5). Still, since we are on the cusp of a shift in thinking about this subject, it is useful for these newer ideas to be addressed and placed in the context of the word "biocompatibility."

The reader is also referred to complementary views on the subject of the evolving concept of biocompatibility (Bryers et al., 2012; Ratner, 2011; Veiseh and Vegas, 2019; Williams, 2016).

Understanding biocompatibility is central to understanding biomaterials and their clinical outcomes.

In Vitro Assessment of Cell and Tissue Compatibility

MICHAEL F. WOLF[1], KELLY P. COLEMAN[2], EDWARD A. RANKIN[2], GREGORY M. LEWERENZ[2]

[1]Medtronic, Corporate Science and Technology, Minneapolis, MN, United States

[2]Medtronic, Physiological Research Laboratories, Minneapolis, MN, United States

Introduction

This chapter explains how in vitro methods may be used to assess the biological safety of medical device materials. While such methods unavoidably utilize simplified systems as compared to the complex in vivo milieu, they are valuable because they provide insight into potential in vivo tissue and cellular responses. Many in vitro methods have been standardized through a global harmonization process. These standardized tests serve a key role in the biological safety evaluation of medical devices and materials. In the following pages, the scientific basis for each test is examined. Also presented are examples of special in vitro techniques developed in response to a growing shift toward devices that combine drugs or biological agents to improve therapy. It should be noted that results of in vitro tests described in this chapter are often supported with additional in vivo testing (see Chapter 2.3.4).

Background Concepts

At the cellular and molecular level, the presence of a biomaterial has the potential to perturb the local surroundings, which may impact any number of proteins, genes, pathways, molecular modules and networks, and cells. The compatibility of such perturbations—that is, the particular response of a cell or tissue to the material and vice versa—is defined by the extent to which the response is deleterious to the microenvironment or the *material*. Adding to this complexity is the wide range of tissue interfaces and types of materials used in today's medical device applications.

Exogenous chemicals found inside the body are referred to as *xenobiotics*. Any chemical leaching from a device or material falls under this definition. Thus, assessing the cellular and tissue compatibility of a device/material often involves examination of the potential xenobiotic chemicals that it may release. Whether these released chemicals trigger an unacceptable response in the host biological microenvironment is key to determining the biological safety of the device/material.

Exogenous chemicals found inside the body are referred to as xenobiotics. Any chemical leaching from a medical device or material falls under this definition. Thus, assessing the cellular and tissue compatibility of a device/material often involves examination of the potential xenobiotic chemicals that it may release.

Chemicals that possess potentially harmful or adverse properties are referred to as *toxicants*.[1] The response to a toxicant coming from a device/material is greatly influenced not only by the material itself, but also by the type of exposure. Exposure characteristics include the *route* and *site* of exposure (e.g., brain tissue vs. subcutaneous tissue, or skin contact vs. vascular tissue contact, direct or indirect circulating blood contact), *duration of exposure* (e.g., minutes to hours vs. permanent implantation), and the potential *frequency of exposure* over the treatment period or lifetime of the host. (Contrast, for example, the exposure a patient with degenerative heart disease receives from a single prosthetic valve implant to the exposure a diabetic individual receives from insulin pump infusion lines replaced every 72 h.) *Chemical reactivity* of a toxicant is an additional key factor that will impact the degree and type of response in the host (Casarett et al., 2003). A particular reaction may occur because of an agent's chemical reactivity, or it may be due to a more specific recognition or reactivity toward a molecular structure in the biological environment. The compatibility of a chemically reactive agent depends on whether or not it elicits undesirable cell responses or damages cellular structures.

[1] These are substances that are produced by, or are a by-product of, anthropogenic (manmade) activities, as opposed to toxins that are made by biological systems (Casarett et al., 2003).

TABLE 2.3.3.1 International Organization for Standardization ISO 10993 *Biological Evaluation of Medical Devices* Standard by Parts Relevant to In Vitro Tests for Cell and Tissue Compatibility

Part[a]	Title (Publication Year: Status)	Focus	In Vitro Tests for Cell and Tissue Compatibility
3	Tests for genotoxicity (G), carcinogenicity (C), and reproductive toxicity (RT) (2014)	In vitro and in vivo tests	• Bacterial reverse mutation assay (G) • In vitro mouse lymphoma tk assay (G) • Chromosomal aberration in mammalian cells (G) • Syrian hamster embryo cell transformation assay (C) • Balb/c 3T3 focus transformation assay (C) • Embryonic stem cell test (RT)
4	Selection of tests for interactions with blood (2017)	In vitro and in vivo tests	• Hemolysis • General suggestions regarding testing for thrombosis, coagulation, platelet function, hematology, and immunology
5	Tests for in vitro cytotoxicity (2009: under revision)	In vitro tests	• Tests on extracts - L929 elution test - Neutral red uptake test (in Annex) - Colony formation test (in Annex) - Methylthiazol-tetrazolium and related tests (in Annex) • Direct contact test • Indirect contact tests - Agar diffusion test - Filter diffusion
10	Sensitization (2010: under revision in 2019)	In vitro and in vivo tests	DPRA, KeratinoSens, LuSens, SENS-IS, IL-18 RhE assay, EpiSensA, SenCeeTox, h-CLAT, U-SENS, IL-8 Luc assay, and GARD
13, 14, 15	Identification and quantification of degradation products from polymeric medical devices (2010); from ceramics (2001); and from metals and alloys (2000: under revision), respectively	In vitro analytical tests	Information for material characterization and toxicological risk assessment
17	Establishment of allowable limits for leachable substances (2002)		
18	Chemical characterization of materials (2005)		
19	Physicochemical, morphological, and topographical characterization of materials (2006)		
23	Tests for Irritation (new standard being finalized in 2019)	In vitro and in vivo tests	Reconstituted human epidermis assay

[a]Parts 1, 2, 7, 9, and 12 are general guidance documents on use of the standard, animal welfare, sterilization residuals, degradation products, and sample preparation, respectively; Parts 4, 6, 10, 11, 16, and 20 are general guidance documents on in vivo testing relevant to local effects after implantation, irritation and delayed-type hypersensitivity, toxicokinetics study of degradation products and leachables, and principles of immunotoxicity testing, respectively. Part 8 was withdrawn and does not exist.

The *degree of response* in the host in relation to the amount of material or toxicant present defines its *dose–response* relationship. This relationship is extremely important in the characterization of toxicants, as it can often depict a threshold dose below which the probability of an adverse response occurring in the host is either very low (the lowest-observed adverse effect level, or LOAEL) or not measurable (the no-observed adverse effect level, or NOAEL). This threshold dose is of key interest when studying the dose–response effect of a device material and attempting to assess its compatibility with cells and tissues. A classic example of the latter is demonstrated in the case of porcine bioprosthetic heart valves treated with glutaraldehyde to increase biostability and durability. Here, low levels of residual glutaraldehyde may produce negative responses in in vitro tests. Nonetheless, the device itself has proven to be safe and enormously beneficial in patients with cardiac valve disease.

Assessing cell and tissue biological safety has historically been evaluated with the in vitro tests described in this chapter. The focus has been on assays for DNA damage, cytotoxicity, cell proliferation, and quantification of specific proteins recognized to be an influential component or end product of a critical pathway or event (Table 2.3.3.1).

Use of Medical Device/Biomaterial Chemical Composition and Their Extracts for Toxicological Risk Assessment and In Vitro Testing

Medical devices are primarily composed of polymers, metals, ceramics, and to a lesser extent xenograft and allograft biological tissues and molecules. Assessing the in vitro cell and tissue compatibility of these solid multidimensional and often multicomponent devices presents significant challenges. Not surprisingly, these challenges have led to the development of international standards on device or test material evaluation and sample preparation methods (ISO 10993-1:2018 and ISO 10993-12:2012, respectively).

Challenges encountered in sample preparation include: (1) how to properly bring diverse material and device test samples into a standardized and appropriate level of contact with test systems; (2) how to treat composite materials and devices; (3) how to treat degradable materials and devices; (4) how to account for potential material interactions, given the frequency of composite devices; and (5) other confounding factors. Examples of the latter include device size, supplier variability and proprietary issues, tissue contact differences, implant duration diversity, potential manufacturing residues and contamination, and varying biological responses due to individual patient genetics, age, size, sex, and disease state. For in vitro testing, a simplifying premise is that compatibility is most readily verified by focusing on the impact of chemical constituents that may potentially be released, or actually are released as intended in the case of biodegradable materials, from the device/material in vivo. For example, while most polymers used in medical devices are made from clinically proven, relatively inert, high molecular weight materials, it is their low molecular weight leachable components (i.e., residual monomers, oligomers, catalysts, processing aids, additives, and contaminants) that often present a concern. The presence and extent of such leachables depends on a host of factors, such as the source of the material, differing manufacturing processes, and the intended function of the additive(s). In addition, new chemical species may be formed during secondary manufacturing processes, such as heat treatments, irradiation, welding, and sterilization. This is why standards emphasize testing of final finished devices to ensure that test samples have undergone all manufacturing processes (including packaging and sterilization) and are truly representative of what the patient will receive.

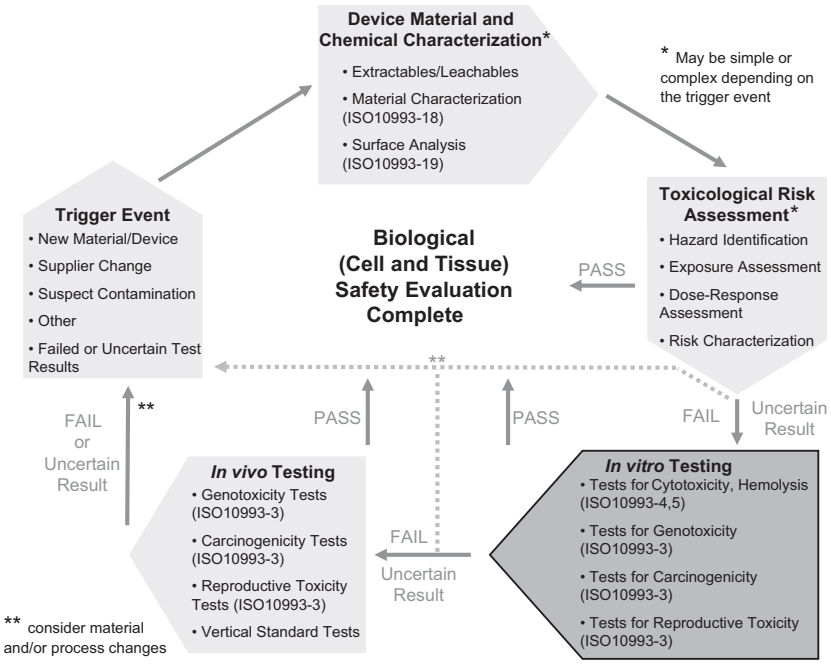
In devices composed of inorganic materials such as metals, alloys, and ceramics, the release of metal ions (e.g., through wear debris, corrosion, or leaching) may also be a cause for concern. Once free, metal ions have the potential to form complexes with proteins and/or DNA due to their structure and/or valence state. These complexes may, in turn, disrupt a number of biological processes (ISO 10993-3:2014; Shamsi and Krantz, 2013).

The potential toxicity of a device material is determined by a *toxicological risk assessment*. Such assessments involve: (1) identifying hazardous chemicals present in medical devices; (2) assessing the extent of a patient's potential exposure to these chemicals; (3) determining the dose–response relationship of each chemical; and (4) combining this information to characterize the risk. Risk assessment calculations are based upon conservative worst-case exposure scenarios. Such scenarios often assume that all leachable chemical constituents will be released into the patient during the first 24 h to determine acute exposure risk, or over 31 days to determine chronic exposure risk. (In clinical practice this is unlikely to occur, but these are nevertheless common conservative assumptions designed to protect patients.) In these calculations, tolerable intakes (TIs) for chemicals of concern are determined using safe exposure level values (e.g., NOAEL or LOAEL), and uncertainty factors (UFs) to account for human genetic variation (UF_1), interspecies extrapolation from animals to humans (UF_2), and quality and relevance of the experimental data (UF_3). A margin of safety (MOS) is then calculated (TI divided by the worst-case exposure dose) to verify that exposure to the chemical of concern does not present a health risk (ISO 10993-17:2002). Supporting toxicity information is frequently found on free government websites or in proprietary commercial databases.[2] ISO 10993-1:2018 recommends that toxicological risk assessments be conducted as a precursor to biological testing (Fig. 2.3.3.1). The underlying rationale is that a well-thought-out and thorough risk assessment may negate the need for most or all expensive and time-consuming in vitro and in vivo biological testing.

The potential toxicity of a material is determined by a *toxicological risk assessment*. Such assessments involve: (1) identifying hazardous chemicals present in medical devices; (2) assessing the extent of a patient's potential exposure to these chemicals; (3) determining the dose–response relationship of each chemical; and (4) combining this information to characterize the risk. A well-thought-out and thorough risk assessment may negate the need for expensive and time-consuming in vitro and in vivo biological testing.

Detailed guidance for preparing in vitro testing samples is provided throughout ISO 10993 *Biological evaluation of medical devices*, Parts 1, 3, 4, 5, and 12 (ISO 10993-1:2018; ISO 10993-3:2014 Annex D, 10993-4:2017; 10993-5:2009; 10993-12:2012). Sample preparation for in vitro biological tests requires careful attention due to each test's volume and extractable percentage requirements. Extraction procedures should: (1) exaggerate the clinical conditions of use; (2) take into account the chemical characteristics of the test and control samples; (3) not cause significant changes in the physicochemical properties of the sample (e.g., degrade or dissolve the material); (4) test the device or material in its intended clinical use state (e.g., identically packaged and sterilized); (5) consider use of both a polar and a nonpolar extraction solvent to simulate the body's aqueous and lipophilic environments

[2] Free online sites include ToxNet, IPCS-InChem, ATSDR, ECHA, SIDS, ICE, NICNAS, and CICADS. Commercial databases include BIOSISToxicology, Toxfile, RTECS, ToxCenter, and ToxPlanet.



• **Figure 2.3.3.1** Schematic depicting the process that occurs to establish the preclinical biological safety of a medical device material. Material characterization and toxicological risk assessment precede in vitro testing for cell and tissue compatibility. In vivo testing may follow, but only if warranted based upon in vitro findings. Note: *structural alerts* refer to chemical structures of varying concern that may be linked to known toxicological mechanisms.

(Table 2.3.3.2); (6) understand potential impact to the in vitro test system; (7) be performed in chemically inert sterile closed containers; (8) be conducted for appropriate duration; and (9) be carried out at a suitable temperature, particularly when using cell culture media as an extraction vehicle. It is also mandatory to use and document the appropriate ratio of sample quantity (e.g., surface area or mass) to extract volume, the proper extract storage conditions, and proper/minimal time delay in testing samples in extractable/leachable studies.

In Vitro Assays to Assess Cell and Tissue Compatibility in Medical Device/Biomaterial Evaluation for Regulatory Purposes

The primary purpose of a preclinical biological safety evaluation of a material or device is to protect humans from potential biological risks arising from the use of the material or device (ISO 10993-1:2018). Standardizing this process safeguards consumers, but also provides industry and governments with a common and accepted scientific basis for evaluating new medical technologies. The most widely recognized guidance documents for this purpose are the ISO 10993 series of standards for the biological and clinical evaluation of medical devices developed by the International Organization for Standardization (ISO) Technical Committee 194 (for further information see https://www.iso.org/committee/54508.html).

Five of the ISO 10993 standards (Parts 3, 4, 5, 10, and 23) describe certain considerations and particular methodologies for in vitro assessment of material/device compatibility with cells and tissues (Table 2.3.3.1). These methods are discussed in further detail later. As benchtop material surface and chemical analytical tests focusing on the material characterization elements of the toxicological risk assessment (described earlier) are themselves indirect tests for cell and tissue compatibility, these ISO 10993 standards are included for reference (Parts 13, 14, 15, 17, 18, and 19). In addition, the in vivo approaches included in the 10993 standards, and many device-specific *vertical standards*, are also important to proper cell and tissue biocompatibility testing.

In Vitro Tests for Genotoxicity, Carcinogenicity, and Reproductive Toxicity: ISO 10993-3

Much of our understanding of cellular processes stems from the study of genetics and our ability to manipulate and characterize DNA and RNA (and the proteins they regulate). The ability to show the impact of these manipulations has been crucial as well. Such information has increased our understanding of how genetic anomalies lead to human disease and defects and has provided critical insight into the mechanisms of carcinogenesis. This awareness has also provided medical device material and component suppliers, device manufacturers, and regulatory bodies with

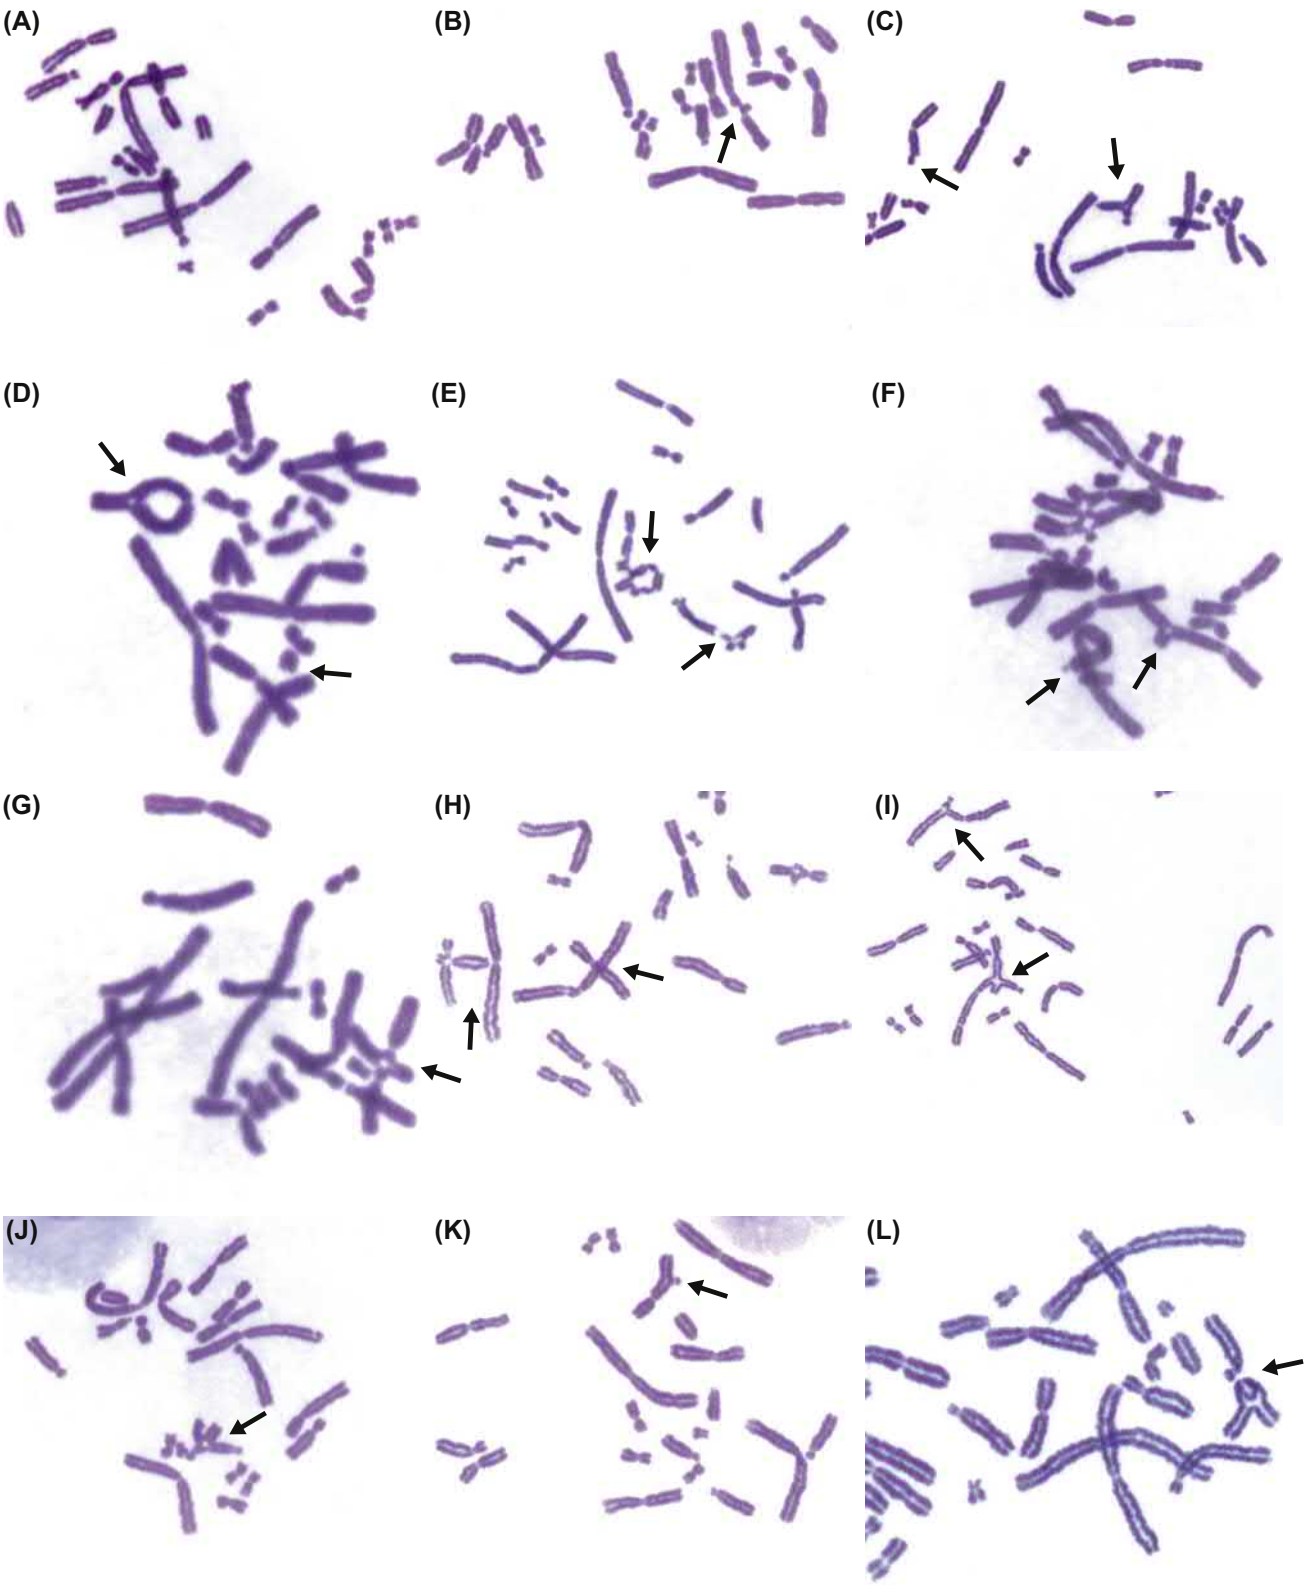
TABLE 2.3.3.2 In Vitro Tests Under ISO 10993 Part 3: Tests for Genotoxicity, Carcinogenicity, and Reproductive Toxicity

In vitro Test Category	Test[a]	Assay Basis	Information Gained
Genotoxicity	Bacterial reverse mutation assay (Ames test)	*Reverse mutation assay*. Small changes in prokaryotic DNA induced by a test material or extract thereof result in a quantifiable change in phenotypic expression of a target gene	Determines if a device material[b] has potential to react with DNA and cause altered DNA expression. Caveat: has potential for false positives.
Genotoxicity	In vitro mouse lymphoma tk assay	*Forward mutation assay*same as reverse mutation test above but assay utilizes a eukaryotic cell line	Same as above. Note: This test may be more predictive than tests using prokaryotic cell lines.
Genotoxicity	Chromosomal aberration	*Chromosome morphology analysis*. Quantification and categorization of mammalian cell chromosome aberrations	Determines if a device material[b] shows potential to interfere with normal DNA replication and/or division processes leading to changes in normal chromosome morphology
Carcinogenicity	Syrian hamster embryo cell transformation assays[a]	*Morphological transformation of normal karyotype primary cells*. Assay designed to mimic two-stage carcinogenesis model (initiation and promotion)	Determines if a device material[b] has potential to transform normal cells to cells with morphologies and behavior consistent with tumorigenic cells
Carcinogenicity	Balb/c 3T3 focus transformation assay[a]	*Macroscopic and microscopic morphological categorization of foci*. Assay uses immortalized aneuploid fibroblastic cell line; assay can mimic two-stage carcinogenesis model	Determines if a device material[b] has potential to transform cells into cells with morphologies consistent with tumorigenic cellscaveat: time consuming and mixed reproducibility.
Reproductive/ developmental toxicity	Embryonic stem cell (ESC) test[a]	*Biostatistically derived, prediction-model equations* utilizing values for 50% inhibition of ESC differentiation, 50% inhibition of cell growth of ESC cells, and 50% inhibition of cell growth of BALB/c 3T3 cells	Determines if a device material[b] has potential to be embryotoxic (teratogenic); presumes (with its limitations) that demonstration of toxicity at this stage may be indicative of concern for impact at other stages of reproduction

[a]See https://www.elsevier.com/books-and-journals/book-companion/9780128161371 for assay details.
[b]Device material extract/leachable chemical(s), or a metabolic derivative(s) thereof.

increasingly sophisticated in vitro tools and standardized methods for screening materials and chemicals for potential health concerns falling under this category.

In the context of biomaterials science, genotoxicity refers to the potential of the solid device material, and/or its constituent chemicals, biodegradation products, metabolites, leachables, or contaminants, to induce a detrimental effect on DNA, or on the genetic processes of a host cell or tissue (ISO 10993-3:2014). To thoroughly screen the genotoxic potential of a new device or material, the Part 3 standard relies on well-established in vitro test methods that were modified for devices from historical Organization for Economic Cooperation and Development (OECD) guidelines for testing chemicals. These guidelines describe primary tests that look at gene mutations in prokaryote bacteria (see ISO 10993-33:2015 clause 6), cytogenetic evaluation of chromosomal damage in eukaryotic mammalian cells (i.e., chromosome aberration test [see ISO 10993-33:2015 clause 7; Fig. 2.3.3.2]), gene mutation in mouse lymphoma cells (ISO 109933-33:2015 clause 9), and formed micronuclei in human/mammalian peripheral blood lymphocytes or certain rodent cells (see ISO 10993-33:2015 clause 8). A favored eukaryotic test is the mouse lymphoma tk assay, based on its ability to evaluate for both point mutations (ability to affect only one or a few nucleotides in a gene) and clastogenicity (inducing disruption or breakage of chromosomes leading to sections of the chromosome being deleted, added, or rearranged). These are the two main classes of genetic damage addressed in ISO 10993-3. Taken together, when each in vitro assay is negative, the results indicate a low potential for genotoxicity. When one or more of the tests give a positive result, the device or material is presumed to have a genotoxic potential. In the latter case, in vivo assays can be considered to further evaluate the genotoxicity of the device or material. The combined results of such testing can then be evaluated by weight of evidence or mode of action approaches (see ISO 10993-33:2015 clauses 10 and 11 for in vivo methods, and ISO 10993-3:2014 in general). See the Biomaterials Science textbook https://www.elsevier.com/books-and-journals/book-companion/9780128161371 for details on the bacterial reverse mutation and chromosome aberration assays.



• **Figure 2.3.3.2** Some common chromosome aberrations seen after exposure of CHO cells to extracts from test materials and/or positive controls. (A) Normal spread; (B) chromosome break; (C) chromatid break and triradial; (D) double minute and ring; (E) complex rearrangements and many breaks; (F) complex rearrangements and triradial; (G) quadraradial; (H) quadraradials; (I) triradial; (J) quadraradial; (K) interstitial deletion; and (L) chromosomal interchange. Note: in this type of testing, chromatid gaps, isochromatid gaps, and uncoiled chromosomes are identified but are not computed in the analysis. *Arrows* point to each type of aberration. See https://www.elsevier.com/books-and-journals/book-companion/9780128161371 for further details.

In the context of biomaterials science, genotoxicity refers to the potential of the solid device/material, and/or its constituent chemicals, biodegradation products, metabolites, leachables, or contaminants to cause an undesirable effect on DNA itself, or on the genetic processes of a host cell or tissue (ISO 10993-3:2014).

Along with tests for genotoxicity, carcinogenicity is also addressed in ISO 10993-3:2014. Although devices and materials indicating a genotoxic potential may be presumed to have a carcinogenic potential, a toxicological risk assessment focused on carcinogenic effects is strongly advised before proceeding to carcinogenicity testing. This is based on the predictive potential of the in vitro assays, the need to abide by stipulations in ISO 10993-1, ISO 10993-2, and ISO 10993-6 to eliminate unnecessary use of animals, and on the known mechanisms of carcinogenesis. These mechanisms have clearly shown that not all genotoxins are carcinogens, and vice versa. That is, some chemical carcinogens act through pathways that disrupt cellular metabolic processes (rather than DNA integrity) to induce uncontrolled cell division leading to tumor formation. Therefore careful consideration must be given to a material's history of safe clinical use and chemical characterization before proceeding to carcinogenicity studies.

Given the complex processes involved in carcinogenesis, standard carcinogenicity testing (when called for) requires time-consuming and costly in vivo models. As a result, several non-OECD in vitro alternatives designed to mimic stages of the complex multistep carcinogenic process have been developed for prescreening and are mentioned in the standard. The particular in vitro tests that have received the greatest attention are referred to as "cell transformation assays" (e.g., the Syrian Hamster Embryo Cell Transformation Assay and the BALB/c 3T3 Focus Transformation Assay—see the Biomaterials Science textbook https://www.elsevier.com/books-and-journals/book-companion/9780128161371 for details). In these assays the transformed cells (resulting from exposure to test xenobiotics or device/material extracts) that have acquired the characteristics of malignant cells have also demonstrated the ability to induce tumors in susceptible animals. Other cellular features indicative of transformation to a tumorigenic phenotype include alteration of individual cell morphology, development of anchorage-independent replication, and formation of disordered patterns of colony growth.

The final topic covered in this section is reproductive and developmental toxicity. Careful review of a device's history of safe clinical use and a thorough toxicological risk assessment based on chemical characterization are necessary before in vivo or in vitro testing is considered. Here, attention is directed at the potential exposure of the material/device, or any of its constituents, to the host reproductive tissues, an embryo/fetus, or a potential nursing child. With sufficient and supportive toxicity data from absorption, distribution, metabolism, and excretion studies and the published literature, there is often no need for reproductive toxicity testing (ISO 10993-3:2014). Furthermore, this type of testing is not required where a toxicological risk assessment has established steps to appropriately mitigate situations of reproductive and developmental toxicity concern.

Current testing for reproductive and developmental toxicology relies heavily upon established in vivo models, given the complexity of the phenomena being investigated (modified OECD standards indicated in ISO 10993-3: 2014). However, a variety of alternatives to whole animal testing are becoming increasingly available. For example, the in vitro embryonic stem cell test (EST) has received particular attention due to its correlation to primary embryonic cells and whole embryos. Here, a validation study funded by the European Centre for the Validation of Alternative Methods (ECVAM) found a strong correlation between three in vitro embryotoxicity tests across a diverse group of chemicals presenting different embryotoxic potentials (ECVAM, 2009). Details of the EST test can be found on the Biomaterials Science textbook https://www.elsevier.com/books-and-journals/book-companion/9780128161371.

Medical devices/materials with circulating blood contact, no matter the duration, should be evaluated for reproductive/developmental toxicity, as even acute exposure to a teratogen could impact a developing fetus or embryo. In addition to blood-contacting devices, applications of concern include intrauterine devices, urinary catheters, and energy-releasing radioactive seeds used in oncology that may come into close or direct contact with reproductive tissues, an embryo, or fetus.

As discussed earlier, medical devices are typically composed of solid materials, which often must be extracted in vitro to mimic leaching that may occur in the body. The resultant extracts are often complex chemical mixtures, which are different from the single-chemical assessments upon which genotoxicity tests were developed. These complex mixtures then require several refined analytical chemistry techniques to identify specific agents of concern. In addition, analyses are further complicated by the fact that metabolic activation often plays a central role in the genotoxic potential of a material or chemical. To account for this, genotoxicity testing should include a parallel set of test extracts exposed to an in vitro metabolic activation system.[3] This is done to capture chemicals called *promutagens* (compounds that are not mutagenic by themselves but may be activated into mutagens by metabolic processes). The most common activator used is the S9 fraction culled from rat livers. In the Bacterial Reverse Mutation Assay, for instance, the metabolic enzymes in prokaryotic cells differ from those of normal intact mammalian cells. Likewise, eukaryotic cells may present a metabolic deficiency or may lack normal metabolic enzymes. In vitro tests for genotoxicity, carcinogenicity, and reproductive/developmental toxicity must therefore include a mammalian

[3] An in vitro metabolic activation system is commonly derived from a mammalian tissue homogenate (usually liver). The most commonly employed metabolic activation system is referred to as S9. This is a standard rat liver metabolic-activating system that refers to the supernatant fraction of the homogenate obtained after a 9000 g centrifugation (Malling and Frantz, 1974).

metabolic activator to detect the presence of metabolically activated promutagens and toxicants in the device extracts.

Table 2.3.3.2 briefly summarizes the in vitro tests for genotoxicity, carcinogenicity, and reproductive/developmental toxicity as mentioned in ISO 10993-3. Recall that the in vitro methods described in Table 2.3.3.2 are considered applicable *only* when the need to evaluate a medical device for potential genotoxicity, carcinogenicity, or reproductive/developmental toxicity has been established. This is determined through a toxicological risk assessment process based on material characterization data (Fig. 2.3.3.1, and ISO 10993-1, -17, and -18 [ISO/TC 194, 2018, 2002, and 2005, respectively]). When the risk assessment recommends in vitro testing, the limitations are that no single genotoxicity test is capable of detecting all relevant toxic agents, and that not all test methods are equally well developed or validated for the testing of medical devices or materials. Consequently, to effectively evaluate genotoxicity, a battery of tests is often performed. The standard indicates that one prokaryotic test together with one eukaryotic test are sufficient for this initial battery.

In Vitro Tests for Interactions with Blood: ISO 10993-4

A significant proportion of today's medical devices contact blood. These devices span a variety of limited, prolonged, and permanent contact applications, and the nature of the blood contact varies widely. Important factors at the blood interface include the material, blood flow, surface area, blood anticoagulation and dilution, plus the presence of blood trauma and other tissues. Given the importance of this interface, and the range of blood-contacting device applications, this area of testing has a separate ISO 10993 standard (ISO 10993-4:2017). This subject is also given special treatment in Chapters 2.2.6 and 2.3.5. Table 2.3.3.3 identifies some of the most

TABLE 2.3.3.3 Commonly Applied In Vitro Tests by Key Category of Material/Device Compatibility With the Cellular and Protein Elements in Blood

In Vitro Test Area	Test	Assay Basis[a]	Information Gained
Thrombosis	Thrombus assessment	Assessment of extent and sites of thrombus formation using gross imaging, histology, and scanning electron microscopy	Thrombus presence may indicate material *or* flow-related thrombogenesis. Caveat: acute exposure and in vitro nature of human or animal blood studies may not give observations relevant to actual in vivo chronic performance.
Coagulation	Assays for coagulation proteins (examples include TAT and FPA)	*Enzyme-linked immunosorbent assay* for key coagulation factors. TAT is proportional to thrombin and FPA is proportional to fibrin.	Estimate of coagulation cascade activation. High levels may indicate extensive device or material-related thrombin activity and fibrin formation. Caveat: may also reflect surgical trauma and/or tissue injury; levels may be subject dependent; and levels are highly impacted by type and amount of anticoagulant present, such as heparin
Platelets and platelet function	Platelet counting and assays that assess platelet degranulation	*Electronic particle counting and enzyme-linked immunosorbent assay* for granule-release proteins, e.g., βTG or PF4	Estimates platelets being consumed or activated in response to a material or device. Caveat: platelet aggregation, activation and granule release are highly impacted by thrombin.
Hematology	Material-induced hemolysis Mechanical-induced hemolysis Differential cell blood count (CBC) analysis	*Colorimetric assay* for plasma-free hemoglobin (pfHb); *electronic particle counting* for CBC	pfHb indicates red blood cell damage in response to a material or device, either from extracts/leachants from the device material(s), or from physical forces from the device; CBC provides basic monitor of cell numbers
Immunology	Complement pathway activation via C3a and/or SC5b9 protein assessment	*Enzyme-linked immunosorbent assay* for key complement protein fragments	May indicate device material has potential to activate the alternative complement pathway (caveat: complement activation is surface area, surface chemistry, and anticoagulant dependent).

FPA, Fibrinopeptide A; *PF4*, platelet factor 4; *pfHb*, plasma-free hemoglobin; *TAT*, thrombin–antithrombin III complex; *βTG*, β-thromboglobulin. SC5b9 is the terminal component of the complement system. Note: TAT, FPA, βTG, PF4, and complement assays are commonly used in in vitro characterization studies, as well as in routine preclinical testing. Also, the meaningfulness of findings in in vitro studies is directly proportional to how well the in vitro model replicates actual clinical use conditions of blood flow and temperature, freshness of blood, device exposure surface area, anticoagulation, and other factors.

[a]Samples from proper in vitro or in vivo simulated use.

commonly applied in vitro tests by the key categories of concern in material/device interaction with blood. These assays focus on evaluating the device or material for potential to bring about red blood cell damage and lysis, cause thrombosis, interact with platelets, and stimulate alternative pathway immune reactions (i.e., complement pathway activation).

Just as there are a host of unique blood-contacting considerations associated with each device application, in vitro testing for blood interaction requires unique models and carefully designed and controlled experiments. Models must be designed to mimic the conditions expected in clinical use (e.g., temperature, fresh/not aged blood (Leendert et al., 2016), blood flow, test material surface area:blood ratio (cm^2/mL blood), anticoagulant conditions, and contact duration). See also Münch et al. (2000), Tepe et al. (2002), Sinn et al. (2011), and Girdhar et al. (2018).

Despite the availability of various in vitro assays and models for characterization of materials with blood, lack of validation and questions on relevance to chronic in vivo responses have made such testing more common in acute blood exposure applications and feasibility studies, rather than as standard regulatory requirements (see Braune et al., 2013). An exception is the in vitro use of radiolabeled platelets for platelet stability studies on storage containers for transfusions (Holme et al., 1993; BEST Collaborative, 2006). Most often, a device in its final design is tested in an in vivo model, alongside a legally–marketed comparator device, with a subsection of the study dedicated to specific tests or measurements that characterize blood material/device interactions.

For basic material characterization of blood interaction, the most common in vitro screening tests continue to be the direct and indirect hemolysis assays (ISO 10993-4:2017, ASTM F756). These particular assays may be viewed as special cytotoxicity tests where human or animal red blood cells are used rather than the mouse fibroblast cells used in standard cytotoxicity testing. The second most common in vitro hematological assay applied today is for complement pathway activation. Here, ELISA (enzyme-linked immunosorbent assays) for C3a and/or SC5b9 protein fragments are used to estimate a material's potential for activation of the alternative pathway complement system (see Chapter 2.2.4 of this textbook). The utility of such testing on small surface area devices is controversial because it is not certain if clinical adverse events mediated by complement activation occur on these devices.

In Vitro Tests for Cytotoxicity: ISO 10993-5

A general sequence of events is assumed to take place upon host exposure to a toxicant. First, the toxicant can remain locally or be transported systemically by a combination of active transport processes, for example, via entry into the vasculature and diffusion through tissues. The toxicant can then either: (1) alter the local biological environment causing a general molecular, organelle, cellular, or tissue/organ dysfunction, or (2) interact with specificity to a particular endogenous target molecule such as a protein, membrane component, or DNA. Both scenarios can lead to perturbations in normal cell function and repair processes, leading to cytotoxicity.

The exposure of a single toxicant to a host presents a slightly different situation compared to exposure to a mixture of potential toxicants leaching from a medical device/material. Nevertheless, similar complex biological perturbations are believed to take place when toxicant exposure comes from a medical device material. Classic examples include chemicals that alter local pH and osmolality; solvents and detergents that disturb cell membranes and alter transmembrane gradients; elements that physically deter normal inter- or extracellular transport phenomena; chemicals that facilitate aberrant phosphorylation of proteins; xenobiotics that dysregulate electrically excitable cells; and agents that disrupt mitochondrial function (Chapter 2.3.2 of this textbook) (Gregus and Klaassen, 2003). Mediators of tissue inflammation and fibrosis, as well as agents causing necrosis and apoptosis, are other well-known examples. The phenomenon of fibrotic tissue encapsulation that is invariably associated with implanted medical devices is yet another feature that distinguishes, and potentially limits, toxicant exposure associated with device materials (Chapters 2.2.1 and 2.2.2 of this textbook).

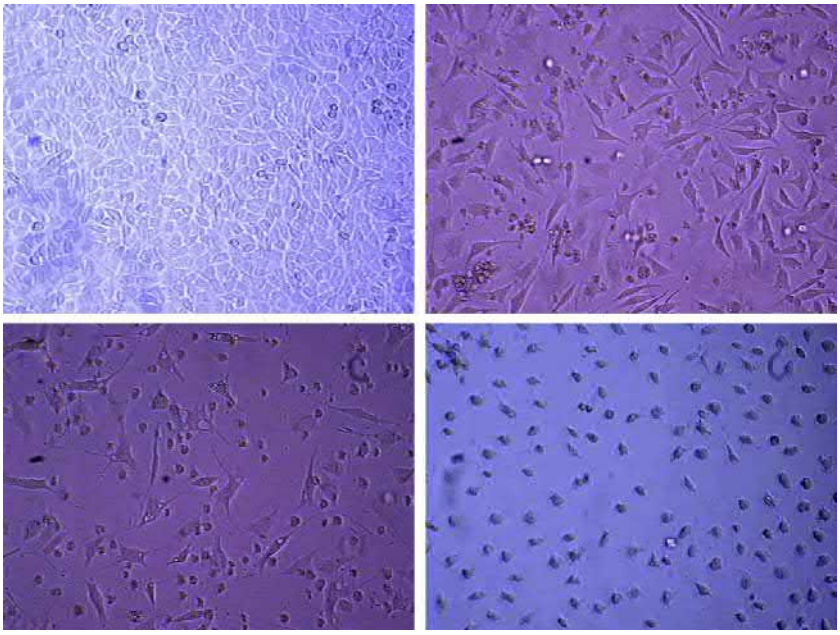
> Chemicals that possess potentially harmful or adverse properties are referred to as *toxicants*. When released from a medical device or material, toxicants can remain locally or be transported systemically by a combination of active transport processes, such as entry into the vasculature and diffusion through tissues. A toxicant can then either: (1) alter the local biological environment causing a general molecular, organelle, cellular, or tissue/organ dysfunction, or (2) interact with specificity to a particular endogenous target molecule, such as a protein, membrane component, or DNA. Both scenarios can lead to perturbations in normal cell function and repair processes leading to cytotoxicity.

Table 2.3.3.4 presents the most commonly used in vitro tests to assess medical devices or their component materials for cytotoxicity. It should be noted that these tests detect general toxicity pathways and mechanisms. Thus, the nature of the tests is not inclusive of all possible toxicity pathways. These tests have, however, demonstrated appropriate usefulness in human health risk assessment, which is the main objective of the ISO 10993 standards. As with any test, each has its limitations and criticisms. Typically, exposure is only of short duration, only a few toxicity pathways are tested, and false positives can occur. In addition, some tests utilize a subjective visual morphological scoring procedure (Fig. 2.3.3.3), whereas others use rapid analysis with colorimetric methods and numerical assessment. Finally, one should be aware that the 2009 version of ISO 10993-5 recommends quantitative cytotoxicity assessment over qualitative methods, and that quantitative methods have a more stringent pass/fail criteria. See Table 2.3.3.4 and https://www.elsevier.com/books-and-journals/book-companion/9780128161371 for further details of each test.

TABLE 2.3.3.4 In Vitro Tests Under ISO 10993 Part 5: Tests for Cytotoxicity

Assessment	Test[a]	Assay Basis	Information Gained[b]
Qualitative	L929 elution test	*Light microscopy and cell morphology scoring using mouse L929 fibroblast cells*. Cells examined at 100× to evaluate cellular characteristics and the percent of apparent cell lysis according to a defined scoring system	Determines if a device material *extract* has potential to cause cell morphology changes and/or lysis
	Direct contact tests	*Light microscopy and cell morphology scoring following layering sample(s) onto mouse L929 fibroblast cell monolayers*. Cells examined to evaluate cellular characteristics and the percent of apparent cell lysis according to a defined scoring system.	Determines if a device material *itself* has potential to be cytotoxic. Caveat: care must be taken to avoid confounding impact of uncontrolled physical interactions.
	Indirect contact tests *Agar diffusion test* *Filter diffusion test*	Same as direct contact test but with test material physically separated from cell monolayer by a nominal 2 mm agarose layer or 0.45 μm pore cellulose acetate filter paper, respectively. Same scoring system as direct contact.	Determines if a device material *itself* has potential to release agents that may be cytotoxic. Caveat: may only be relevant for leachables that can pass through agarose.
Quantitative[c]	Neutral red uptake (NRU) test	*Colorimetric assay of NR uptake in BALB/c 3T3 cells.* Neutral red (NR) acts via a noncytotoxic penetration into live cells and accumulation in intracellular lysosomes. Cells exposed to a cytotoxic xenobiotic(s) show loss of integrity and function and decreased NR uptake and binding.	Determines if a device material *extract* has potential to be cytotoxic. Numerical assessment makes NRU assay less subjective than L929 elution test.
	V79 colony formation assay	*Colony enumeration and calculation of plating (colony formation) efficiency using Chinese hamster lung cell (V79) culture system.* Plating efficiency of a test material is measured against the negative control group.	Determines if a device material extract has potential to be cytotoxic
	Methylthiazol-tetrazolium (MTT) and related tests	*Microculture tetrazolium assay (MTA).* Colorimetric assay using water-soluble MTT compound. Upon exposure to L929 cells, MTT is reduced enzymatically or through direct reaction with NADH or NADPH. A bright blue formazan product forms with intensity proportional to number of viable cells present.	Determines if a device material *extract* has potential to be cytotoxic. Note: other MTA tests that form similar formazan products are also used.

[a]See https://www.elsevier.com/books-and-journals/book-companion/9780128161371 for assay details.
[b]Positive results may require additional testing and justification to establish safe use.
[c]Common scoring criteria among the quantitative assessment methods determine noncytotoxicity for plating or viability values >70% of negative control. Potential cytotoxic values fall below the 70% threshold.



• **Figure 2.3.3.3** Representative light microscopic images of L929 cells in the L929 elution test. (A) and (D) represent the negative and positive controls showing no cell cytotoxicity and approximately 100% cytotoxicity, respectively. Images (B) and (C) represent approximately 50% and 80% cytotoxicity, respectively.

Application-Specific In Vitro Assays Considered in Proof-of-Concept Testing

Classically, assessing the cell or tissue compatibility of a material or device has centered on applying in vitro and in vivo methods to establish a low risk for adverse impact on the host. However, one area of biomaterials science that has been rapidly evolving is *bioactive materials*, which have been modified to impart desirable effects on certain proteins, cells, or tissues. Concepts of this nature typically target one or more specific protein, cellular, or tissue reactions recognized to play a role in how the device or material interacts with the host in a specific application. The following four case studies are intended to illustrate this point, and to show how contemporary in vitro testing technology has played a critical role in demonstrating the capacity of special composite medical device materials to improve certain cellular and tissue responses.

Classically, assessing the cell or tissue compatibility of a material or device has centered on applying in vitro and in vivo methods to establish a low risk for adverse impact on the host. Biomaterials science, however, has been rapidly evolving in the area of *bioactive materials*, which are materials that have been modified to impart desirable effects on certain proteins, cells, or tissues. Concepts of this nature typically target one or more specific protein, cellular, or tissue reactions recognized to play a role in how the device or material interacts with the host in a specific application.

Future Challenges in In Vitro Assessment of Cell and Tissue Compatibility

The task of regulatory agencies and device manufacturers is to select the appropriate combination of supporting information and testing that ensures product safety, device performance, and patient outcome. This task is becoming more complicated because of the expanding repertoire of device applications, specialty materials, and associated biological interfaces.

In light of this complexity, standard tests must be well designed, scientifically sound, and broadly applicable and predictive. As a result, preclinical safety testing faces challenges that include: (1) questions about predictive power; (2) concerns with costs and completion times; (3) issues with the selection and design of appropriate animal models; (4) validation and acceptance of novel in vitro tests; and (5) lengthy development and approval timelines for new methods.

Thankfully, progress is being made in addressing these challenges. First, ISO 10993-1, which provides overall guidance for the biological evaluation of medical devices, was recently revised (2018). Like the previous standard, this version emphasizes that biological evaluation of medical devices or materials should follow a three-step process: (1) material characterization; (2) toxicological risk assessment; and (3) biological testing. Given the extensive information available today on medical device materials, including history of safe clinical use, the intent of the Part 1 standard is to focus on characterization and risk assessment to reduce the amount of biological testing required.

In cases where biological testing is indicated, ISO 10993-1:2018 states that validated and reliable in vitro test methods: "shall be considered for use in preference to in vivo tests," and that: "whenever possible, in vitro screening shall be carried out before in vivo tests are commenced." This guidance is clearly intended to minimize the use of in vivo testing.

A second area of progress involves the development of in vitro assays that are designed to replace in vivo methods. In recent years, news articles and published reports have pointed to a paradigm shift in toxicology testing involving in vitro cell-based assays (NRC, 2007; Schmidt, 2009; US EPA, 2009). In the United States, the TOX21 partnership between the Environmental Protection Agency, National Toxicology Program, National Institutes of Health, and the Food and Drug Administration is an example of this shift. TOX21 is focused on applying new scientific tools in computational, informational, and molecular science to identify and characterize chemicals on the basis of how they activate toxicity pathways inside cells (preferably of human origin). This move away from traditional whole animal toxicity testing to cell-based assays seeks to identify new mechanisms of chemical activity in cells, and to develop better predictive models of human response to toxicants. Results of these models will help regulators make more informed decisions based on actual human toxicity data instead of animal data, which is often suspect and controversial.

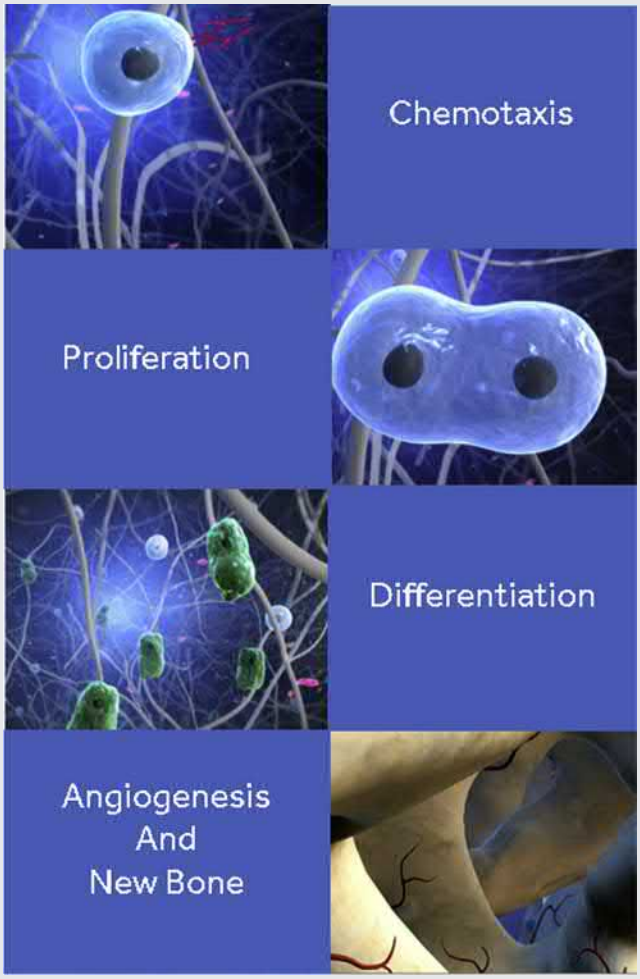
CASE 1 RECOMBINANT HUMAN BONE MORPHOGENETIC PROTEIN IN ABSORBABLE COLLAGEN SPONGE BONE GRAFTS

When bone becomes damaged through traumatic or degenerative processes, one form of therapy involves replacement of the compromised area with bone graft material. Autologous tissue is a common choice, with iliac crest bone the preferred material given its availability and degree of cellularity, which favors healing. Unfortunately, harvesting this bone graft often results in postoperative pain and increased morbidity. To reduce these complications, avoiding the use of iliac crest bone has become more common. Other graft options, such as local bone harvested during the surgical procedure, have been supplemented with either synthetic calcium phosphate ceramics or demineralized allograft bone. However, the quantity of local bone graft available is often limited and contains fewer live cells compared to iliac crest bone (Dempster et al., 1993).

Osteoinductive factors isolated from demineralized bone matrix (Urist and Strates, 1971), now known as bone morphogenetic proteins (BMPs), provide an alternative to autologous bone graft. When the human BMP-2 protein was recombinantly manufactured (recombinant human bone morphogenetic protein or rhBMP-2) and delivered on an absorbable collagen sponge (ACS) scaffold, it was found to induce new bone formation. This was first demonstrated using simple in vitro tests to gauge the bioactivity of the material. In demonstrating chemotactic properties, in vitro studies showed that rhBMP-2 stimulated specific chemotactic migration of bone-forming cells (Lind et al., 1996; Fiedler et al., 2002). In vitro studies also showed that rhBMP-2 could increase the proliferation of several pluripotent cell lines, which are capable of differentiating

(Continued)

CASE 1 RECOMBINANT HUMAN BONE MORPHOGENETIC PROTEIN IN ABSORBABLE COLLAGEN SPONGE BONE GRAFTS—CONT'D



• **Figure 2.3.3.4** Schematic showing the primary cell influences of bone morphogenetic protein (chemotaxis, proliferation, and differentiation) that together lead to angiogenesis and new trabecular bone generation.

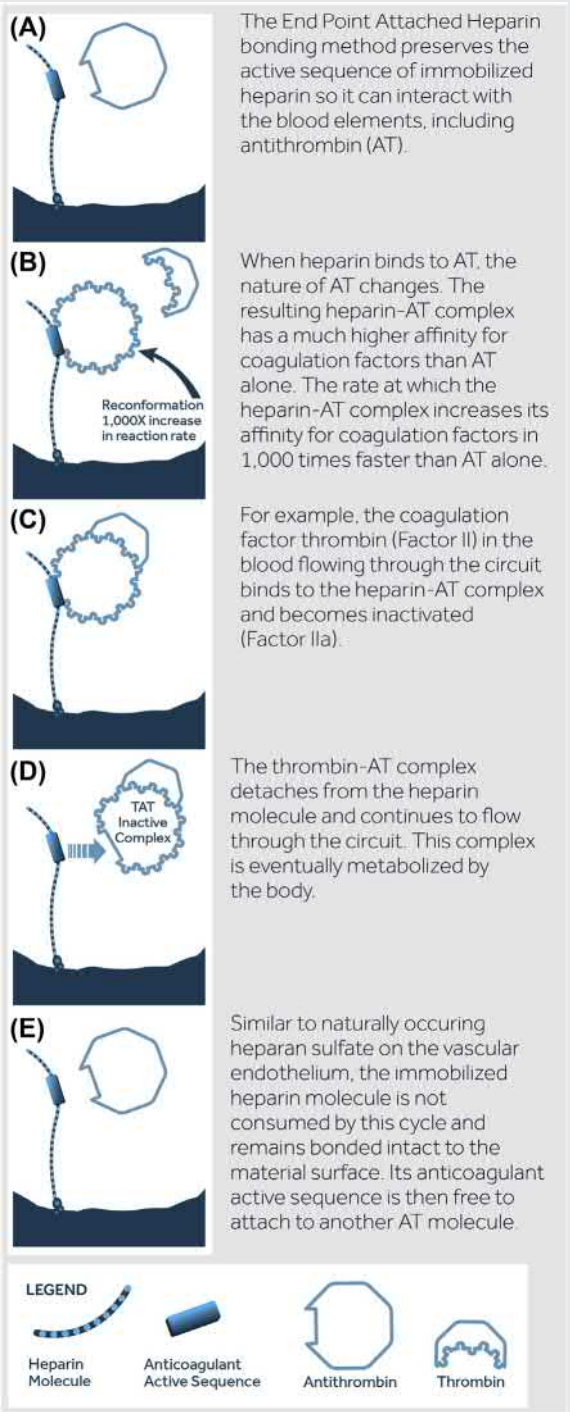
into osteoblasts (Yamaguchi et al., 1991; Mayer et al., 1996; Puleo, 1997; Wilke et al., 2001; Akino et al., 2003). In addition, in vitro studies of rhBMP-2 demonstrated that rhBMP-2 binds to specific receptors on the surface of certain stem cells (e.g., mesenchymal stem cells), and causes them to differentiate into bone-forming cells (Schmitt et al., 1999; Wilke et al., 2001). Furthermore, rhBMP-2 indirectly stimulates angiogenesis through this increased availability of osteoblasts that secrete vascular endothelial growth factor (Deckers et al., 2002; Grosso et al., 2017). Together, these studies showed the crucial role that BMP could have on new bone growth. Today, given the capacity of rhBMP-2 to induce alkaline phosphatase (AP) activity (Cheng et al., 2003; Luu et al., 2007), an in vitro AP activity test has been developed for quality control assessment of commercial product. This test uses controlled exposures of rhBMP-2 to the W20-17 bone marrow stromal cell line in combination with the synthetic AP substrate *p*-nitrophenol phosphate to assess inductive capacity. Clinically, rhBMP-2 combined with ACS is now used as an effective substitute to autologous bone in certain bone graft procedures (Fig. 2.3.3.4).

CASE 2 HEPARIN COATINGS IN BLOOD-CONTACTING MEDICAL DEVICE APPLICATIONS

Recognizing that processes associated with coagulation play a major role in adverse events observed with blood-contacting devices, material scientists have focused on ways materials can be made to better mimic the hemostatic properties of native endothelium—the special cellular lining of the entire vasculature. One early observation was that endothelial cell surfaces have high negative charges, and this characteristic may impart a portion of their hemostatic properties (i.e., by repelling the negatively charged platelets) (Coleman, 2000). In addition, it was observed that *heparan* sulfate, a proteoglycan that is structurally and functionally similar to the anticoagulant heparin, is naturally present across the cell surface of vascular endothelium (Olsson et al., 2000). These molecules are chemically linked to the surface of endothelial cells in a manner that exposes the polysaccharide chains to protein molecules in blood. One particular plasma protein, the serine protease inhibitor called antithrombin (AT), upon binding to a specific chemical sequence on the heparan sulfate molecule, develops a high specificity for deactivating key proteins in the coagulation process, namely thrombin and factor Xa (Marcum et al., 1984; Coleman, 2000). This is precisely the mechanism of action of heparin itself, a polysaccharide that is not naturally found in the circulatory system, but rather is ubiquitously present in connective tissue. Here, heparin binds to AT at a unique binding site; the AT molecular configuration is altered, increasing the rate of enzyme–inhibitor complex formation by a factor of 1000 or more (Rosenberg et al., 2001); then, the enzyme–inhibitor complex detaches from heparin leaving it available to interact with other AT molecules (Olsson et al., 2000). Heparin is not consumed in this process, but rather acts as a catalyst (Fig. 2.3.3.5).

CASE 2 HEPARIN COATINGS IN BLOOD-CONTACTING MEDICAL DEVICE APPLICATIONS—CONT'D

Pioneering work by Larm et al. (1983) first described a method of attaching heparin to solid materials through reactive aldehyde groups present at the ends of heparin molecules. Using this approach, the immobilized heparin mimics the orientation of the heparan sulfate molecule on the vascular endothelium, with heparin's active sequence exposed and available to interact with blood elements. Importantly, the active AT binding region does not become involved in the surface attachment chemistry (Fig. 2.3.3.6).



• **Figure 2.3.3.5** (A) Heparin attached to a solid material is oriented so that its active sequence can interact with the blood elements. (B) When heparin binds to antithrombin (AT), its tertiary structure changes resulting in a heparin–AT complex that has a much greater affinity for coagulation factors than AT alone. The heparin–AT complex has a 1000-fold increased affinity for interaction with thrombin compared to AT alone. (C) For example, an active coagulation factor, Factor IIa (thrombin), in the blood flowing past the material binds to the heparin–AT complex and becomes inactivated. (D) The thrombin–AT complex detaches from the heparin molecule and is eventually metabolized by the body. (E) Similar to naturally occurring heparan sulfate on the vascular endothelium, immobilized heparin is not consumed by this cycle and remains available to attach to other AT molecules.

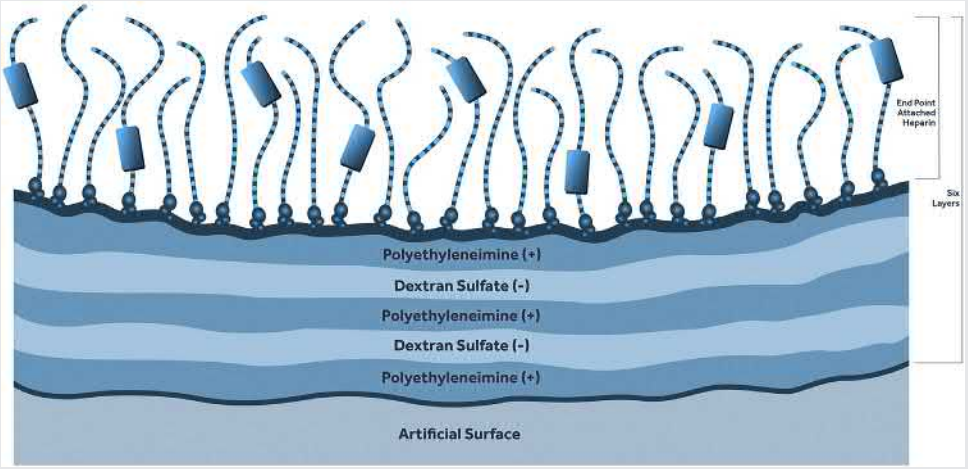
CASE 2 HEPARIN COATINGS IN BLOOD-CONTACTING MEDICAL DEVICE APPLICATIONS—CONT'D



• **Figure 2.3.3.6** Attachment of heparin to material surfaces uses a stable covalent bond to the end of the molecule and orients the heparin so that its anticoagulant active sequence is free to interaction with the blood.

Numerous in vitro approaches have been applied to establish the hematologic compatibility of such heparin-modified surfaces. The starting approach, however, is a demonstration in an in vitro system that the immobilized heparin applied to the surface retains its intended biological activity. Here, heparin-coated materials or devices are first exposed to an excess of AT. This saturates the AT binding sites on the immobilized heparin. The uptake of this biologically active inhibitor is then quantified by subsequent exposure to a known quantity of active thrombin. Assessment of residual thrombin activity using a synthetic chromogenic substrate (e.g., S2238 or rhodamine 110, bis-[*p*-tosyl-L-glycyl-L-prolyl-L-arginine amide]) and analysis using a kinetic microplate reader completes the test. Immobilized heparin bioactivity is reported in international units of thrombin (T) deactivated per square centimeter of test material (IUT_{deac}/cm^2). Using this particular in vitro analysis, specific heparin activity can be measured on the various material components in cardiopulmonary bypass equipment that are coated with immobilized heparin.

In light of the detailed information available today on medical device materials, often including extensive histories of clinical use, the ISO 10993-1 standard calls for evaluation of medical devices or materials to follow a three-step process: (1) material characterization; (2) toxicological risk assessment; and (3) biological testing. In the latter area, in vivo testing remains critical. However, technology and regulations are driving a move away from traditional whole animal toxicity models toward cell-based assays that identify actual mechanisms of chemical activity in cells. This, in turn, will lead to development of better predictive models of human response to toxicants. Results of these models will help regulators make more informed decisions based on actual human toxicity data instead of animal data, which is often suspect and controversial.

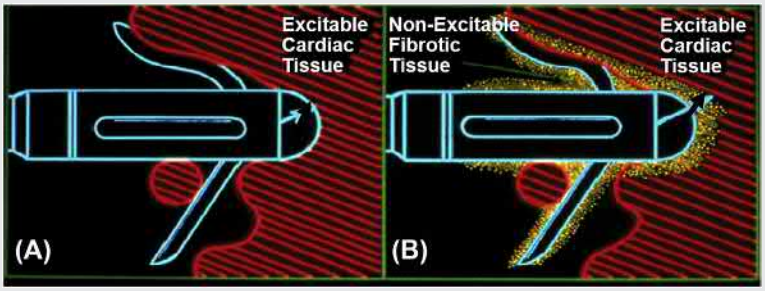
The ECVAM is one of the key leaders driving the development of in vitro methods. Over the past 20 years, ECVAM has validated or endorsed a variety of alternative methods. These include the EST for embryotoxicity, the reduced Local Lymph Node Assay for skin sensitization, the EpiSkin, EpiDerm, and SkinEthic RHE in vitro assays for skin irritation, the human Cell Line Activation Test, KeratinoSens assay, Direct Peptide Reactivity Assay, U937 cell line activation test (U-SENS), and the LuSens assay for assessing skin sensitization, plus the EpiOcular and SkinEthic HCE eye irritation tests (Spielmann et al., 2007; Grindon et al., 2008a,b; also see ECVAM's website: https://ec.europa.eu/jrc/en/eurl/ecvam).

Other governmental organizations dedicated to the validation of alternative methods include the Interagency Coordinating Committee on the Validation of Alternative Methods in the United States, the Japanese Center for the Validation of Alternative Methods, the Korean Center for the Validation of Alternative Methods, and the Canadian Centre for Validation of Alternative Methods. These groups are all part of a global consortium known as the International Cooperation on Alternative Test Methods, which seeks to expand and strengthen cooperation, collaboration, and communications among national validation organizations on the scientific validation and evaluation of new alternative testing methods proposed for regulatory health and safety assessments (ICATM, 2009).

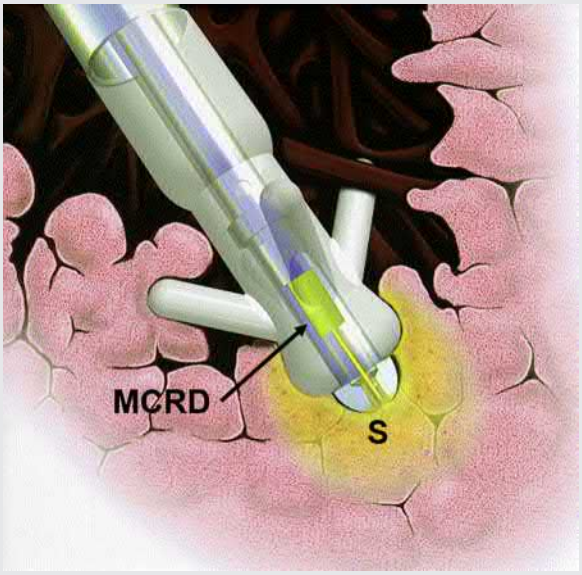
Efforts by these governmental organizations, along with work in academia and industry, will lead to the development and adoption of more sensitive and predictive human cell-based in vitro tests designed to replace in vivo methods (Basketter, 2008; Natsch and Emter, 2008).

For instance, in the medical device industry an idea has recently emerged concerning the most common in vivo tests in the ISO 10993 series: irritation and sensitization (ISO 10993-10:2010); systemic toxicity (ISO 10993-11:2017); material-mediated pyrogenicity (ISO 10993-11:2017); along with hemolysis and thrombogenicity (ISO 10993-4:2017). Replacing all of these tests with validated and reliable in vitro methods is being termed the "In Vitro Six-Pack" (Table 2.3.3.1). For example, the rabbit intracutaneous irritation assay will be replaced by reconstructed human epidermal assays (to that end

CASE 3 STEROID-ELUTING ELECTRODES IN PACEMAKER APPLICATIONS



• **Figure 2.3.3.7** Cross-section of typical tissue response at the interface of a cardiac pacing lead electrode and endocardial tissue: (A) immediately at implantation and (B) after 8 or more weeks after implantation. Nonelectrically excitable fibrotic tissue is seen around the electrode.

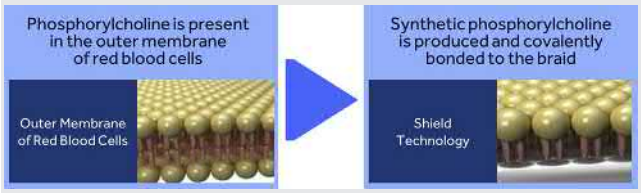


• **Figure 2.3.3.8** Depiction of a tined steroid-eluting pacing lead electrode positioned against cardiac tissue. The *yellow* zone represents steroid (S) eluting into the local tissue from a monolithic controlled release device (MCRD) consisting of drug in a silicone matrix.

One problem of early lead electrodes used in cardiac pacing was that the pacing threshold often increased over time. *Pacing threshold* is the minimum voltage that the electrode needs to deliver to cardiac tissue to consistently depolarize/excite the muscle into contraction. An increase in this threshold can cause pacing failure and/or escalate energy consumption on the battery—a factor that can ultimately reduce the longevity of the implanted device. Such an increase in pacing threshold was found to be associated with the inflammatory reaction at the electrode tip insertion site (Timmis et al., 1983; Benditt et al., 1989). It is the inflammatory response-induced tissue capsule formed around the electrode that results in an increase in impedance at the electrode–tissue interface (Fig. 2.3.3.7). To mitigate this problem a process for delivering antiinflammatory steroid drugs from the electrode tip was developed (Fig. 2.3.3.8). Through gradual elution, the steroid mitigates the foreign-body response at the electrode tip, and results in a minimal-to-zero threshold rise as a function of implant time (Benditt et al., 1989). Here, the drug-imparted control of the cell and tissue response at the minute tip of the pacing device mitigates a deleterious response that shortens device life and triggers less accurate sensing.

A critical development in this technology was demonstrating an appropriate and nontoxic level of steroid delivered to the cardiac cells and tissues. To examine the delivery rate and prove this point, in vitro elution studies were conducted on test electrodes immersed in fresh pooled human plasma agitated at 37°C. Here the elution rate was seen to follow an exponential function that, when analyzed graphically, displayed a bimodal relationship. This is explained by considering the origin and path the steroid must follow to reach the tissue. Initially, steroid within the electrode pores and on the surface of the silicone-based monolithic controlled-release device (MCRD "plug") located in the lead tip readily dissolves and diffuses across a concentration gradient to the host tissue. Then, upon acclimation to exposure to the blood plasma and moisture penetration into the MCRD, additional dissolved steroid from within the MCRD faces the extra barrier of passing through the silicone matrix. Importantly, throughout the elution time course, the amount of steroid released remains lower than the threshold of toxicological concern for the targeted patient population.

CASE 4 BIOMATERIAL SURFACE MADE TO RESEMBLE A CELL PHOSPHOLIPID BILAYER



• **Figure 2.3.3.9** Phosphorylcholine (PC) is present in the outer layer of the cell phospholipid bilayer of all cells, such as red blood cells. PC coating technology such as the Shield Technology presents the PC head groups on the blood-contacting surface of a device, thus mimicking the natural cell phospholipid membrane.

Phosphorylcholine (PC) is present in the outer layer of the cell phospholipid bilayer (Fig. 2.3.3.9, left). Due to its favorable biomimetic properties, PC has been attractive as a coating on vascular devices such as stents to improve material thrombogenicity (Wijns et al., 2014). In one application involving an intraluminal flow diverter device for intracranial aneurysm treatment, covalent attachment of synthetic PC to the metallic surface (Fig. 2.3.3.9, right) results in a uniform atomic level (~3 nm thick) of PC on the surface. The reduction in material thrombogenicity due to the PC was subsequently confirmed in several in vitro studies with significant reduction in thrombus accumulation on the device together with thrombin generation and platelet activation measurements comparable to negative controls (Girdhar et al., 2015, 2018). Importantly, in vivo studies with direct visualization of the thrombus on the device (Clarencon et al., 2018) have corroborated these findings, along with an ex vivo shunt study in a nonhuman primate model that demonstrated the reduction in thrombogenicity with covalently bound PC to be similar to that obtained on the uncoated device in the presence of an antiplatelet drug (Hagen et al., 2017).

a new ISO 10993-23 standard has been developed that includes this in vitro irritation test) (De Jong et al., 2018), while the guinea pig maximization test for sensitization may be replaced with assays that measure certain marker genes. In addition, the US National Toxicology Program is actively evaluating for quantitative structure–activity relationship alternatives to the rodent acute systemic toxicity test. Plus, as a replacement for the rabbit pyrogenicity test, the monocyte activation test, may soon be validated for use in evaluating medical devices and materials for endotoxin and nonendotoxin-induced pyrogenicity. Also, testing labs have begun adapting the ASTM F756 hemolysis test for use with human blood rather than rabbit blood. Furthermore, as a replacement for the canine thrombogenicity test, experts have been developing simple and dynamic flow in vitro loop models using human blood to assess thrombogenicity risks from devices and materials (Münch et al., 2000; Tepe et al., 2002; Sinn et al., 2011; and Girdhar et al., 2015, 2018).

Lastly, as the ISO 10993 standards have been revised, they have recognized new bioanalytical techniques. One example is the inclusion of the methylthiazol-tetrazolium assay in ISO 10993-5 as a supplement or replacement for traditional categorical assessment cytotoxicity analysis. Also, ELISA assays for measuring factors indicative of material-related coagulation and thrombosis are more officially recognized (ISO 10993-4:2017).

Summary Remarks

This chapter has focused on current in vitro methods used to evaluate the biological compatibility of medical devices and materials. The methods were presented from two perspectives: (1) in vitro assays that are accepted internationally for preclinical biological safety evaluations and risk assessments, and (2) specialized material- and application-specific in vitro assays designed for certain cell and tissue responses. As the latter area is complex and growing at a pace that is much faster than typical method standardization, some contemporary case examples were presented that reflect this additional and increasingly important type of in vitro test. These cases demonstrate that specifically designed in vitro assays have proven to be critical in moving new medical device therapies into clinical practice.

Today, materials in new device concepts do not often go through an *early* evaluation using the ISO 10993 process. Instead, engineers and material scientists often use other types of tests in proof-of-concept in vitro studies, in which the majority of device prototypes use well-characterized biocompatible materials with long histories of safe use. This approach is driven by the desire to bring new therapies to the market quickly, using new technologies that improve device performance via promoting improved cell and tissue interaction properties.

As the range of medical device materials and applications expands, the challenges faced by product engineers, materials scientists, regulatory agencies, and standards developers will certainly grow. Nevertheless, progress will no doubt continue to be made in the development and application of in vitro assays to support new therapies, improved medical materials, and advances in patient care.

Chapter Questions

1. List the five ISO 10993 standards that discuss in vitro tests for cell and tissue compatibility.
2. In Part 3 of the ISO 10993 standards, the three areas of testing describe tests for genotoxicity, carcinogenicity, and reproductive toxicity. Name one type of in vitro test in each category and use one to three sentences to describe the basic scientific premise behind each test.
3. In one to three sentences describe Part 4 of the ISO 10993 standards and list the five categories of the type of testing done under this part of the standard.
4. Define toxicant and xenobiotic. What is the main distinction between these terms?
5. You have been asked to test a certain new medical device material for cytotoxicity, and for thoroughness you have been asked to perform two tests. Name two tests for cytotoxicity that you would apply and describe the scientific basis behind each test.
6. In vitro tests to establish cell and tissue compatibility can be broken down into two general areas of testing: (1) standardized screening tests such as those described in the ISO 10993 standards, and (2) specialized device-specific or material-specific tests that are often used to evaluate a special bioactive property of the material. In the latter, name one such bioactive material, the molecular/biochemical nature of the *bioactivity*, and describe the specific bioactive test performed to ascertain bioactivity.
7. What do the acronyms NOAEL, LOAEL, TI, and MOS stand for? Given that a TI for chemical X is 1.0 mg/kg and the worst-case exposure dose of chemical X is 0.0003 mg/kg, calculate the MOS for chemical X.
8. Draw the basic geometry of a normal chromosome, then draw a chromosome that presents an interstitial deletion. What category of in vitro test does this question describe?
9. Describe the molecular mechanism behind immobilized heparin applied to medical devices.
10. Describe two events that could trigger the need for an in vitro assessment of cell or tissue compatibility and describe two of the immediate next steps in the assessment.

2.3.4

In Vivo Assessment of Tissue Compatibility

JAMES M. ANDERSON[1], FREDERICK J. SCHOEN[2], NICHOLAS P. ZIATS[1]

[1]Department of Pathology, Case Western Reserve University, Cleveland, OH, United States

[2]Pathology and Health Sciences and Technology (HST), Harvard Medical School, Department of Pathology, Brigham and Women's Hospital, Boston, MA, United States

Introduction

The goal of in vivo assessment of tissue compatibility of a biomaterial, prosthesis, or medical device is to determine the biocompatibility (as a key component of safety) of the biomaterial, prosthesis, or medical device in a biological environment. Indeed, biocompatibility is a critical element in the performance of an implanted medical device, and many complications of clinical devices derive from inadequate biocompatibility. Moreover, the concept of biocompatibility has evolved in recent years as biomaterials technology has become more sophisticated, particularly in permitting the biomaterial to effect complex, and potentially beneficial, interactions with the surrounding tissues (Hench and Pollak, 2002; Williams, 2008, 2019; see Chapter 2.3.2). Thus, the contemporary definition of biocompatibility focuses on the ability of a medical device to perform with an appropriate host response in a specific application, and biocompatibility assessment serves as a measurement of the magnitude and duration of the pathophysiologic mechanisms that determine the host response. From a practical perspective, the in vivo assessment of tissue compatibility of medical devices is carried out to determine that the device performs as intended, and presents no significant harm to the patient or user simulating clinical use. In this chapter, the term "medical device" will be used to describe biomaterials, prostheses, artificial organs, and other medical devices, and the terms "tissue compatibility assessment," "biocompatibility assessment," and "safety assessment" will be considered to be synonymous.

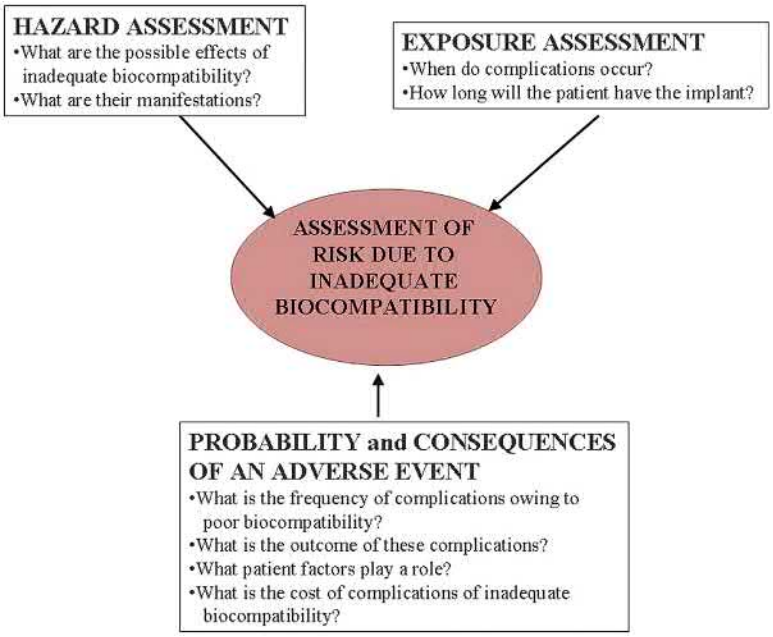
The in vivo assessment of tissue compatibility is necessary to establish the biocompatibility, safety, and function (efficacy) of a medical device and its components under conditions of intended use. Intended use conditions are also utilized to select in vitro tests and animal models that will provide essential information to determine biocompatibility.

Extensive efforts have been made by government regulatory agencies, e.g., the US Food and Drug Administration (FDA), and standards organizations, e.g., ASTM International (**ASTM International, 2018 Annual Book of ASTM Standards, Volume 13.01**), the International Organization for Standardization (ISO), and US Pharmacopeia (USP), to provide procedures, protocols, guidelines, and standards that may be used in the in vivo assessment of the tissue compatibility of medical devices. This chapter draws heavily on the ISO 10993 standard, Biological Evaluation of Medical Devices, in presenting a systematic approach to the in vivo assessment of tissue compatibility of medical devices.

The nature and extent of risk due to inadequate biocompatibility may be conceptualized as shown in Fig. 2.3.4.1. The first consideration in the selection of biomaterials to be used in device design should be the chemical, toxicological, physical, electrical, morphological, and mechanical properties of the biomaterial(s) to fulfill the intended use. Relevant to the overall in vivo assessment of tissue compatibility of a biomaterial or device is knowledge of the chemical composition of the materials, and the nature, degree, frequency, and duration of exposure of the device and its constituents to the tissues in which it will be utilized. Table 2.3.4.1 presents a list of biomaterial components and characteristics that may affect the overall biological responses of the medical device. The range of potential biological hazards is broad, and may include short-term effects, long-term effects, or specific toxic effects, which should be considered for every material and medical device. However, this does not imply that testing for all potential hazards will be necessary or practical.

Selection of in Vivo Tests According to Intended Use

As it is recognized that biomaterial–tissue interaction may vary with the anatomic site and duration of exposure, and



• **Figure 2.3.4.1** The risks associated with inadequate biocompatibility are a composite function of the exposure (i.e., nature and duration), the hazard (i.e., effects on the recipient), and the probability and consequences of complications.

application-specific conditions, in vivo tests for assessment of tissue compatibility are chosen to simulate end-use applications. To facilitate the selection of appropriate tests, medical devices with their component biomaterials can be categorized by the nature of tissue contact of the medical device, and by its duration of contact. Table 2.3.4.2 presents medical device categorization by nature of tissue contact and contact duration. The tissue contact categories and subcategories, as well as the contact duration categories, have been derived from standards, protocols, and guidelines utilized in the past for safety evaluation of medical devices. Certain devices may fall into more than one category, in which case testing appropriate to each category should be considered.

Biomaterial and Device Perspectives in In Vivo Testing

Two perspectives may be considered in the in vivo assessment of tissue compatibility of biomaterials and medical devices. The first perspective involves the utilization of in vivo tests to determine the general biocompatibility of newly developed biomaterials for which some knowledge of the tissue compatibility is necessary for further research and development. In this type of situation, manufacturing and other processes necessary to the development of a final product, i.e., the medical device, have not been carried out. However, the in vivo assessment of tissue compatibility at this early stage of development can provide additional information relating to the proposed design criteria in the production of a medical device. While it is generally recommended that the identification and quantification of extractable chemical entities of a medical device should precede biological evaluation, it is quite common to carry out preliminary in vivo assessments to determine if there may be unknown or as-yet unidentified chemical entities that

produce adverse biological reactions. Utilized in this fashion, early in vivo assessment of the tissue compatibility of a biomaterial may provide insight into the biocompatibility, and thereby may permit further development of this biomaterial into a medical device. Obviously, problems observed at this stage of development would require further efforts to improve the biocompatibility of the biomaterial, and to identify the agents and mechanisms responsible for the adverse reactions. As the in vivo assessment of tissue compatibility of a biomaterial or medical device is focused on the end-use application, it must be appreciated that a biomaterial considered compatible for one application may not be compatible for another.

The second perspective regarding the in vivo assessment of tissue compatibility of medical devices focuses on the biocompatibility of the final product, that is, the fabricated medical device in the condition in which it is to be implanted. Thus, issues related to desired fabrications, interactions between biomaterials, and to mechanical conductors, etc., may come into play. Although medical devices in their final form and condition are commonly implanted in carefully selected animal models to determine function, as well as biocompatibility, it may be inappropriate to carry out all of the recommended tests necessary for regulatory approval on the final device. In these situations, some tests may initially be carried out on biomaterial components of devices that have been prepared under manufacturing and sterilization conditions, and other processes utilized in the final product (see Table 2.3.4.3).

Specific Biological Properties Assessed by In Vivo Tests

In this section, brief perspectives on the general types of in vivo tests are presented. Details regarding these tests are found in the lists of standards provided at the end of this chapter. ISO 10993 standards advise that the biological evaluation of all medical device materials include testing for cytotoxicity, sensitization, and irritation. (Cytotoxicity tests are considered in vitro tests.) Beyond these fundamentals, the selection of further tests for in vivo biocompatibility assessment is based on the characteristics and end-use application of the device or biomaterial under consideration.

Sensitization, Irritation, and Intracutaneous (Intradermal) Reactivity

Exposure to, or contact with, even minute amounts of potential leachables from medical devices or biomaterials can result in allergic or sensitization reactions. Sensitization tests estimate the potential for contact sensitization to medical devices, materials, and/or their extracts. Symptoms of sensitization are often seen in skin, and tests are often carried out topically in guinea pigs. Test design should reflect the intended route (skin, eye, mucosa) and nature, degree, frequency, duration, and conditions of exposure of the biomaterial in its intended clinical use. While sensitization reactions are immune system responses to contact with chemical substances, ISO guidelines suggest irritation to be a local tissue inflammation response to chemicals, without a systemic immunological component. The most severely irritating chemical leachables may be discovered prior to in vivo studies by careful material characterization and in vitro cytotoxicity tests. Irritant tests emphasize utilization of extracts of the biomaterials to determine the irritant effects of potential leachables. Intracutaneous (intradermal) reactivity tests determine the localized reaction of tissue to intracutaneous injection of extracts of medical devices, biomaterials, or prostheses in the final product form. Intracutaneous tests may be applicable where determination of irritation by dermal or mucosal tests is not appropriate. Albino rabbits are most commonly used, however newer ISO guidelines refer to determination of skin irritation using reconstructed human epidermis as an alternative to animal testing (ISO 10933-23).

Since these tests focus on determining the biological response of leachable constituents of biomaterials, their extracts in various solvents are utilized to prepare the injection solutions. Critical to the conduct of these tests is that the preparation of the test material and/or extract solution should be chosen to include testing for both water-soluble and fat-soluble leachables.

Systemic Toxicity: Acute, Subacute, and Subchronic Toxicity

Systemic toxicity tests estimate the potential harmful effects in vivo on target tissues and organs away from the point of contact (i.e., site of implantation) with either single or multiple exposures to medical devices, biomaterials, and/or their extracts. These tests evaluate the systemic toxicity potential of medical devices that release constituents into the body. These tests also include pyrogenicity testing, which assesses the induction of a systemic inflammatory response, often measured as fever.

In tests using extracts, the form and area of the material, the thickness, and the surface area to extraction vehicle volume are critical considerations in the testing protocol. Appropriate extraction vehicles, i.e., solvents, should be chosen to yield a maximum extraction of leachable materials for use in the testing. Mice, rats, or rabbits are the usual animals of choice for the conduct of these tests, and oral, dermal, inhalation, intravenous, intraperitoneal, or subcutaneous application of the test substance may be used, depending on the intended application of the biomaterial. Acute toxicity is considered to be the adverse effects that occur after administration of a single dose or multiple doses of a test sample given within 24 h. Subacute toxicity (repeat dose toxicity) focuses on adverse effects occurring after administration of a single dose or multiple doses of a test sample per day during a period of from 14 to 28 days. Subchronic toxicity is considered to be the adverse effects occurring after administration of a single dose or multiple doses of a test sample per day given during a part of the lifespan, usually 90 days but not exceeding 10% of the lifespan of the animal.

Pyrogenicity tests are also included in the system toxicity category to detect material-mediated fever-causing reactions to extracts of medical devices or material. Although the rabbit pyrogen test has been the standard, the Limulus amebocyte lysate (LAL) reagent test has been used increasingly in recent years and is considered an appropriate testing method. It is noteworthy that no single test can differentiate pyrogenic reactions that are material mediated per se from those due to endotoxin contamination.

Genotoxicity

In vivo genotoxicity tests are carried out if indicated by the chemistry and/or composition of the biomaterial (see Table 2.3.4.1) or if in vitro test results indicate potential genotoxicity [changes in deoxyribonucleic acid (DNA) that could lead to changes in cellular proliferation, differentiation, and/or function]. Initially, at least three in vitro assays should be used, and two of these assays should utilize mammalian cells. The initial in vitro assays should cover the three levels of genotoxic effects: DNA destruction; gene mutations; and chromosomal aberrations (as assessed by cytogenetic analysis). In vivo genotoxicity tests include the micronucleus test and the in vivo mammalian bone marrow cytogenetic tests—chromosomal analysis, the rodent dominant lethal tests, the mammalian germ cell cytogenetic assay, the mouse spot test, and the mouse heritable translocation assay. Not all of the in vivo genotoxicity tests need be performed; the most common test is the rodent micronucleus test. Genotoxicity tests are performed with appropriate extracts or dissolved materials using appropriate media, as suggested by the known composition of the biomaterial.

Implantation

Implantation tests assess the local pathological effects on the structure and function of living tissue induced by a sample of a material or final product at the site where it is surgically implanted or placed into an implant site or tissue appropriate to the intended application of the biomaterial or medical device. In some cases, the anatomic site of implantation used for biocompatibility evaluation is not the same as the site of ultimate use, but has representative mechanisms and consequences of tissue–biomaterial interaction (e.g., subcutaneous implantation in rodents of bioprosthetic heart valve materials to study calcification that occurs as a major clinical limitation in humans; see Chapter 2.4.5). The most basic evaluation of the local pathological effects is carried out at both the gross level and the microscopic level. Histological (microscopic) evaluation is used to characterize various biological response parameters (Table 2.3.4.4). To address specific questions, more sophisticated studies may need to be done. Examples include immunohistochemical staining of histological sections to determine the types of cells present, and studies of collagen formation and destruction. For short-term implantation evaluation out to 12 weeks, mice, rats, guinea pigs, or rabbits are the most common animals utilized in these studies. For longer-term testing in subcutaneous tissue, muscle, or bone, animals such as rats, guinea pigs, rabbits, dogs, sheep, goats, pigs, and other animals with relatively long life expectancies are suitable. If a complete medical device is to be evaluated, larger species may be utilized so that human-sized devices may be used in the site of intended application. For example, substitute heart valves are usually tested as heart valve replacements in sheep, whereas calves are usually the animal of choice for ventricular assist devices and total artificial hearts.

In all aspects of biocompatibility testing, it is important to recognize that the effects of the material on the surrounding tissues are generally superimposed on the events occurring during physiological wound repair induced by the surgery of implantation. This is particularly important in shorter term experiments.

TABLE 2.3.4.4 Biological Response Parameters as Determined by Histological Assessment of Implants

Number and distribution of inflammatory cells as a function of distance from the material/tissue interface
Thickness and vascularity of fibrous capsule
Quality and quantity of tissue ingrowth (for porous materials)
Degeneration as determined by changes in tissue morphology
Presence of necrosis
Other parameters such as material debris, fatty infiltration, granuloma, dystrophic calcification, apoptosis, proliferation rate, biodegradation, thrombus formation, endothelialization, migration of biomaterials or degradation products

Hemocompatibility

Hemocompatibility tests evaluate effects on blood and/or blood components by blood-contacting medical devices or materials. In vivo hemocompatibility tests are usually designed to simulate the geometry, contact conditions, and flow dynamics of the device or material in its clinical application. From the ISO standards perspective, five test categories are indicated for hemocompatibility evaluation: thrombosis; coagulation; platelets; hematology; and immunology (complement and leukocytes). Two levels of evaluation are indicated: Level 1 (required); and Level 2 (optional). Regardless of blood contact duration, hemocompatibility testing is indicated for three categories of medical devices: (1) external communicating devices—blood path indirect; (2) external communicating devices—circulating blood; and (3) blood-contacting implant devices. Chapter 2.3.5 gives further details on the testing of blood–material interactions.

Several issues are important in the selection of tests for hemocompatibility of medical devices or biomaterials. In particular, the hemocompatibility depends not only on the material's characteristics, but also on the fluid mechanics of the device (i.e., stasis promotes thrombus formation), and the coagulability of the blood. Thus, in vivo testing in animals may be convenient, but anatomic differences among species and species-related differences in blood reactivity must be considered, and these may limit the predictability of any given test in the human clinical situation. While blood values and reactivity between humans and nonhuman primates are very similar, European Community law prohibits the use of nonhuman primates for blood compatibility and medical device testing. Hemocompatibility evaluation in animals is complicated by the lack of appropriate and adequate test materials, for example, appropriate antibodies for immunoassays. Use of human blood in hemocompatibility evaluation implies in vitro testing, which usually requires the use of anticoagulants that are not generally present with the device in the clinical situation, except for perhaps the earliest implantation period. Although species differences may complicate hemocompatibility evaluation, the utilization of animals in short- and long-term testing is considered to be appropriate for evaluating thrombosis and tissue interaction.

Chronic Toxicity

Chronic toxicity tests determine the effects of either single or multiple exposures to medical devices, materials, and/or their extracts during a period of at least 10% of the lifespan of the test animal, e.g., over 90 days in rats. Chronic toxicity tests may be considered an extension of subchronic (subacute) toxicity testing, and both may be evaluated in an appropriate experimental protocol or study.

Carcinogenicity

Carcinogenicity tests determine the tumorigenic potential of medical devices, materials, and/or their extracts from either single or multiple exposures or contacts over a period of the major portion of the lifespan of the test animal. Both carcinogenicity (tumorigenicity) and chronic toxicity may be studied in a single experimental study. With biomaterials, these studies focus on the potential for solid-state carcinogenicity, i.e., the Oppenheimer effect (see Chapter 2.2.7). Thus, in carcinogenicity testing, controls of a comparable form and shape should be included; polyethylene implants are a commonly used control material. The use of appropriate controls is imperative as animals may spontaneously develop tumors, and statistical comparison between the test biomaterial/device and the controls is necessary. To facilitate and reduce the time period for carcinogenicity testing of biomaterials, the FDA is exploring the use of transgenic mice carrying the human prototype c-Ha-ras gene as a bioassay model for rapid carcinogenicity testing.

Since tumors associated with clinical medical devices have been rare (see Chapter 2.2.7) carcinogenicity tests should be conducted only if data from other sources suggest a tendency for tumor induction. However, considerations of carcinogenicity may become important in some future applications in which pluripotential stem cells produced by any methodology are used.

Reproductive and Developmental Toxicity

These tests evaluate the potential effects of medical devices, materials, and/or their extracts on reproductive function, embryonic development (teratogenicity), and prenatal and early postnatal development. The application site of the device must be considered, and tests and/or bioassays should only be conducted when the device has a potential impact on the reproductive potential of the subject.

Biodegradation

Biodegradation tests determine the effects of a biodegradable material and its biodegradation products on the tissue response. They focus on the amount of degradation during a given period of time (the kinetics of biodegradation), the nature of the degradation products, the origin of the degradation products (e.g., impurities, additives, corrosion products, bulk polymer), and the qualitative and quantitative assessment of degradation products and leachables in adjacent tissues and in distant organs. The biodegradation of biomaterials may occur through a wide variety of mechanisms, which in part are biomaterial dependent, and all pertinent mechanisms related to the device and the end-use application of the device must be considered. Test materials comparable to degradation products may be prepared and studied to determine the biological response of degradation products anticipated in long-term implants. An example of this approach is the study of metallic and polymeric wear particles that may be present with long-term orthopedic joint prostheses. Moreover, for intentionally biodegradable scaffolds used in tissue engineering (see Chapter 2.6.3), biodegradation and the attendant tissue response are important to follow histologically. Further insights on biodegradation are available in Chapters 1.3.2F, 1.3.3D and Section 2.4.

Immune Responses

Immune response evaluation is not a component of the standards currently available for in vivo tissue compatibility assessment. However, ASTM, ISO, and the FDA currently have working groups developing guidance documents for immune response evaluation where pertinent. Synthetic materials are not generally immunotoxic (see Chapter 2.2.3). However, immune response evaluation is necessary with modified natural tissue implants such as collagen, which has been utilized in a number of different types of implants and may elicit immunological responses. The Center for Devices and Radiological Health of the FDA released a draft immunotoxicity testing guidance document in 1998 (Langone, 1998), whose purpose is to provide a systematic approach for evaluating potential adverse immunological effects of medical devices and constituent materials. However, there have only been updated documents on pharmaceuticals and not medical devices (S8 Immunotoxicity Studies for Human Pharmaceuticals, 2005). Immunotoxicity is any adverse effect on the function or structure of the immune system or other systems as a result of an immune system dysfunction. Adverse or immunotoxic effects occur when humoral or cellular immunity needed by the host to defend itself against infections or neoplastic disease (immunosuppression) or unnecessary tissue damage (chronic inflammation, hypersensitivity, or autoimmunity) is compromised. Potential immunological effects and responses that may be associated with one or more of these effects are presented in Table 2.3.4.5.

Representative tests for the evaluation of immune responses are given in Table 2.3.4.6. Table 2.3.4.6 is not all-inclusive, and other tests that specifically consider possible immunotoxic effects potentially generated by a given device or its components may be applicable. Examples presented in Table 2.3.4.6 are only representative of the large number of tests that are currently available. However, direct and indirect markers of immune responses may be validated and their predictive value documented, thus providing new tests for immunotoxicity in the future. Direct measures of immune system activity by functional assays are the most important types of tests for immunotoxicity. Functional assays are generally more important than tests for soluble mediators, which are more important than phenotyping. Signs of illness may be important in in vivo experiments,

TABLE 2.3.4.5 Potential Immunological Effects and Responses

Effects

TABLE 2.3.4.6 Representative Tests for the Evaluation of Immune Responses

Functional Assays	Phenotyping	Soluble Mediators	Signs of Illness
Skin testing	Cell surface markers	Antibodies	Allergy
Immunoassays (e.g., ELISA)	MHC markers	Complement	Skin rash
Lymphocyte proliferation	Chemokines	Immune complexes	Urticaria
Plaque-forming cells	Basoactive amines	Cytokine patterns(T-cell subsets)	Edema
Local lymph node assay	–	Cytokines (IL-1, IL-1ra, TNFα, IL-6, TGF-β, IL-4, IL-13)	Lymphadenopathy
Mixed lymphocyte reaction	–	–	–
Tumor cytotoxicity	–	–	–
Antigen presentation	–	–	–
Phagocytosis	–	–	–

but symptoms may also have a significant role in studies of immune function in clinical trials and postmarket studies.

Combination devices where drugs (or cells) are utilized within medical devices should also be considered for immune response evaluation. Hypersensitivity reactions have been reported with drug-eluting coronary stents (DES). With DES, concomitantly prescribed medications such as clopidogrel (platelet inhibitor) have been considered the causative agent for hypersensitivity, as well as the DES itself (Nebeker et al., 2006).

Selection of Animal Models for In Vivo Tests

Animal models are used to predict the clinical behavior, safety, and biocompatibility of medical devices in humans (Table 2.3.4.7). The selection of animal models for the in vivo assessment of tissue compatibility must consider the advantages and disadvantages of the animal model for human clinical application. Several examples follow, which exemplify the advantages and disadvantages of animal models in predicting clinical behavior in humans.

Preclinical testing in animal models is an important part of the regulatory process, used to determine the safety and efficacy of devices prior to human clinical trials. The choice of the animal model and the selection of in vitro tests should be made according to the intended use of the respective medical device, prosthesis, or biomaterial.

TABLE 2.3.4.7 Animal Models for the In Vivo Assessment of Medical Devices

Device Classification	Animal
Cardiovascular	
Heart valves	Sheep
Vascular grafts	Dog, pig
Stents	Pig, rabbit, dog
Ventricular assist devices	Calf
Artificial hearts	Calf
Ex vivo shunts	Baboon, dog
Orthopedic/Bone	
Bone regeneration/ Substitutes	Rabbit, dog, pig, mouse, rat Dog, goat, nonhuman primate
Total joints—hips, knees	Sheep, goat, baboon
Vertebral implants	Rabbit, pig, dog, nonhuman primate
Craniofacial implants	Rabbit, dog
Cartilage	Dog, sheep
Tendon and ligament substitutes	Goat
Neurological	
Peripheral nerve regeneration	Rat, cat, nonhuman primate
Electrical stimulation	Rat, cat, nonhuman primate
Ophthalmological	
Contact lens	Rabbit
Intraocular lens	Rabbit, monkey

A single test animal may not assess all pertinent clinically important complications. For example, as described earlier, sheep are commonly used for the evaluation of heart valves (see Chapter 2.5.2A). This is based on size considerations, and also the propensity to calcify tissue components of bioprosthetic heart valves and thereby be a sensitive model for this complication. Thus, the choice of this animal model for bioprosthetic heart valve evaluation is made on the basis of accelerated calcification, the major clinical problem, assessed in rapidly growing animals which has its clinical correlation in young and adolescent humans. Nevertheless, normal sheep may not provide a sensitive assessment of the propensity of a valve to thrombosis, which may be potentiated by the reduced flow seen in abnormal subjects, but diminished by the specific coagulation profile of sheep.

The in vivo assessment of tissue responses to vascular graft materials is an example in which animal models present a particularly misleading picture of what generally occurs in humans. Virtually all animal models, including nonhuman primates, heal rapidly and completely with an endothelial blood-contacting surface. Humans, on the other hand, do not show extensive endothelialization of vascular graft materials, and the resultant pseudointima from the healing response in humans has potential thrombogenicity. Consequently, despite favorable results in animals, small-diameter vascular grafts (less than 4 mm in internal diameter) usually yield early thrombosis in humans, the major mechanism of failure which is secondary to the lack of endothelialization in the luminal surface-healing response.

Originally, the porcine coronary artery model was considered the model of choice for the evaluation of arterial stents. More recently, the rabbit iliac artery model for the evaluation of drug-eluting stents has been considered to be more realistic, as endothelialization is slower in the rabbit model than in the porcine model, and inflammation is not as extensive in the rabbit (Nakazawa et al., 2008). Thus, endothelialization, healing, and inflammation in the rabbit iliac artery model may be closer to these responses in humans than the porcine coronary artery model.

The use of appropriate animal models is an important consideration in the safety evaluation of medical devices that may contain potential immunoreactive materials. The in vivo evaluation of recombinant human growth hormone in poly(lactic-*co*-glycolic acid) (PLGA) microspheres demonstrates the appropriate use of various animal models to evaluate biological responses and the potential for immunotoxicity. Utilizing biodegradable PLGA microspheres containing recombinant human growth hormone (rhGH, Cleland et al., 1997) used Rhesus monkeys, transgenic mice expressing hGH, and normal control (Balb/C) mice in their in vivo evaluation studies. Rhesus monkeys were utilized for serum assays in the pharmacokinetic studies of rhGH release, as well as tissue responses to the injected microcapsule formulation. Placebo injection sites were also utilized, and a comparison of the injection sites from rhGH PLGA microspheres and placebo PLGA microspheres demonstrated a normal inflammatory and wound-healing response

with a normal focal foreign-body reaction. To further examine the tissue response, transgenic mice were utilized to assess the immunogenicity of the rhGH PLGA formulation. Transgenic mice expressing a heterologous protein have been previously used for assessing the immunogenicity of structural mutant proteins. With the transgenic animals, no detectable antibody response to rhGH was found. In contrast, the Balb/C control mice had a rapid onset of high-titer antibody response to the rhGH PLGA formulation. This study points out the appropriate utilization of animal models to not only evaluate biological responses, but also one type of immunotoxicity (immunogenicity).

Future Perspectives on In Vivo Medical Device Testing

As presented earlier in this chapter, the in vivo assessment of tissue compatibility of biomaterials and medical devices is dependent on the end-use application of the biomaterial or medical device. In this sense, the development and utilization of new biomaterials and medical devices will dictate the development of new test protocols and procedures for evaluating these new products. Furthermore, it must be understood that the in vivo assessment of tissue compatibility of biomaterials and medical devices is open ended, and new end-use applications will require new tests.

> The future development of medical devices is anticipated to provide more complexity to the composition and construction of these devices and, thus, to the array of potential biomaterial–tissue interactions. Future assessments will require a more sophisticated approach to test protocols and methodologies that must clearly identify biocompatibility and function. In this regard, new tests, methods, and animal models may have to be developed to adequately and appropriately characterize the biocompatibility and function of these new devices. Therefore, the development of guidelines and standards is dynamic and constantly evolving, driven by the complexity of new devices developed for application in tissue engineering, regenerative medicine, and nanomedicine.

Over the past half-century, medical devices and biomaterials have generally been "passive" in their tissue interactions. That is, a mechanistic approach to biomaterial–tissue interactions has rarely been used in the development of biomaterials or medical devices. Heparinized biomaterials are an exception to this, but considering the five subcategories of hemocompatibility, these approaches have a minimal impact on the development of blood-compatible materials.

In the past decade, increased emphasis has been placed on bioactivity and tissue engineering in the development of biomaterials and medical devices for potential clinical application. Rather than a "passive" approach to tissue interactions, bioactive and tissue-engineered devices have focused on an "active" approach in which biological or tissue components, i.e., growth factors, cytokines, drugs, enzymes, proteins, extracellular matrix components, and cells that may or may not be genetically modified, are used in combinations with synthetic, i.e., passive, materials to produce devices that control or modulate a desired tissue response. Obviously, in vivo assessment of the targeted biological response of a tissue-engineered device will play a significant role in the research and development of that device, as well as in its safety assessment. It is clear that scientists working on the development of tissue-engineered devices will contribute significantly to the development of in vivo tests for biocompatibility assessment, as these tests will also be utilized to study the targeted biological responses in the research phase of the device development.

Regarding tissue-engineered devices, it must be appreciated that biological components may induce varied effects on tissue in the in vivo setting. For example, a simplistic view of the potentially complex problems that might result from a device releasing a growth factor to enhance cell proliferation is presented. The presence of a growth factor may result in markedly different cell proliferation, differentiation, protein synthesis, attachment, migration, shape change, etc., which would be cell-type dependent. Thus, different cell-type dependent responses in an implant site, reacting to the presence of a single exogenous growth factor, may result in inappropriate, inadequate, or adverse tissue responses. These perspectives must be integrated into the planned program for in vivo assessment of tissue compatibility of tissue-engineered devices. Moreover, a major challenge to the in vivo assessment of tissue compatibility of tissue-engineered devices is the use of animal tissue components in the early phase of device development, whereas the ultimate goal is the utilization of human tissue components in the final device for end-use application. Novel and innovative approaches to the in vivo tissue compatibility of tissue-engineered devices must be developed to address these significant issues. Finally, the development of clinically useful tissue-engineered devices will require enhanced understanding of the influence of the patient and biomechanical factors on the structure and function of healed and remodeled tissues. It will also require new methodology for assessment of biocompatibility, and the dynamic progression of remodeling in vivo (Mendelson and Schoen, 2006).

Careful studies of retrieved implants to establish biomarkers and mechanisms of structural evolution will be critical (see Chapter 2.1.5).

Introduction

Thousands of devices fabricated from synthetic materials or processed natural materials are interfaced with blood for a wide range of medical procedures (see Section 2.5, particularly Chapters 2.5.2 and 2.5.3). Blood-contacting materials have a unique set of requirements, and most are quite different from implants in soft tissue or bone. The most obvious complication is the undesirable formation of a thrombus or clot, but many other reactions can impact performance when a synthetic material is interfaced with blood. How can the biomaterials engineer know which materials might be best used in the fabrication of a blood-contacting device? It would be ideal if this chapter could end with a definitive list of "blood-compatible" biomaterials that might be used in blood-contacting medical devices (note that generalized suggestions are offered near the end of this chapter). The considerations driving the interpretation of blood interaction tests are sufficiently complex that such a list of materials cannot be presented. The reader should appreciate this point after working through this chapter.

This chapter outlines methods and concerns in evaluating the blood compatibility of biomaterials and medical devices. It does not automatically follow that if the materials comprising a device are blood compatible, then a device fabricated from those materials will also be blood compatible. This important point should be clear by the end of this chapter. Before considering the evaluation of materials and devices, the reader should be familiar with the protein and cellular reactions of blood coagulation, platelet responses, and fibrinolysis, as discussed in Chapter 2.2.6. The history of methods to assess blood compatibility is addressed in Ratner (2000).

Background and Principles of Blood–Materials Interactions Assessment

What Is Blood Compatibility?

Blood-compatibility assessment would be straightforward if, following the introductory paragraph, there were a list of standard tests that might be performed to evaluate blood compatibility. By simply performing the tests outlined in such a list, a material could be rated "blood compatible" or "not blood compatible." Unfortunately, no widely recognized, standard list of blood-compatibility tests exists. Due to the complexity of blood–materials interactions (BMI), there is a basic body of ideas that must be mastered to appreciate what blood interaction tests actually measure. This section introduces the rationale for BMI testing, and addresses a few important measurement schemes.

"Blood compatibility" can be defined as the property of a material or device that permits it to function in contact with blood without inducing adverse reactions. But this simple definition offers little insight into what a blood-compatible material is. More useful definitions become increasingly complex. This is because there are many mechanisms for the body to respond to material intrusions into the blood. A material that will not trigger one response mechanism may be highly active in triggering an alternative pathway. The mechanisms by which blood responds to materials have been discussed in Chapter 2.2.6. This chapter will integrate many of these ideas, and provide a framework for BMI (and blood-compatibility) assessment. A unique collection of discussions and commentary on the state of knowledge regarding the phenomena related to blood compatibility provides

supplemental depth to many of the considerations raised here (Jaffer and Weitz, 2019; Brash et al., 2019; Gorbet et al., 2019; Maitz et al., 2019).

Blood compatibility is impacted by the biochemistry of coagulation, the mechanisms of blood–materials interactions (BMI), and the design and function of a device in the bloodstream. This chapter will integrate many of these ideas and provide a framework for BMI and blood-compatibility assessment.

Blood compatibility can also be viewed from a different perspective, i.e., by considering a material that is *not* blood compatible (a thrombogenic material). Such a material would produce specific adverse reactions when placed in contact with blood: formation of clot or thrombus composed of various blood elements; shedding of thromboemboli (detached thrombus); destruction of circulating blood components; activation of the complement system; and other immunologic pathways (Salzman and Merrill, 1987). Most often, in designing blood-contacting materials and devices, our aim is to minimize these generally undesirable blood reactions. Are these reactions always undesirable? Consider the case of a hemostatic device that is designed to rapidly induce clotting.

Why Measure Blood Compatibility?

Many devices and materials are presently used in humans to treat, or to facilitate treatment of, health problems. Such devices include the extracorporeal pump-oxygenator (heart–lung machine) used in many surgical procedures, hollow fiber hemodialyzers for treatment of kidney failure, catheters for blood access and blood vessel manipulation (e.g., angioplasty), heart assist devices, stents for luminally supporting blood vessels, and devices for the permanent replacement of diseased heart valves (prosthetic heart valves) and arteries (vascular grafts). Since these and other blood-contacting devices have been successfully used in patients for 40 or more years, and are judged to be therapeutically beneficial, it is reasonable to ask: (1) is there a continued need for assessing BMI, and (2) are there important problems that remain to be addressed? The answer in both cases is an emphatic "yes."

To address point 1, the ongoing need for BMI measurement, consider that existing devices are frequently modified by incorporation of new design features or materials primarily intended to improve durability and physical and mechanical characteristics, i.e., devices may be modified to improve characteristics other than BMI. However, since these changes may also affect blood responses, and since BMI are not entirely predictable based on knowledge of device composition and configuration, blood-compatibility testing is nearly always required to document safety.

There are substantial problems with devices used today in the bloodstream (point 2). The performance of many existing devices is frequently less than optimal (Jaffer and Weitz, 2019; Baumann Kreuziger and Massicotte, 2015; Byrne and Joner, 2015; Ratner, 1993a, 2000, 2007). For example, prolonged cardiopulmonary bypass and membrane oxygenation can produce a severe bleeding tendency. Mechanical heart valves occasionally shed emboli to the brain, leading to stroke. Angiographic catheters can also generate strokes. Synthetic vascular grafts perform less well than grafts derived from natural arteries or veins; graft failure due to thrombosis can lead to ischemia (lack of oxygen) and death of downstream tissue beds; small diameter synthetic vascular grafts (<4 mm i.d.) perform so poorly that they are rarely used. Thus while performance characteristics have been judged to be acceptable in many instances (i.e., the benefit/risk ratio is high), certain existing devices could be improved to extend their period of safe operation (e.g., oxygenators) and to reduce adverse BMI long term (e.g., heart valves). Furthermore, many devices are only "safe" when anticoagulating drugs are used (e.g., oxygenators, mechanical heart valves, hemodialyzers). Device improvements that would reduce adverse BMI, and thereby minimize the need for anticoagulant therapy, would have important implications both for health (fewer bleeding complications due to drug effects) and cost (complications can be expensive to treat). The reusability of devices that can undergo repeated blood exposure in individual patients (e.g., dialyzers) is also an important economic consideration.

For certain applications there are no devices presently available that perform adequately (due to adverse BMI), even when antithrombotic drugs are used. Thus there are needs for devices that could provide long-term oxygenation for respiratory failure, complete cardiac support, and intravascular measurement of physiologic parameters and metabolites (O_2, CO_2, pH, glucose). Also, there are demands for long-term, small diameter vascular grafts (<5 mm i.d.) and other conduits (e.g., stents and stent grafts) for reconstruction of diseased arteries and veins. Overall, there is a compelling need for continued and improved methods for evaluating BMI.

What Is Thrombogenicity?

A thrombogenic device may cause a localized accumulation of protein and cellular blood elements. Cardiovascular devices may also induce regions of disturbed flow or stasis that lead to the formation of blood clots. These accumulations or clots may compromise device functions, such as flow of blood through artificial blood vessels, mechanical motions of heart valves, gas exchange through oxygenators, removal of metabolic waste products through dialysis membranes, etc. Local blood reactions may also impact other parts of the host organism, i.e., systemic effects might be noted. Thus thrombi may detach from a surface (embolize) and be carried downstream, eventually occluding a blood vessel of comparable size and impairing blood flow distal to the site of occlusion. When the tissue dependent on this blood flow becomes necrotic, it is termed an infarct. Chronic devices may produce steady-state destruction or "consumption" of circulating blood elements (e.g., mechanical destruction of red cells by heart prostheses producing anemia or removal of platelets due to ongoing thrombus

formation or platelet activation), with a concomitant rise in plasma levels of factors released from those blood elements (e.g., plasma hemoglobin, platelet factor 4). This consumption may lower the concentration in blood of that component or be masked by increased production. Mediators of inflammatory responses and vessel tone may also be produced or released from cells (e.g., platelets, white cells, the complement pathway) following blood–surface interactions that can affect hemodynamics and organ functions at other sites. Thus "thrombogenicity" may be broadly defined as the extent to which a device, when employed in its intended use configuration, induces the adverse responses outlined earlier. While all artificial surfaces will interact with blood, an acceptably nonthrombogenic device can be defined as one that would produce neither local nor systemic effects with significant health consequence to the host organism.

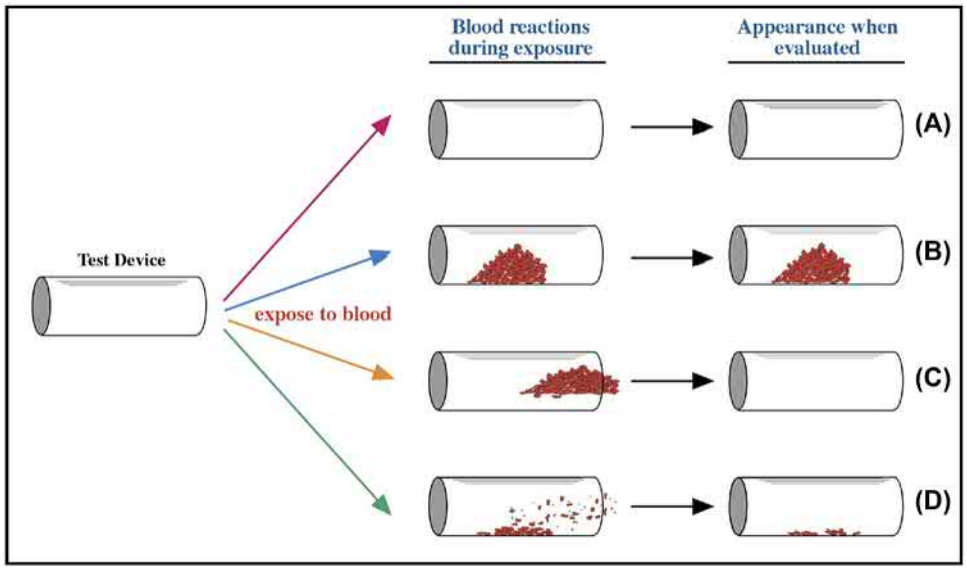
Thrombogenicity may be broadly defined as the extent to which a device, when employed in its intended use configuration, induces adverse responses.

With "thrombogenicity" now defined as adverse outcomes associated with device usage, the obvious goal is to design and improve devices using materials that are blood compatible (nonthrombogenic) for specific applications. Ideally, the biomaterials engineer would like to consult a handbook for a list of materials useful in the fabrication of a blood-contacting device. Unfortunately, there is little consensus as to the materials that are blood compatible (Ratner, 1984). Because of this lack of consensus, there is no "official" list of blood-compatible materials. As a result, in the construction of a new blood-contacting device the biomaterials engineer generally consults published studies or directly performs blood-compatibility assessment studies on candidate materials.

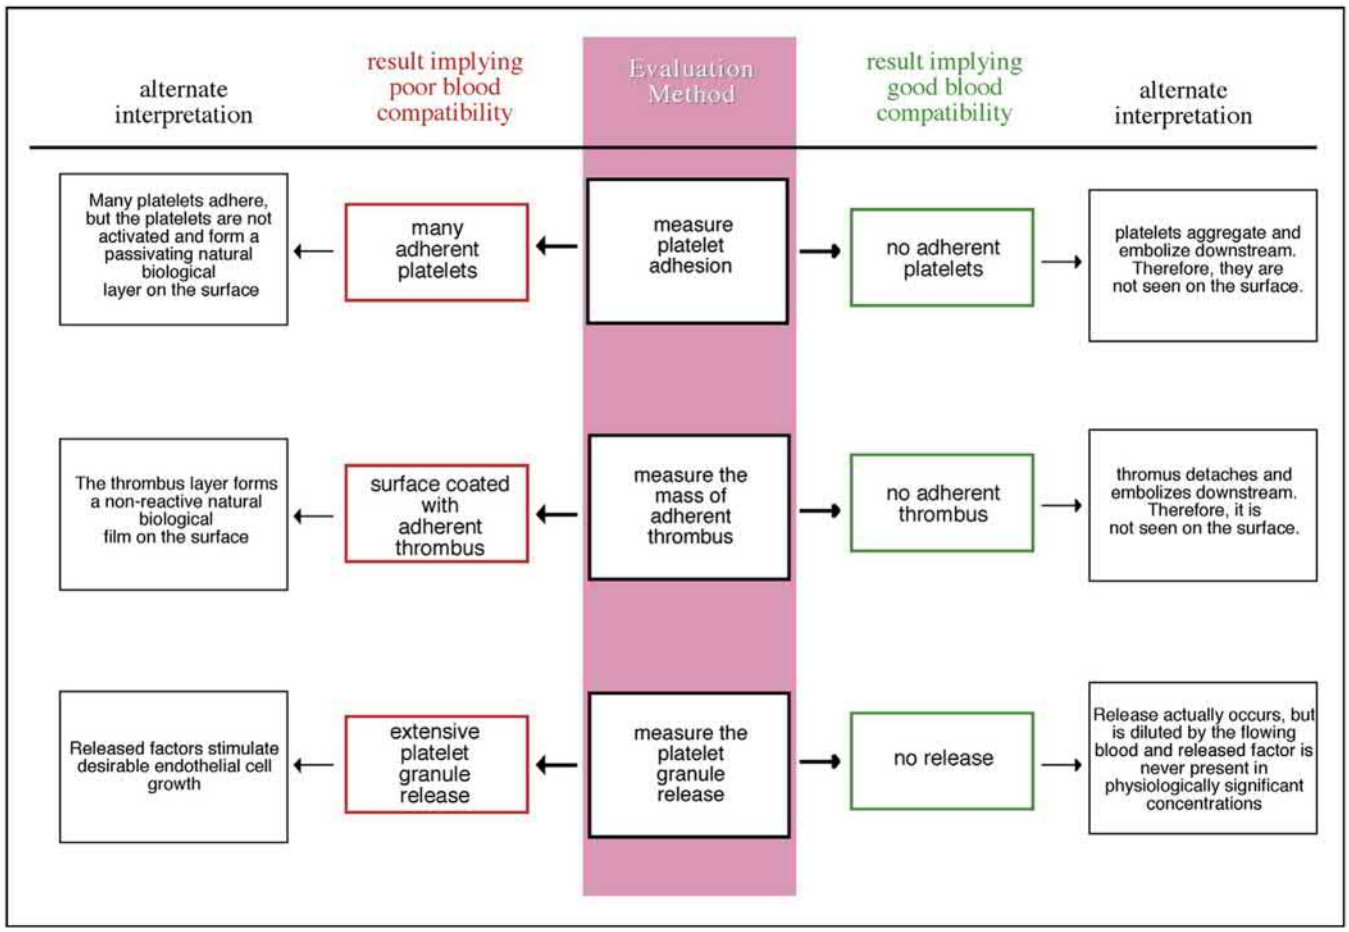
Understanding the blood compatibility of specific materials used in blood-contacting devices is complex because:

(1) The types of blood-contacting devices used are numerous (see Chapters 2.5.2 and 2.5.3), and the device design will impact the apparent thrombogenicity of materials used in those devices.
(2) Blood-contacting devices are commercially manufactured, and manufacturers are, for competitive reasons, reluctant to discuss specific chemical compositions or changes made to raw materials in the device design.
(3) The possible blood responses are numerous, complex, dynamic, and often not fully understood.
(4) It is difficult and expensive to measure device thrombogenicity (clinically significant local thrombosis or systemic effects) in a systematic way, in either experimental animals or humans.

Most tests purported to measure blood compatibility in fact evaluate certain BMI, which are the events that occur (and observations that are made) when blood contacts a material. Fig. 2.3.5.1 illustrates how alternate interpretations can be applied to data from "blood-compatibility" tests. This concept is further expanded upon in Fig. 2.3.5.2. These alternate interpretations often invalidate or modify conclusions drawn from such tests. For accuracy, the term "BMI assessment" will be used for the remainder of this chapter, instead of "blood-compatibility test." Based upon the characteristics of the evaluation method (i.e., what is really being measured) the biomaterials scientist must relate



• **Figure 2.3.5.1** Possible scenarios for blood–materials interactions and alternate interpretations of testing outcome. This example points out limitations of evaluating only local thrombus formation at fixed time points. (A) The device remains free of thrombus after exposure to blood; (B) a large thrombus forms and adheres tightly, as is observed at the endpoint; (C) a large thrombus forms but detaches (embolizes); (D) the surface is highly reactive toward blood but deposited material is quickly removed through microembolism and/or lysis. Inspection of devices (C) and (D) could lead to the incorrect conclusion that these surfaces are blood compatible.



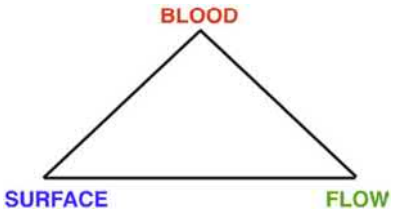
• **Figure 2.3.5.2** Alternate scenarios that can be applied for interpreting results of blood–materials interaction assays.

the significance of the events being observed (the BMI) to the blood compatibility of the material or device. A solid understanding of the physical and biological mechanisms of blood–materials interactions is required to make this connection in a rational way.

Most tests purported to measure blood compatibility in fact evaluate BMI, which are the events that occur when blood contacts a material. For example, is a material that adheres platelets not blood compatible? Figs. 2.3.5.1 and 2.3.5.2 demonstrate alternate interpretations of such data.

In more specific terms, BMI are the interactions (reversible and irreversible) between surfaces and blood solutes, proteins, and cells (e.g., adsorption, absorption, adhesion, denaturation, activation, spreading) that occur under defined conditions of exposure time, blood composition, and blood flow. Since each of these variables influence BMI, we generally cannot: (1) extrapolate results obtained under one set of test conditions to another set of conditions; (2) use short-term testing to predict long-term results; and (3) predict in vivo device performance based on BMI testing of materials per se in idealized flow geometries. Nonetheless, such tests have provided important insights into the mechanisms of thrombus formation in general, and the relationships between BMI and blood compatibility. These studies also permit some general guidelines for device construction and, to a limited extent, may allow prediction of device performance in humans. These points are addressed in subsequent sections of this chapter.

The foregoing considerations suggest that no material may be simply "blood compatible" or "nonthrombogenic," since this assessment will depend strongly on details of the test system or usage configuration. In fact, under conditions of sluggish (low shear) blood flow or stasis, most if not all artificial materials may become associated with localized blood clotting and thus be considered "thrombogenic." This is because synthetic materials, unlike the vascular endothelium (the perfect "blood-compatible material" that lines all blood vessels), cannot actively inhibit thrombosis and clotting by directly producing and releasing inhibitors or by inactivating procoagulant substances. The possibility that there may be no "biomaterials solution" for certain situations or that device performance could be improved by emulating strategies found in nature has led some investigators to consider coating devices with endothelial cells, antithrombotic drugs, or anticoagulating enzymes. These "antithrombogenic" approaches appear promising, and are being widely explored (Maitz et al., 2019). As for conventional synthetic materials



• **Figure 2.3.5.3** Virchow's triad.

and devices, establishing the usefulness of biologic surfaces and drug delivery devices requires appropriate methods for evaluating their blood interactions. An important point is that we use millions of devices in contact with blood each year in patients with generally good outcomes. It is not that the problem of blood compatibility is impossible to solve, but outcomes can often be improved by optimizing BMI.

We use millions of devices in contact with blood each year in patients with generally good outcomes. The problem of blood compatibility is complex, but outcomes can often be improved by optimizing BMI.

Key Considerations for BMI Assessment

In 1856, Rudolph Virchow implied that three factors contribute to the coagulation of blood: blood chemistry, blood-contacting surface, and flow regime (commonly referred to as Virchow's triad—Fig. 2.3.5.3).

This assessment is still valid and provides a framework for more formally introducing the variables important in any system intended to evaluate BMI. Also, the interaction time of blood with materials (ranging from seconds to years) has an impact on BMI. As described in the following paragraphs, these variables may each profoundly influence the results and interpretation of BMI testing. It is assumed that the reader has reviewed the mechanisms of blood response to artificial surfaces, as outlined in Chapter 2.2.6.

Blood: A Fragile Fluid That Is Readily Compromised

The source of the blood and methods for its handling can strongly influence BMI. Human blood and blood from various animal species have been employed in BMI assessment in vitro and in vivo, both in the presence and absence of anticoagulants. Blood reactivity is also influenced by manipulations in vitro, the surface-to-volume ratio of blood in extracorporeal circuits, and the use of pumps for blood recirculation. These aspects are discussed later and summarized in Table 2.3.5.1.

Although there are general similarities in the blood chemistry of all mammals, there are also differences characteristic of each species. In particular, blood may vary with respect to blood proteins (concentrations and functionality), and cells that participate in coagulation, thrombosis, and fibrinolysis (Chapter 2.2.6). The size of blood-formed elements may also differ. A comparison of blood chemistry between humans and the more commonly used animal species has been published (McIntire et al., 1985). While human blood is obviously preferable for BMI, it is often impossible to use human blood in certain experiments. In addition, there are significant health concerns in experimenting with human blood, and animals are commonly used for both in vitro and in vivo studies. Unfortunately, most investigations have employed a single animal species or blood source. There have been few comparisons between human and animal blood responses for evaluating BMI in particular test situations (also see Chapter 2.3.6). Differences between human and animal blood responses can be large, and such differences should lead to caution in directly interpreting experimental results. Furthermore, the variation is generally not simply a "less" or "more" reactive consideration; rather, some species may have less platelet reactivity offset by more coagulation or fibrinolytic activity. Activation may be more sensitive to some agonists and less for others. Similarly, the animal response to anticoagulants and antiplatelet agents may vary substantially from humans. Following the implantation of chronic blood-contacting devices (e.g., vascular grafts) there may be large differences between humans and other animal species in terms of device healing, which will be reflected as differences in the *time course* of BMI. Furthermore, while laboratory animals serving as blood donors for BMI experiments may represent a relatively homogeneous population in terms of age, health status, blood responses, etc., the human donors of blood for research (and recipients of blood-contacting devices) may vary considerably in terms of these parameters. Consider, for example, human diet, drug use (e.g., aspirin, alcohol), overall health, and even donor sex (males and females were found to have different platelet responses in experiments in our laboratory). Thus the

TABLE 2.3.5.1 Factors Important in the Acquisition and Handling of Blood for Blood–Materials Interactions (BMI) Experiments

- Species of the blood donor
- Health, gender, and age of the blood donor
- Blood reactivity of the donor (individual physiological differences)
- Time interval between blood draw and BMI experiment
- Care with which the puncture for the blood draw was made or if drawn from an indwelling catheter
- Temperature (for blood storage and testing)
- Anticoagulation
- Drugs and anesthetics present in the blood
- Cellular activation or damage due to centrifugation and separation operations
- Activation due to contact with foreign surfaces prior to the BMI experiment (syringe, needle, blood bag, bottles, tubing, etc.)
- Blood damage due to the air–blood interface
- Blood damage due to pumping and recirculation

results obtained with animal species must be viewed with caution if conclusions are to be drawn as to the significance of the results for humans. Even the blood drawn from one human can give misleading results when generalizations to all humans are attempted.

Despite these limitations, animal testing has been helpful in defining *mechanisms* of BMI and thrombus formation, and the interdependence of blood biochemical pathways, the nature of the surface, and the blood flow regime. In addition, while results of animal testing may not quantitatively predict results in humans, in many cases results can be qualitatively similar and allow for relative comparisons between materials and devices. These aspects are discussed further later. In general, studies in lower animal species, such as the rabbit, rat, and guinea pig, may be useful to screen for profound differences between materials, for example, by incorporation of an antithrombotic drug delivery system into an otherwise thrombogenic device. Short-term screening to identify markedly reactive materials, and longer-term studies to evaluate healing and its impact on BMI can also be performed in species such as sheep and pig. When differences in BMI are likely to be modest (for example, as a consequence of subtle changes in surface chemistry or device configuration) the ranking of materials based on tests with lower animal species may be different from results that would be obtained in humans.

In vitro testing generally requires anticoagulation of the blood that can have a profound effect on BMI. In vivo testing and the use of extracorporeal circuits are also commonly performed with anticoagulants. Two anticoagulants are frequently used: sodium citrate, a calcium ion chelator required for certain reactions of platelets and coagulation proteins, and heparin, a natural polysaccharide used to block the action of the coagulation protease thrombin (Chapter 2.2.6). Both can markedly affect BMI. In particular, the removal of calcium ions may profoundly depress platelet–surface reactions, and the capacity of platelets to aggregate and form thrombi. Thus the relationship between BMI in the presence of citrate anticoagulant and "thrombogenicity" in the absence of anticoagulant is questionable. Similar concerns apply to heparin anticoagulation. Although this agent is less likely to interfere with the earliest platelet reactions, thrombus formation may be impaired by inhibition of thrombin activity. The use of heparin is appropriate for evaluation of devices where heparinization is used clinically (e.g., oxygenators, dialyzers). In general, results with anticoagulated blood cannot be used to predict performance in the absence of anticoagulants. A discussion of anticoagulants in the context of BMI has been presented (McIntire et al., 1985).

Blood is a fragile fluid that begins to change from the moment it is removed from the body. It may become more active (activated) or less active (refractory). Thus BMI evaluations with blood externalized from the normal circulatory system for more than a few hours are questionable. If purified blood components or cells are used (e.g., platelets, fibrinogen), studies must be performed to ensure that they remain functionally normal. In most cases the volume of blood used, relative to test surface area, should be large. Similarly, the area of nontest surfaces, including exposure to air interfaces, should be minimized. Changes in blood temperature, test surface temperature, or exposure to bright light sources (Haycox et al., 1991) can also produce artifactual results. When blood is pumped, the recirculation rate (fraction of total blood volume pumped per unit time) should be minimized, since blood pumping alone can induce platelet and red cell damage, platelet release reactions, and platelet refractoriness (Haycox and Ratner, 1993). If care is taken to ensure that critical experimental variables are well controlled, a recent multicenter study has indicated that concordant results and conclusions can be reached in measuring acute platelet adhesion and activation by selected biomaterials between laboratories and within a study (Braune et al., 2017). Although the complexity of this assessment was low, only looking at platelet adhesion from plasma, similar attempts to control variability in other BMI assessment processes may allow more comparative data to be considered as candidate materials are considered for a given application.

Blood is a complex, fragile fluid, and outcomes of BMI studies will be strongly impacted by the animal species (or human donor), blood-handling protocols, and storage time.

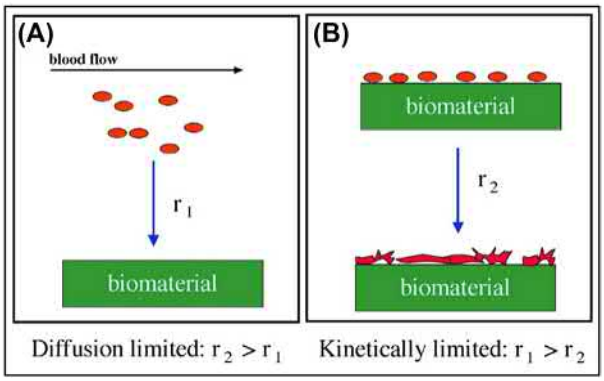
Flow: Blood Interactions Dictated by Shear and Mass Transport

Blood flow controls the rate of transport (by diffusion and convection) of proteins, cells, and thrombi in the vicinity of artificial surfaces and thus plays a critical role in the multistep process of thrombus growth. This subject has been reviewed (Brass and Diamond, 2016; Panteleev et al., 2015; and Chapter 2.1.6). Platelet diffusion in flowing blood, and early platelet attachment to surfaces, may be increased 50–100-fold by the presence of red blood cells that greatly enhance the movement of platelets across parallel streamlines. While physiological blood shear forces probably do not damage or activate platelets directly, such forces can dislodge platelet aggregates and thrombi (embolization) to distal circulatory beds. At supraphysiologic shear stresses, as might occur in stenoses or in the flow paths of some devices, shear activation of platelets can be a concern. Similarly, red cells may also be subject to mechanical damage and release chemical factors enhancing platelet reactivity (Turitto and Baumgartner, 1987).

A number of studies using well-characterized flow geometries have suggested that the initial attachment of platelets to artificial surfaces increases with increasing blood flow or, more specifically, with increasing wall shear rate (the slope of the velocity profile at the surface). Under conditions of low wall shear rate flow (less than ~1000/s), early platelet adhesion (over the first minutes of exposure) may depend more upon the platelet arrival rate (i.e., platelet availability) than on substrate surface properties (Friedman et al., 1970). Under these conditions the platelet–surface reaction rate is said to be *diffusion controlled*. At higher shear rates, platelet

adhesion may depend less upon platelet transport to the surface, and more on the reactions triggered by surface properties (*reaction controlled*, Schaub et al., 2000); thus studies designed to assess the role of surface properties are best performed under flow conditions where platelet transport is not limiting. Following initial platelet adhesion, subsequent processes of platelet aggregation and in vivo thrombus formation (over minutes to hours) are predominantly *reaction controlled*. For example, platelet accumulation on highly thrombogenic artificial surfaces (e.g., fabric vascular grafts) or biologic surfaces (e.g., collagen) may be rapid, and dependent on both the substrate reactivity and factors influencing platelet availability (shear rate, hematocrit, and platelet content of blood) (Harker et al., 1991). Under other circumstances, the rate of platelet–surface interactions may be almost entirely reaction controlled. For example, with smooth-walled artificial surfaces that repeatedly embolize small platelet aggregates continuously over days, the overall rate of platelet destruction depends strongly on material properties, but not on blood flow rate or circulating platelet numbers over wide ranges of these variables (Hanson et al., 1980). These concepts of diffusion and reaction control are further explained in Fig. 2.3.5.4.

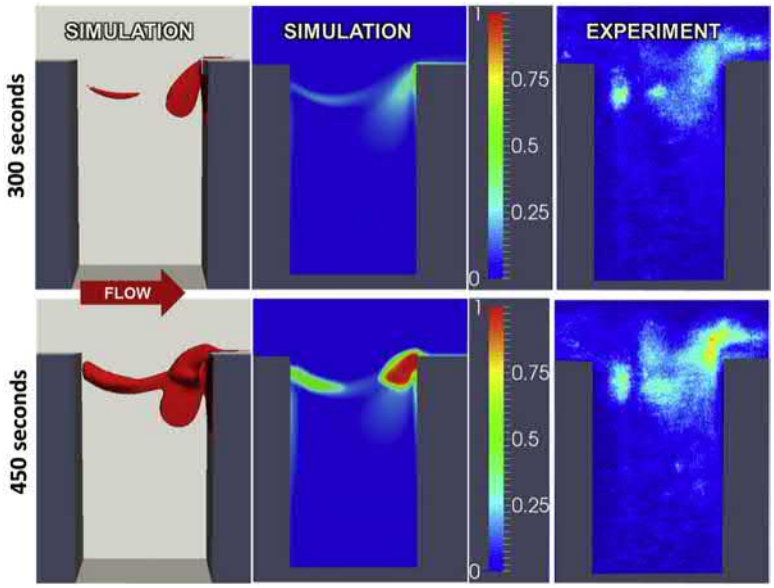
It has been observed that under arterial flow conditions (high wall shear rate), thrombus that forms in vivo may be largely composed of platelets ("white thrombus"), while thrombus that forms under venous flow conditions (low shear rate) may contain mostly red cells entrapped in a fibrin mesh ("red thrombus"). The process of platelet thrombus formation may not be affected by administration of heparin (i.e., arterial thrombosis may be heparin resistant), while venous thrombosis is effectively treated with heparin. This insensitivity of platelet reaction to heparin in high shear blood flow is somewhat surprising, since the procoagulant enzyme thrombin, one of the most potent activators of platelets, is strongly inhibited by heparin. These observations have been incorrectly interpreted to mean that arterial thrombosis and venous thrombosis are separable processes, with the former depending only on platelet reactions, and the latter depending only on surface protein-triggered coagulation events. However, while platelet-dependent (arterial) thrombosis may be little affected by heparin, it is blocked quite effectively by other inhibitors of thrombin (Hanson and Harker, 1988; Wagner and Hubbell, 1990), indicating that heparin is limited in its capacity to block the thrombin enzyme when thrombin is produced locally in high concentrations through reactions that may be catalyzed on the platelet surface (Chapter 2.2.6). The formation of fibrin, due to the action of thrombin on fibrinogen, is also important for thrombus formation and stabilization since: (1) fibrinolytic enzymes can reduce platelet thrombus formation, and (2) arterial thrombi are often composed of alternating layers of platelets and fibrin. Thus in most circumstances, thrombin is a key promotor of *local* platelet and fibrin accumulation (on surfaces) under both high shear and low shear conditions. Thrombi may differ in appearance, because under high flow conditions, thrombin and precursor procoagulant enzymes (e.g., Factor Xa) may be diluted sufficiently to prevent *bulk phase* clotting and trapping of red cells.



• **Figure 2.3.5.4** The effects of flow and material surface properties on platelet transport to, and reaction with, surfaces. One can define two rate processes: r_1, the rate of platelet transport from blood to the surface (higher in rapidly flowing blood), and r_2, the rate of reaction of a platelet with the surface. (A) In low wall shear rate blood flow, platelets can be slow to reach the surface and r_1 dominates the kinetics of the reaction—for reactive surfaces, the surface can be "starved" of platelets for reaction. (B) In high wall shear rate blood flow, platelets are transported to the surface much more rapidly than they can react with the surface, and the intrinsic reactivity of the surface, r_2, can be observed.

Modeling of the coupled effects of flow and surface-associated reactions on biomaterial thrombosis has been the subject of growing interest as the power of numerical simulations and computational processing have increased. The potential future benefit of such approaches is apparent. By selecting parameters that reflect the activation status and reactivity of a typical patient's blood, by defining a geometry and boundary conditions for a device blood flow path, and by inputting parameters that reflect a given biomaterial surface's propensity to support platelet adhesion, activation, and coagulation cascade activation, a simulation could predict whether and where thrombus was likely to form. Using such a simulation, parameters could be altered to minimize the risk for such deposition. In particular, the flow path could be altered to improve transport and minimize risk in some parts of the device, or a less activating material or surface treatment could be applied in an area at high risk.

Despite important advances, such coupled models are not yet routine, although computational fluid dynamics models are commonly applied to cardiovascular device design to minimize "hot spots" of high shear stress, recirculation, or stagnation (Bluestein, 2017). From a biomaterials perspective, the challenge in defining the needed surface activation parameters to use in coupled simulations is highlighted in this chapter. The blood parameters are also challenging to define for a patient population, as would be the effect of anticoagulant therapy. An example of the current state of thrombosis modeling of relevance to biomaterial and device design is shown in Fig. 2.3.5.5 (Wu et al., 2017). For a disturbed flow situation introduced by a crevice in the wall of the flow path, the modeling captures some of the characteristics of the experimentally observed



• **Figure 2.3.5.5** Modeling of thrombus deposition from blood flowing over a crevice (similar to what might be found at a seam or joint within a blood pump). The computational simulation (*left and middle panels*) is shown to generally predict the nonintuitive regions of platelet deposition versus flow chamber experiments with fluorescently labeled platelets flowing in whole blood over a crevice with a Ti6Al4V alloy surface at $t = 300$ and 450 s and a crevice length of $Lc = 0.075$ mm. *Center and right panels* indicate volume fraction of platelets in the near-wall region of the channel. (From Wu, W.T., Jamiolkowski, M.A., Wagner, W.R., Aubry, N., Massoudi, M., Antaki, J.F., 2017. Multi-constituent simulation of thrombus deposition. Sci. Rep. 7, 42720.)

early platelet deposition. Experimental studies with similar disturbed flow path geometries and biomaterial surfaces of different thrombogenicity have shown the relative effects of changing the flow disturbance (crevice size) versus employing less thrombogenic materials (Jamiolkowski et al., 2016), although the contact times for both the simulations and experiments noted are short.

In summary, thrombus formation requires the transport by flow of platelets and coagulation proteins to surfaces. Fibrin polymerization, as well as local platelet activation and recruitment into growing thrombi, requires conversion of prothrombin to thrombin, the end product of a sequential series of coagulation reactions that are also catalyzed by platelets, and may be amplified or inhibited by various feedback mechanisms (Chapter 2.2.6). Blood flow regulates each reaction step, such that under low (venous) flow conditions fibrin formation is abundant; thrombi may resemble coagulated whole blood with many entrapped red cells. Under high (arterial) flows, platelets stabilized by much smaller amounts of fibrin may comprise the greater proportion of total thrombus mass. Modeling of flow-related effects in thrombosis is rapidly advancing and may offer a means to better design blood biocompatible devices in the future.

Thrombus formation requires the transport by flow of platelets and coagulation proteins to (and from) surfaces. Absence of flow, low shear flow, and high shear flow can each give dramatically different BMI results.

Surfaces: Actively Studied, but Least Well Defined, of the BMI Variables

Many different artificial surfaces, in various device applications, are used in contact with blood. It is well documented that surface physicochemical properties of materials can influence early events, for example, on protein adsorption (Chapter 2.1.2) and platelet adhesion—yet how these effects relate to subsequent thrombus formation remains uncertain.

When placed in contact with blood, most, if not all, artificial surfaces first acquire a layer of adsorbed blood proteins whose composition and mass may vary with time in a complex manner depending on substrate surface type (Chapter 2.1.2). This layer mediates the subsequent attachment of platelets and other blood cells that can lead to the development of thrombi. The relationship between material properties, the protein layer, and the propensity of a material or device to accumulate thrombus is not well understood because: (1) protein–surface reactions involve complex, dynamic processes of competitive adsorption, denaturation, and activation; (2) cell–surface interactions may modify the protein layer, i.e., cells may deposit lipid and protein "footprints" derived from the cell membrane; (3) the importance of specific adsorbed proteins for subsequent cell interactions, especially in vivo, is not well defined; and (4) there have been few *relevant* tests in which both protein adsorption and later thrombus formation have been assessed. Under conditions of low blood shear, the capacity of negatively charged surfaces (such as glass)

to activate intrinsic coagulation (via Factor XII) can lead to thrombin production, with subsequent platelet deposition and fibrin clot formation. Under other circumstances the availability on surfaces of adhesive plasma proteins, such as fibrinogen, will be important for regulating cell attachment and subsequent thrombus formation (Brash et al., 2019; Sivaraman and Latour, 2010).

With anticoagulated blood, initial platelet attachment to a variety of surfaces may be comparable and limited to a partial platelet monolayer, suggesting that surface properties may be "inconsequential" for early platelet adhesion, especially where platelet transport to the surface may be rate limiting (Friedman et al., 1970). In the absence of anticoagulants, initial platelet attachment may vary, but no general relationship to substrate surface properties has been demonstrated. In attempts to establish such relationships, thrombus formation has been studied using devices implanted in animals and composed of various materials, including polymers, metals, carbons, charged surfaces, and hydrogels. Correlations have been sought between the blood response and surface properties, such as charge (anionic–cationic), hydrophilicity, hydrophobicity, polarity, contact angle, wettability, and critical surface tension (Kaelble and Moacanin, 1977; McIntire et al., 1985; Salzman and Merrill, 1987; Williams, 1987). These parameters have not proven satisfactory for predicting device performance even in idealized test situations, reflecting the complexity of the phenomena being investigated, the limitations of animal experiments and, in some cases, the inadequate characterization of material surface properties (see Chapters 1.2.4 and 3.1.9, and Ratner, 1993a).

In many cases, material properties are constrained by the specific mechanical and morphological needs of the intended blood-contacting device application. For example, vascular grafts and the sewing ring of prosthetic heart valves are composed of fabric or porous materials to permit healing and tissue anchoring. Other materials must be permeable to blood solutes and gases (dialysis and oxygenator membranes) or distensible (pump ventricles, balloon catheters). These design constraints often necessitate complex flow geometries. In general, devices with flow geometries that cause regions of flow recirculation and stasis tend to produce localized clotting in the absence of heparin anticoagulation. On a microscopic scale, surface imperfections and crevices may serve as foci to initiate thrombus formation, as noted earlier. While surface smoothness is usually desirable, many devices having a fabric or microporous surface (e.g., vascular grafts) function well if the layer of thrombus that forms is not thick enough to interfere with device function and does not embolize.

The lack of consensus on the blood compatibility of materials was pointed out by Ratner (1984). This is a consequence of the complex, multifactorial nature of BMI. Assigning a label of "blood compatible" or ranking materials as to their suitability for use in blood is still fraught with uncertainty, and at best would need to be specifically qualified with the device and operating conditions considered.

Blood Interaction Times With Materials and Devices

Different events may occur at short and long BMI times. Consider the case of a patient supported by a ventricular assist device where a thromboembolic event (stroke) occurs after several months of uneventful support. What changed at this late time point to trigger the event? Blood chemistry will certainly vary as a patient's health changes, for instance, with an infection, or with health changes due to the device action (e.g., improved diet and exercise resulting in more robust immune and hemostatic systems). Anticoagulation and antiplatelet medications need to be managed. The device may change as it interacts with the blood and nearby tissue. The embolus that triggered the event may be one of a long series of shed emboli that statistically happened to be of a large enough size this time, and followed a path to a region of the cerebrovasculature where an infarct would be noticed and had adequate mechanical properties not to break down. Clearly, many variables are in play, and BMI may present an ongoing risk. A test performed where blood contacts a device for seconds or minutes may yield a result that will have limited meaning for devices used for hours or days, or which may be implanted chronically. Thus measurements of protein adsorption (an early event) can, in some cases, predict levels of platelet adhesion. But platelet adhesion alone is not an adequate measure of thrombogenicity, and it does not predict local or systemic thrombogenic effects that could be harmful. Still, several studies indicate that an early maximum in platelet thrombus accumulation may be seen within hours of device exposure, and this can be sufficient to produce device failure (e.g., small diameter vascular graft occlusion) (Harker et al., 1991). Therefore short-term testing (over hours) may be appropriate for predicting the clinical usefulness of devices that can produce an acute, severe thrombotic response.

Evaluation of BMI

A summary of some (or historically important) in vitro and in vivo testing procedures commonly used to evaluate BMI is presented in this section. A few relevant case studies with commentary are included. We emphasize that a thorough characterization of surface properties is critical for the interpretation of these tests (Chapters 1.2.4 and 1.4.2, and Ratner, 1993b), since the surface composition of materials is often significantly different from "as received and labeled." A few specific tests that have been historically influential and tests that are used today are summarized in Table 2.3.5.2.

BMI can be evaluated in vitro and in vivo. Also, we can look at the BMI of either the biomaterials in isolation in a test configuration or the blood interactions of real devices. There are typically unique systems and geometries for in vitro, in vivo, and device-based assays. However, there are commonalities in the measurements of blood parameters. For example, blood can be circulated through a tube in vitro, circulated through an implanted biomaterial shunt in vivo, or circulated through a hemodialyzer (in vivo

TABLE 2.3.5.2 A Partial List of Blood–Materials Interactions Tests

- Qualitative assessment (look at the thrombus)
- Count adherent blood elements
- Observe and categorize platelet morphology
- Measure platelet release molecules
- Clotting times and related coagulation assays
- Measure soluble products of thrombosis
- Platelet consumption
- Flow cytometry to measure activation of cells in the bulk phase
- Microparticles or microaggregates (flow cytometry)
- Embolus measurement

or in vitro). In all cases, the blood emerging from the test system might be assessed by a partial thromboplastin time test, measurement of soluble by-products of thrombotic reactions, or a flow cytometric analysis of activated platelets. Thus the methods for contacting blood with biomaterials, and the methods for assessing blood change, can often be considered independently.

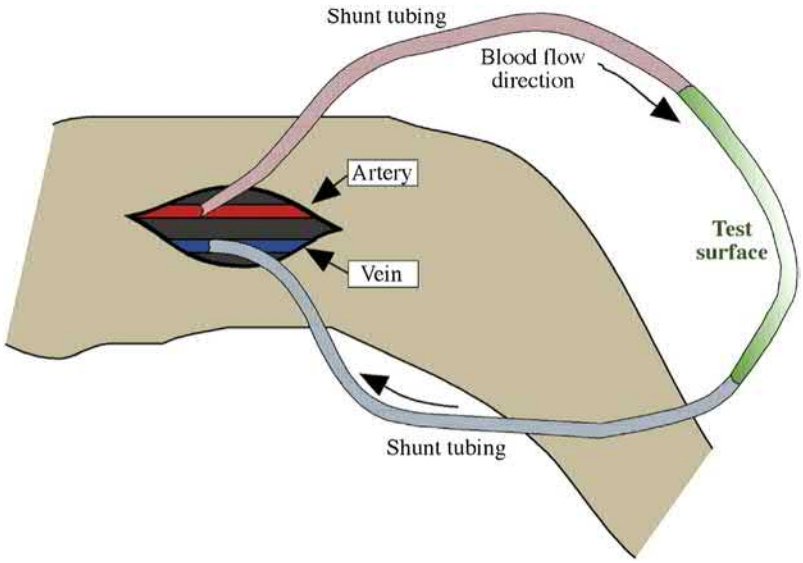
In Vitro Tests

In vitro BMI tests involve placing blood or plasma in a container composed of a test material, in a container containing the test material, or recirculating blood through a flow system in which test materials contact blood under well-defined flow regimes that simulate physiologic flow conditions. Many flow geometries have been studied, including tubes, parallel plates, packed beds, annular flows, rotating probes, and spinning disks. The historical (but still relevant) literature on these test methods has been reviewed (McIntire et al., 1985; Turitto and Baumgartner, 1987), and has yielded considerable insight into how proteins and platelets are transported to, and react with, artificial surfaces. Such studies provided a wealth of morphologic information at the cellular level regarding details of platelet–surface and platelet–platelet interactions (Sakariassen et al., 1989). However, as discussed earlier, these tests are usually of short duration, and are strongly influenced by the blood source, handling methods, and use of anticoagulants. Thus, in vitro test results generally cannot be used to predict longer-term BMI and in vivo outcomes, and can provide only the most general guidelines for the selection of materials for particular devices. However, in vitro tests may be useful for screening materials that are highly reactive toward blood.

Tests of the whole blood clotting time and variations thereof involve placing nonanticoagulated whole blood (or blood anticoagulated with sodium citrate, which is then recalcified) into containers of test material (or adding the test material to the container) and measuring the time for a visible clot to form. Materials that quickly activate intrinsic coagulation and cause blood to clot within a few minutes (like glass surfaces) are probably unsuitable for use in devices with low shear blood flow or in the absence of anticoagulants. These tests are known by names such as whole blood clotting time, activated partial thromboplastin time, and whole blood recalcification time. An older variant of these tests, frequently mentioned in the early biomaterials literature, is the Lee–White clotting time test.

Possibly the most commonly performed assay for BMI involves quantifying platelets deposited onto surfaces and visualizing platelet reaction to surfaces. The limitations of these tests have been discussed and are reiterated in this section. Still, these assessments are so commonly performed that some discussion is appropriate. The limitations of these platelet attachment tests are important to consider up front: (1) are the platelets mass transport limited in arriving at the surface?; (2) are dynamic events such as transient adhesion, release, and/or emboli formation being missed due to limited time points for observation?; (3) are the platelets active or refractory (unresponsive)?; (4) can species differences in platelet adhesiveness have large effects on the observed numbers of platelets?; (5) can platelets spread into extremely thin surface films be difficult to observe or count (Haycox and Ratner, 1993)?; and (6) are platelet deposition studies typically short term, and thus generally have limited meaning for devices that reside for longer periods of time in blood? A promising approach to address the significance of surface adherent platelets for blood compatibility is to consider not only platelet number, but also platelet morphology (Waples et al., 1996). Platelets on surfaces can appear discoid without dendrites (unactivated), and then might show various degrees of activation (spread, mildly dendritic, highly dendritic, etc.). Such platelet morphologies can be assessed using light microscopy, fluorescent methods, or scanning electron microscopy. It is also possible to assess the activity of the deposited platelets in terms of their support of coagulation reactions by annexin V binding (Nechipurenko et al., 2019). Nonadherent platelets may be assessed in the bulk phase with flow cytometric techniques to quantify activation status (Ye et al., 2010; Blit et al., 2011) to allow further consideration of the scenarios indicated in Fig. 2.3.5.1.

Recirculation of heparinized blood or citrated blood through tubular devices and materials may lead to platelet activation and/or platelet deposition onto highly thrombogenic materials, with the appearance in plasma of proteins released from platelets (Kottke-Marchant et al., 1985; Haycox and Ratner, 1993). Thus these and similar methods may identify materials that might cause rapid platelet accumulation in vivo over short time periods, and therefore be unsuitable for certain applications such as small diameter vascular grafts or blood conduits. Both recirculation tests and in vitro clotting assays can be



• **Figure 2.3.5.6** Illustration of an arteriovenous (A-V) shunt placed between the femoral artery and vein (in the leg) of an experimental animal. Materials to be tested (in this case a tubular device) are interposed between inlet and outlet segments of the shunt.

considered for preliminary screening and identification of materials that could be highly thrombogenic. Most artificial surfaces in common use in blood-contacting devices would probably "pass" these tests. Since small differences in test results are of little significance for predicting material performance in actual use applications, these tests are not appropriate for optimizing or refining material properties. In vivo testing is more appropriate for discerning finer distinctions in blood reactivity, and such tests are discussed next.

In Vivo Tests of BMI

Many studies have been performed in which test materials, in the form of rings, tubes, and patches, are inserted for short or long time periods into the arteries or veins of experimental animals (McIntire et al., 1985; Salzman and Merrill, 1987; Williams, 1987). Here are a few concerns and considerations for such tests:

(1) The timing and type of measurements may be such that important blood responses are unrecognized. In particular, the measurement of gross thrombus formation at a single point in time may lead to incorrect conclusions about local thrombus formation (e.g., Fig. 2.3.5.1), and does not provide assessment of systemic effects of thrombosis such as embolization and blood element consumption.

(2) With more commonly used animal species (e.g., sheep, dogs), blood responses may differ from humans both quantitatively and qualitatively.

(3) The blood flow conditions of the model may not be controlled or measured, and in fact may not even be relevant for actual implant device geometries.

(4) There may be variable blood vessel trauma and tissue injury that can cause local thrombus formation through the extrinsic pathway of blood coagulation (Chapter 2.2.6).

Evaluations of BMI may be performed in animals having arteriovenous (A-V) or arterioarterial shunts, i.e., tubular blood conduits placed between an artery and vein or between an artery and artery. A-V shunts have been studied in a variety of animals, including baboons, dogs, pigs, and rabbits (McIntire et al., 1985). Qualitatively similar results have been obtained with shunts in dogs and baboons (Hanson et al., 1980; Sefton et al., 2000). An A-V shunt system is illustrated in Fig. 2.3.5.6. Once surgically established, shunts may remain patent (not occluded) for long periods of time (months) without the use of anticoagulants. Test materials or devices are simply inserted as extension segments or between inlet and outlet portions of the chronic shunt. These systems have many advantages: (1) blood flow is easily controlled and measured; (2) native or anticoagulated blood can be employed; (3) the animal's physiology removes damaged blood elements and makes new blood with each circulation through the body; and (4) both short-term and long-term BMI, including both local and systemic effects, can be evaluated. The downsides of these tests are demanding surgery, high expense, and ethical issues associated with chronic shunting of larger animals.

As an example, consider the A-V shunt model in baboons—baboons are used because they are hematologically similar to humans. The blood responses to tubular biomaterials and vascular grafts have been quantitatively compared with respect to: (1) localized thrombus accumulation; (2) consumption of circulating platelets and

fibrinogen; (3) plasma levels of factors released by platelets and coagulation proteins during thrombosis; and (4) embolization of microthrombi to downstream circulatory beds (Harker et al., 1991). These studies in primates are consistent with observations in humans that certain commonly used polymers (e.g., polytetrafluoroethylene, polyethylene, plasticized poly(vinyl chloride), silicone rubbers) and some vascular grafts (e.g., polytetrafluoroethylene) are relatively nonthrombogenic in extracorporeal circuits and arteries. Thus results with shunt models, particularly in higher animal species, may be predictive of BMI in humans when employed under comparable flow conditions (laminar unidirectional flow with arterial shear rates). Since extracorporeal shunts exclude modulating effects of blood vessel cells and tissue injury, results with these models may be less relevant to the behavior of devices that are placed surgically or whose responses may be mediated by interactions with the vessel wall as well as the blood (e.g., heart valves, grafts, indwelling catheters, and sensors). It is further noted that due to the expense and ethical considerations associated with the use of primates that BMI testing in this model is increasingly limited to latter stage assessments with device configurations.

In Vivo Evaluation of Devices

Since the blood response to devices is complex and not well predicted by testing of materials per se in idealized configurations, animal testing, and ultimately clinical testing, of functioning devices is required to establish safety and efficacy. Broad guidelines, based on the type of device being considered, are given next and apply to both animal and clinical testing. A summary of in vivo blood responses to devices, and of commonly used methods that have proven useful for evaluating those responses, is given in Table 2.3.5.3. Table 2.3.5.4 lists the wide range of screens that have been used in one group to understand blood interaction with devices, specifically ventricular assist devices (Wagner et al., 2000).

TABLE 2.3.5.3 Some Blood–Material Responses and Their Evaluation

Blood Components	Blood Response	Assessment[a]
Thrombus	Clot	Direct visual and histologic evaluation; noninvasive imaging (angiography, ultrasound, radioisotope, magnetic resonance); evidence of device dysfunction or blood path blockage.
	Thromboembolism	Emboli detection (ultrasound, laser); evidence of organ/limb ischemia; assessment of infarcts in organs; stroke.
Platelets	Consumption	Increased removal of labeled cells; reduced blood platelet count.
	Dysfunction[b]	Reduced platelet aggregation or responsiveness to agonist by FACS in vitro; prolonged bleeding time; altered thromboelastogram
	Activation	Increased plasma levels of platelet factor 4 and β-thromboglobulin; platelet membrane alterations (e.g., by FACS).
Red cells[b]	Destruction	Decreased red cell count; increased plasma hemoglobin.
White cells[b]	Consumption/activation	Decreased counts of white cell populations; increased white cell plasma enzymes (e.g., neutrophil elastase); expression of activation markers (by FACS)
Coagulation factors	Consumption[b]	Reduced plasma fibrinogen or other coagulation factors
	Thrombin generation	Increased plasma levels of prothrombin fragment 1.2 and thrombin:antithrombin III complex.
	Fibrin formation	Increased plasma level of fibrinopeptide A.
	Dysfunction[b]	Prolonged plasma clotting times.
Fibrinolytic proteins	Consumption[b]	Reduced plasma plasminogen level.
	Plasmin generation	Increased plasma level of plasmin:antiplasmin complex.
	Fibrinolysis	Increased plasma level of fibrin D-dimer fragment.
Complement proteins[b]	Activation	Increased plasma levels of complement proteins C3a, C3b, C5a, C5b-9.

FACS, Fluorescence-activated cell sorting.
[a]Monoclonal antibody-based assays for immunoassay kits or flow cytometry may not be available or applicable for detection of nonhuman proteins.
[b]Tests that may be particularly important with long-term and/or large surface area devices.

Devices that have relatively small surface areas and are exposed for short periods of time (hours to days) include catheters, guidewires, sensors, and some components of extracorporeal circuits. With these devices, the primary concern is the formation of significant thrombus that could interfere with device function, e.g., thrombus blocks the diffusion of an analyte to a sensor, occludes the blood vessel, embolizes spontaneously, or is stripped from the device surface when it is removed from the body (e.g., during catheter withdrawal through a vessel insertion site) producing occlusion of distal vessels and tissue ischemia. Devices exposed for short periods that have large surface areas (dialyzers) and complex circuitries (pump-oxygenators) may, in addition, produce: (1) a marked depletion of circulating blood cells and proteins (e.g., platelets and coagulation factors); (2) an immune/inflammatory response through activation of complement proteins and white cells; and (3) organ dysfunction mediated by hemodynamic, hematologic, and inflammatory reactions. Mechanical devices that are used for long periods of time (heart assist devices, extracorporeal membrane oxygenators) may produce profound systemic effects and organ dysfunction such that their use in humans remains challenging.

TABLE 2.3.5.4 Parameters Measured in the Assessment of Blood Interactions With Ventricular Assist Devices

Flow Assessment	Power consumption or torque generation by rotary pump, direct visualization (for some extracorporeal devices), ultrasound and fluorescent image tracking velocimetry
Coagulation	Prothrombin fragment F1.2, thrombin–antithrombin, clotting times
Embolism	Infarcts in end organs (e.g., kidneys, liver), neurologic symptoms, transcranial Doppler ultrasound, flow cytometric assays for the quantification of circulating platelet-containing microaggregates
Fibrinolysis	D-Dimer
Platelet Activation and Deposition	Platelet factor 4, beta thromboglobulin, flow cytometric detection of circulating platelet activation level and agonist responsiveness (e.g., p-selectin expression), platelet deposition (microscopy)
Complement	C3a, C5b-9
Leukocyte Activation	Flow cytometric detection of monocyte tissue factor expression, leukocyte–platelet microaggregates, leukocyte surface activation markers

With both long-term and short-term device applications, thrombus formation can be assessed directly and indirectly. Important indirect assessments include depletion from circulating blood of cells and proteins consumed in the process of thrombus formation, and the appearance in plasma of proteins generated in the process of thrombus formation (e.g., fibrinopeptide A, platelet factor 4) as well as the detection of circulating activated blood cells by flow cytometry (Snyder et al., 2002). For some common devices, thrombosis is inferred through an increase in torque (power consumption) for rotary blood pumps (Scandroglio et al., 2016), decreased gas transfer or increased pressure drop across hollow fiber membrane bundles of blood oxygenators (Kaesler et al., 2019), regurgitant flow by Doppler flow measurements in prosthetic valves, and hemolysis in devices where a high velocity blood flow path is being constricted by putative thrombus to elevate shear stress and damage erythrocytes. Direct assessment of blood flow rate, flow geometry, and extent of flow channel occlusion can in many cases be achieved using sophisticated methods, including angiography, ultrasound imaging, and magnetic resonance imaging. Devices that are removed from the circulation should be visually inspected at the macroscopic and microscopic levels to assess whether thrombus has formed at particular sites or on certain materials. Emboli in flowing blood may be detected using ultrasound-based techniques (e.g., in cerebral arteries by Wilhelm et al., 1999), although these methods are not used widely in preclinical device assessment because of their complexity and translation to some animal models where skull thickness creates challenges. Thrombus formation and rates of platelet destruction by both acutely placed and chronically implanted devices can be determined quantitatively by measurements of platelet lifespan and scintillation camera imaging of radioisotopically labeled blood elements (McIntire et al., 1985; Hanson et al., 1990; Snyder et al., 2002).

While it was noted earlier that there are techniques available to detect thromboemboli when they are being transported in the bloodstream during the implant period, it is much more common in preclinical testing to examine the animal at the conclusion of the study for evidence of thromboembolic damage. In accordance with Figs. 2.3.5.1 and 2.3.5.2, a device may have little to no thrombotic deposition, yet clear evidence of thromboembolism at distal sites can be found. With many devices, such as cardiac valves, some vascular grafts, and circulatory support devices, it is the phenomenon of thromboembolism that is responsible for much of the morbidity and mortality associated with device implantation. As a result, in vivo preclinical testing of these devices routinely involves the assessment of organs where thromboemboli may travel and cause tissue ischemia. A downstream organ that is readily assessed is the kidney,

where thromboembolism results in clear infarcts that can be measured and quantified.

Finally, it is important to emphasize that thrombosis occurs dynamically, such that thrombi continuously undergo processes of both formation and dissolution. Device failure and morbid events represent the imbalance of these processes. Older thrombi may also be reorganized considerably by the enzymatic and lytic mechanisms of white cells. Although thrombotic complications with most devices tend to occur early in the implant period, new thrombus growth may occur at later time points leading to a clinical event (occlusion or thromboembolic stroke) several weeks, months, or even years after implantation and an otherwise unremarkable implant period. While the initial consequences of surgical device placement include tissue injury, thrombosis due to tissue injury, and foreign-body reactions, the flow surface of long-term implants may become covered with a stable lining of cells (e.g., ingrowth of vascular wall endothelial and smooth muscle cells onto and into vascular grafts) or blood-derived materials (e.g., compacted fibrin). Certain reactions of blood elements (e.g., platelets, thrombin) may also stimulate the healing response. Ultimately, long-term devices, such as the small caliber graft, may fail due to excessive tissue ingrowth that could be largely unrelated to biomaterials properties or may be stimulated by the biomaterials.

We summarize this section on device testing by recognizing that many of the device applications just described, as well as laboratory and clinical methods for evaluating their biologic responses, will be unfamiliar to the bioengineer. However, it is important to appreciate that: (1) each device may elicit a unique set of blood responses, both short term and long term; (2) methods are available to assess systemic changes in the blood and host organism that indirectly reflect thrombus formation; and (3) localized thrombus formation can often be measured directly and quantitatively. Whenever possible, serial and dynamic studies should be performed to establish the time course of ongoing thrombus formation and dissolution. These measurements will ultimately predict device performance and allow for both better patient management strategies as well as the rational selection of biomaterials that will minimize adverse blood–device interactions.

Contemporary Concepts in BMI Evaluation

A general trend in the literature in recent years has been the increasing application of specific molecular detection technologies (e.g., monoclonal antibodies, peptides) to provide a more detailed and temporal interrogation of BMI. Two such applications, flow cytometry and targeted thrombus imaging, will be highlighted here and in three case studies.

The use of flow cytometry to analyze activation of blood elements can be an effective method of measuring blood cell reactions and isolating specific pools of cells that have or have not undergone reaction. The basic technology behind flow cytometry (sometimes called fluorescence-activated cell sorting, FACS) involves the laser separation of fluorescently labeled cells from a narrow flowing stream of cells. The fluorescently labeled cells can be diverted from the flow stream to another flow channel where they are counted and harvested, or the fluorescence and light scattering can simply be recorded for each cell to give a precise count of cells exhibiting defined ranges of certain characteristics. One of the earliest studies using flow cytometry for blood-compatibility studies showed that in contact with blood-activating synthetic materials, thrombotic membrane fragments called microparticles are released (Gemmell et al., 1995). Since that important study, flow cytometry has been widely used to look at the upregulation of platelet P-selectin (CD62P), a consequence of α-granule release, monocyte and neutrophil CD11b (Mac-1 receptor) upregulation (Gemmell, 2000), platelet activation by annexin V binding to the negative phospholipid found on activated platelets (Wagner et al., 2000), and a number of other markers relating to platelet activation, white cell activation, and platelet aggregate formation. The power of the flow cytometry method resides in its ability to pinpoint and count selected features in a large pool of cells that can be identified by a fluorescently labeled targeting molecule, such as a monoclonal antibody. The method is applicable to blood that has been contacted with synthetic materials in vitro or in vivo.

While flow cytometry allows interrogation of cells in the bulk phase, the power of labeled targeting molecules can also be leveraged in imaging methods to define regions of thrombotic deposition and the amount of deposition in complex medical device flow paths. On a microscale this can be done with perfusion channels compatible with direct observation of flow and thrombus growth dynamics (Nechipurenko et al., 2019). Using targeted imaging agents, the researcher may look for specific features in the thrombotic process such as fibrin or activated platelets. Such imaging techniques remain limited by expense when performing whole animal imaging or using monoclonal antibodies. In these cases, less expensive targeting agents such as peptides or naturally selective binding molecules (e.g., annexin V for activated platelets) are employed.

Examples of BMI Evaluation

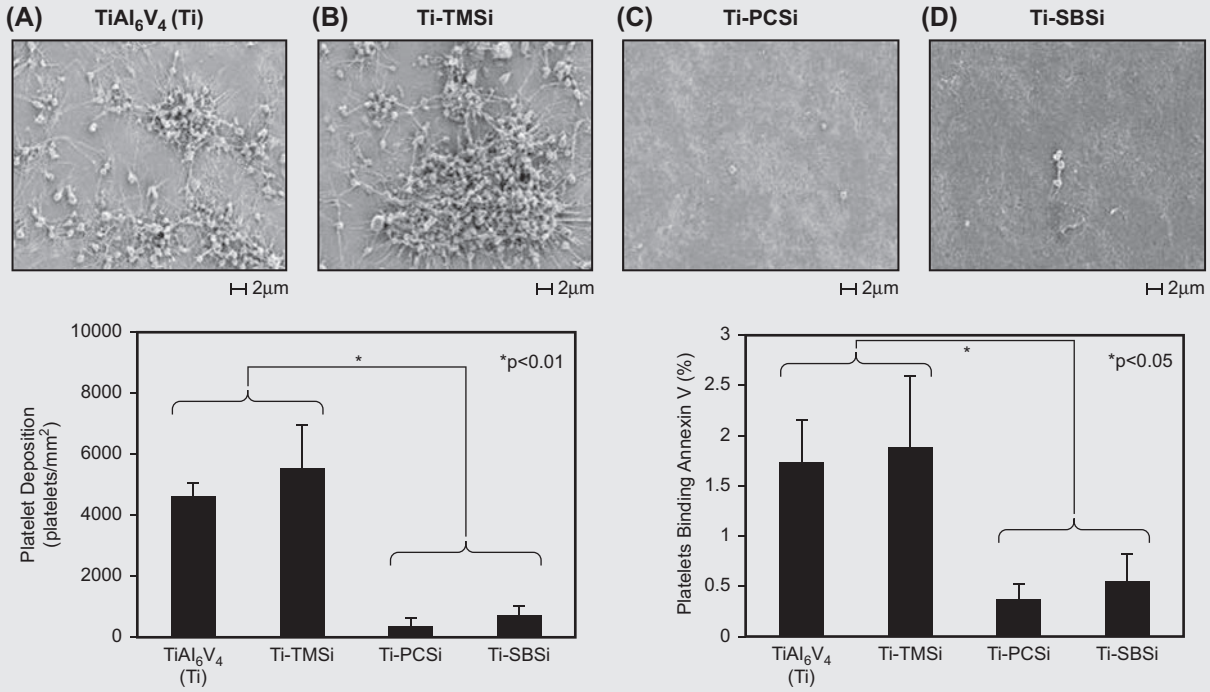
Three case studies will now be presented that place many of the concepts discussed to this point in the context of real-world BMI testing, moving from a well-defined in vitro test system to more complex in vivo testing with a blood-contacting device and targeted imaging applied to devices following clinical use.

CASE STUDY I

Platelet Deposition and Platelet Activation Measured in Vitro (Ye et al., 2010)

Despite the limits of short-term blood contact studies in vitro, such studies can have value as a first-level assessment of relative thrombogenicity and, particularly, to assess if a surface modification is exhibiting a hypothesized reduction in platelet deposition and bulk-phase activation. Such results can then justify progression to more expensive in vivo testing. Fig. 2.3.5.7 shows results from an acute blood contact study of Ti6Al4V (Ti) alloy surfaces with and without zwitterionic surface modifications. This alloy is a commonly used metal in blood contacting devices where high strength and stiffness are required (e.g., blood pumps). For a broader discussion of zwitterionic surface modification, see Chapter 1.4.3A. The surfaces studied were cleaned and oxidized Ti6Al4V (Ti) alloy, trimethoxysilane modified alloy (Ti-TMSi, a non-zwitterionic control) and alloy with one of two types of covalently attached zwitterionic silanating modifiers based on phosphorylcholine (Ti-PCSi) or sulfobetaine (Ti-SBSi).

Heparin-anticoagulated ovine blood was contacted with test surfaces under rocking for 2 h after which platelet deposition was measured quantitatively using a lactate dehydrogenase assay, and deposited platelet morphology was observed with scanning electron microscopy. Activation of platelets that were not deposited on the surface but were present in the bulk phase of contacting blood was measured using flow cytometry with fluorescent annexin V binding. This protein adheres to platelets that have activated and are expressing a membrane surface supportive of coagulation reactions. In Fig. 2.3.5.7, one can see formed platelet aggregates on the surfaces without the zwitterionic modification and these platelets have the classic appearance of activation with numerous extended pseudopodia. Few platelets are seen on the zwitterionic-modified surfaces. The quantified platelet deposition supports the visual results. Flow cytometry results showed that platelets not deposited on the surfaces were also less activated with the zwitterionic surfaces. Not shown in the figure are results that found lower levels of fibrinogen adsorption from a pure protein solution with the zwitterionic materials. The study provides an example of an in vitro evaluation combining assessments of platelet deposition and flow cytometric measurements of platelet activation.



• **Figure 2.3.5.7** (Top) Scanning electron micrographs of (A) TiAl6V4 (Ti), (B) Ti-TMSi, (C) Ti–PCSi, and (D) Ti–SBSi surfaces after contact with fresh, heparinized ovine blood under mixing for 2 h at 37°C. The right two surfaces have been modified with zwitterionic molecules. Note the platelet aggregates and individual platelets with extended pseudopodia indicating activation on the nonzwitterionic surfaces. (Bottom left) Platelet deposition on the same surfaces quantified with a lactate dehydrogenase assay. (Bottom right) Platelet activation in the bulk phase of blood contacted with the surfaces where fewer activated platelets are seen after zwitterionic surface contact. (From Ye, S.H., Johnson, C.A. Jr, Woolley, J.R., Murata, H., Gamble, L.J., Ishihara, K., Wagner, W.R., 2010. Simple surface modification of a titanium alloy with silanated zwitterionic phosphorylcholine or sulfobetaine modifiers to reduce thrombogenicity. Colloids Surf. B Biointerfaces. 79 (2), 357–364.)

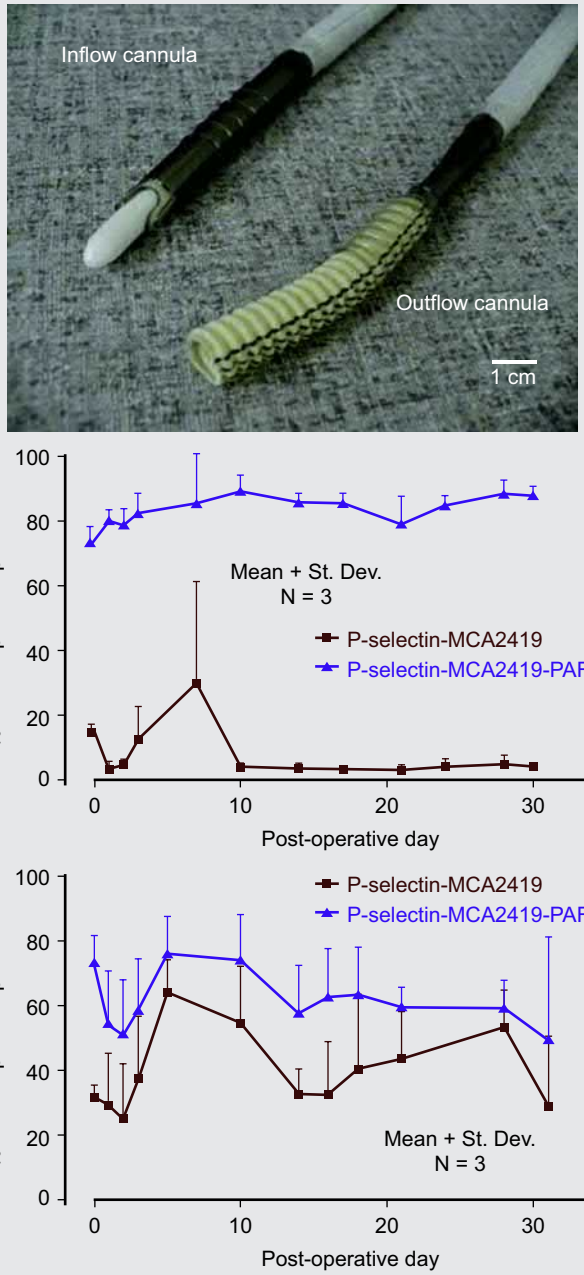
Device Thrombogenicity With Circulating Activated Platelets, Platelet Responsiveness, and Thromboembolic Effects Measured (Johnson et al., 2011)

One of the attractive features of using flow cytometric techniques to assess platelet activation is that it allows the researcher to monitor the status of circulating platelets over the course of a device implant directly, as opposed to only evaluating thrombotic effects at the time of device recovery. As an example of this technique, Johnson et al. (2011) evaluated an extracorporeal, magnetically levitated pediatric circulatory support device and specifically compared different candidate cannula designs. The cannulae are conduits that are placed within the vasculature to serve as inlet and outlet blood paths for this rotary blood pump (Fig. 2.3.5.8). Using an ovine model, the device was connected and functioned for a 30-day period. During the support period, blood was collected and flow cytometry applied to measure CD62P expression on platelet membranes. CD62P, also called p-selectin, is found in the α-granules of platelets. Upon platelet activation the granule fuses with the outer membrane and the CD62P can be detected with an antibody (in this study the antibody is MCA-2419, which cross-reacts with human and sheep CD62P). Flow cytometry is used to determine the percent of platelets that are above a background threshold level of antibody binding. Separate aliquots of the collected blood were stimulated with a potent platelet agonist, platelet-activating factor (PAF), to measure whether the circulating platelet population was responsive or had reduced responsiveness due to ongoing damage from the device. For a less thrombogenic device, one would expect to see low levels of circulating activated platelets, but high levels of platelet activation following PAF stimulation. For a thrombogenic device, higher levels of activated platelets would be observed and the response to PAF would be muted.

In Fig. 2.3.5.8 the temporal results for unstimulated and PAF-stimulated blood are shown for two groups of sheep that had two different cannula designs. At the time of study completion, the kidneys were assessed for infarcts (attributable to thromboembolism) and the device surfaces were assessed for obvious thrombotic deposition. With one type of cannulae (top Fig. 2.3.5.8) platelet activation rose early in the implant period, but then returned to low levels. The relative elevation of the preoperative blood sample at day 0 is attributable to its collection by venipuncture versus latter blood collection through indwelling lines after the implant surgery. Platelet responsiveness to PAF was high throughout the implant period, no thrombi were found on the devices, and few (<4) or no infarcts were found in the kidneys.

In contrast, the second cohort of sheep (bottom Fig. 2.3.5.8), which represented a subset of animals receiving a different cannula design, had a different course of platelet activation. The unstimulated, circulating activated platelet levels were elevated throughout the implant period. Stimulation with PAF showed responsiveness, but the levels attainable were reduced and the gap between unstimulated and stimulated was narrowed versus the other animal group. Furthermore, thrombus deposition was found in the cannula of one animal and all animals had >4 kidney infarcts.

In interpreting these data, the caveats noted earlier in this chapter regarding differences between animal and human blood apply. Also, this device was being developed for the pediatric population, where unique differences exist between human adult and neonatal/pediatric hemostatic systems. Furthermore, the number of animals is low (a common economic constraint), limiting statistical power. However, one can see that such results could provide guidance regarding the selection of a cannula design to consider advancing to subsequent preclinical testing and development based on blood biocompatibility assessed with these methods.



• **Figure 2.3.5.8** (Top) Example of inflow and outflow cannulae that connect the vasculature to a pediatric blood pump. (Middle) Circulating activated platelets reflected in CD62P expression with (platelet activating factor, PAF) or without agonist stimulation during a 30-day implant period in ovine model. In this animal group the postoperative course was not remarkable, few infarcts were found in the kidneys, and there was no gross thrombus on the device. Circulating activated platelet levels were low and platelets responded strongly to PAF. (Bottom) With a different cannula design, a subset of sheep had higher levels of circulating activated platelets and less responsiveness to PAF. At explant, one animal had device thrombus and all animals had >4 kidney infarcts. (From Johnson et al., 2011.)

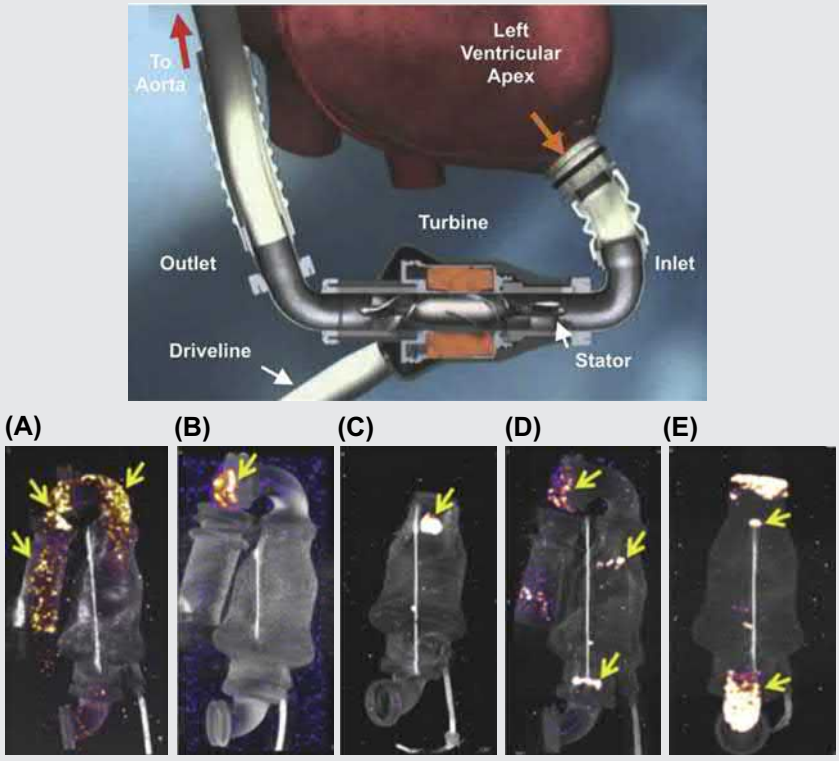
Imaging Thrombotic Deposition in a Complex Device (Cui et al., 2018)

For many blood-contacting devices, thrombotic deposition can be detected and assessed with ultrasound and angiography. These techniques are commonly applied with vascular grafts and prosthetic valves and are utilized in the diagnosis and management of clinical thrombosis. There are also several secondary measures well correlated with thrombotic deposition that can trigger diagnostic imaging or intervention. For oxygenators, the pressure drop across the fiber bundle is such a critical measurement. For rotary blood pumps, power consumption, flow rates, and hemolysis are used clinically with increasing sophistication to assess and address risks to the patient (Scandroglio et al., 2016). In cardiovascular device development these same techniques are employed as surrogates for more direct measurements in animal models during the implant period.

For both clinical and preclinical assessment of device thrombogenicity it would be useful to be able to utilize targeted imaging, where the imaging agent binds specifically to a given marker, such as an activated platelet or fibrin. It would also be desirable if this imaging could be done in regions where simpler imaging methods are not feasible. For example, within and near metallic blood pumps, ultrasound imaging is not possible. Cui et al. (2018) developed a high-avidity fibrin imaging probe incorporating the radiolabel ^{99m}Tc for gamma imaging and using a fibrin-binding peptide sequence as a tetramer. The probe (^{99m}Tc-F4A) was shown to be capable of binding to aged thrombi under high shear and in the presence of anticoagulation. All of these factors have historically been challenging for thrombus-targeted probes. Furthermore, with this imaging modality, the attenuation from the metal pump housing was minor and did not preclude high sensitivity and quantitative image collection.

The probe was used to evaluate thrombus deposition in a commonly applied rotary blood pump (Fig. 2.3.5.9) in a series of patients who had their pumps removed either for heart transplantation or pump exchange. The imaging results in Fig. 2.3.5.9 show areas of fibrin deposition that vary for the different cases. All patients except that for image C had evidence of pump thrombosis at some point during the implantation period by hemolysis or ischemic stroke. In images C, D, and E the areas of the inlet and outlet bearings for the pump have fibrin deposition (yellow arrows). This has been a common risk area for thrombosis in this device.

While this experiment was done on explanted pumps, the probe may be expected to be compatible with future preclinical and clinical studies. Such imaging can help to better map regions at elevated risk (and potentially confirm future predictive models as in Fig. 2.3.5.5 or justify specific design changes) and also be used to better manage individual patient thrombotic risk by guiding anticoagulation management or indicating a need for device exchange. It is important to point out that when devices enter the clinic, the need for thrombogenicity assessment continues. While device design changes at this stage are expensive and time consuming, it is at the clinical stage where all of the caveats noted in this chapter about the limits of in vitro and preclinical testing come to bear impact. By following devices from preclinical through clinical testing, the design engineer gains important insight where in vitro and in vivo testing provided useful guidance or a false sense of security regarding blood biocompatibility.



• **Figure 2.3.5.9** (Top) Schematic for a clinically utilized axial flow ventricular assist device, the HeartMate II. Note the architecture that is reproduced in explanted devices imaged in parts A-–E in the lower section of the figure. (Bottom, A–E) Targeted imaging of fibrin with ^{99m}TC-F4A from five explanted devices after clinical support. The arrows indicate areas of distinct fibrin-rich thrombi. For A and B, deposition is primarily in the inflow region of the device, prior to the rotor. In C, D, and E the bearing areas at the front and back of the rotor are noted regions of fibrin deposition. (From Cui, G., Akers, W.J., Scott, M.J., Nassif, M., Allen, J.S., Schmieder, A.H., Paranandi, K.S., Itoh, A., Beyder, D.D., Achilefu, S., Ewald, G.A., Lanza, G.M., 2018. Diagnosis of LVAD thrombus using a high-avidity fibrin-specific 99mTc probe. Theranostics 8 (4), 1168–1179.)

What Materials Are Blood Compatible?

The biomaterials community still awaits clear guidelines as to which materials are blood compatible. But, from the perspective of one author of this chapter (Ratner), here are a few guidelines that you might use. First, the important distinction must be made that materials will perform differently in low wall shear rate blood flow (venous flow or static blood) and high wall shear rate blood flow (arterial flow). For low wall shear rate materials, heparinized surfaces are often good (although their period of performance may be limited), and hydrogels seem good. Excellent nonfouling surfaces are also promising (see Chapter 1.4.3). For arterial blood flows, highly hydrophobic materials often show promise (silicones, fluoropolymers, and materials with surface-localized, long *n*-alkyl chains). Also, the exceptional nonfouling materials seem promising—these include good-quality poly(ethylene glycol) surfaces, phosphatidyl choline-based surfaces, sulfobetaines, and carboxybetaines (see Chapter 1.4.3). In all cases, the choice of materials will be dictated by the nature of the flow(s) in the actual device in the bloodstream, the mechanical properties required, the length of time in contact with the blood, the use of anticoagulants and antiplatelet agents, and the consequences of embolization at the specific anatomical site. Trial-and-error optimization of suitable candidate materials may be needed to achieve performance appropriate to the specific application.

Conclusions

The most blood-compatible material known is the natural, healthy, living lining of our blood vessels. This "material" functions well by a combination of appropriate surface chemistries, good blood flow characteristics, and active biochemical processes involving removal of prothrombotic substances and secretion of natural anticoagulants. It seems unlikely that we will ever match this performance in a synthetic material or device, although attempts to imitate aspects of the natural system represent a promising strategy for developing a new generation of blood-compatible devices (for example, see Chapters 1.4.3 and 2.2.6). At present, however, synthetic materials that perform less well than the vessel wall, but still satisfactorily, are needed. This chapter provided only a brief outline of the issues involved in evaluating materials and devices to find those that are minimally damaging or activating toward blood. The subject of blood-compatibility testing is complex, and advanced study of the subject is required before considering experiments intended to elucidate basic mechanisms or improve human health. Further discussion elaborating upon the complexity of the issues involved in BMI testing can be found in Ratner (1984, 1993a, 2000) and Gorbet et al. (2019). Detailed discussion on the characterization of materials for biomaterials application and on BMI testing can also be found in a publication coordinated by the Device and Technology Branch of the National Heart, Lung and Blood Institute, National Institues of Health (Harker et al., 1993). Also, see ISO standard 10993-4 (Biological evaluation of medical devices—Part 4: Selection of tests for interactions with blood). The importance of ISO standards is elaborated upon in Chapter 2.3.3.

A 2020 Google Scholar search of the term "blood compatibility" has yielded 8400 references since 2016. The majority of these studies compared biomaterials and then concluded one material was better than another. With such levels of effort exploring this subject, one might assume we would have sound knowledge of what are truly blood-compatible biomaterials. Such a knowledge is still incomplete. This chapter has provided a nuanced view of this subject and should help you the reader to better understand the numerous complexities in pronouncing a biomaterial or device as "blood compatible."

Introduction

The appropriate use of animal models in biomaterials research allows prospective, controlled evaluation of disease processes and candidate therapeutics in a manner that is impossible or unethical in human patients or volunteers. Investigators must consider scientific, practical, and humane issues when developing studies that use animals. High-quality research requires close collaboration between veterinary and research professionals to guide model selection and development, minimize animal pain and distress, and advance the scientific goals of the project. This chapter briefly reviews ethical and regulatory issues, describes available information resources, and discusses the design of surgical facilities, animal selection, anesthesia, and analgesia.

Ethical and Regulatory Overview

Investigators and research institutions have an ethical and legal responsibility to consider animal welfare concerns in research using animals. Russell and Burch expressed the most widely understood ethical principles governing humane design of experiments using animals, summarized in the concept of the "three Rs": replacement, reduction, and refinement (Russell and Burch, 1959).

The first principle, replacement, states that nonanimal models should be used instead of animals to the maximum extent possible. While regulatory agencies require in vivo animal model testing for safety and efficacy of new drugs and devices, in vitro and ex vivo biocompatibility and efficacy screening methods are increasingly common in biomedical research, including the use of "organ on chips" allowing for the study of molecular- and cellular-scale activities in specific human tissues (Fujibayashi et al., 2003; James Kirkpatrick et al., 2007; Pariente et al., 2000; Zhang et al., 2018). These techniques reduce the total number of animals used and allow significant savings in time and resources compared to experimental animal models.

The principle of reduction states that investigators should use the minimum number of animals to allow statistically valid inferences to be drawn from the data. In this context, it is as important to avoid using too few animals as it is too many. Important considerations in determining the statistical power of an animal experiment include inherent variability of the model and expected efficacy of the test therapeutic (Bate and Clark, 2014; Fitts, 2011; Parker and Browne, 2014). Consultation with a biostatistician should be conducted prior to starting animal studies.

Regulatory agencies and institutional review committees require justification of the numbers of animals used in an experiment (National Research Council, 2011; US Congress, 1985a; Silverman et al., 2014). Suggested strategies to reduce animal usage include "(1) rational selection of group size (pilot study, power analysis); (2) careful experimental design; (3) maximizing the use of each animal; (4) minimizing loss of animals; and (5) statistical analysis (maximum information from minimum number of animals)" (Fitts, 2011).

The most important of the "three Rs" is the principle of refinement, which states that investigators should use the least invasive and most modern techniques possible to minimize animal pain and distress (Orlans et al., 1996). Continuous refinement and improvement in animal husbandry and the diagnosis and control of infectious disease has greatly reduced nonexperimental morbidity and mortality in modern research facilities. Surgical models in particular have benefited from advances in veterinary anesthesia, instrumentation (e.g., laparoscopic procedures), and monitoring, which have allowed further reduction and refinement of research animal use.

Governmental Regulations

Widespread acceptance of the "three Rs" and continued public scrutiny of biomedical research oblige investigators and institutions to comply with strict regulatory standards

governing all aspects of research animal use. In the United States, the United States Department of Agriculture (USDA), the Public Health Service (PHS), and the Food and Drug Administration (FDA) are the primary agencies that regulate animal research.

United States Department of Agriculture

The specific focus of animal welfare regulations varies by agency. Well-publicized incidents (Phinizy, 1965; Wayman, 1966) of pet theft and their subsequent mistreatment in research laboratories prompted the US Congress to enact the Animal Welfare Act (AWA) in 1966 (Congress, 2013). The AWA regulates all warm-blooded animals, with some exceptions, such as rats, mice, or birds bred for research. The Animal Welfare Act Regulations (AWAR) are the interpretation of the federal AWA law and contain enforceable standards. In many institutions, the term "regulated species" refers to animals subject to the AWA (e.g., guinea pigs, rabbits, pigs, sheep, nonhuman primates). The USDA enforces the AWA through the Animal and Plant Health Inspection Service. Registered facilities file annual reports of animal usage with the USDA and are subject to unannounced inspection.

Public Health Service

The PHS, through the National Institutes of Health (NIH), is the largest single sponsor of biomedical research using animals and has adopted regulations to ensure humane and scientifically valid use of animals. The Health Research Extension Act of 1985 provides the legislative mandate for the Public Health Service Policy on Human Care and Use of Laboratory Animals (US Congress, 1985b, 1985a). The NIH Office of Laboratory Animal Welfare (OLAW) develops and implements standards for animal care and use at recipient institutions, as described in the Guide for the Care and Use of Laboratory Animals, commonly referred to as "The Guide" (National Research Council, 2011). Institutions receiving PHS support (e.g., funding from the NIH, FDA) must file an "Animal Welfare Assurance" with OLAW indicating sufficient institutional resources to provide proper husbandry and veterinary care. Institutions must also indicate how they will approve and monitor research to ensure scientific integrity and prevent inhumane treatment of animals. Assurances are approved for 5 years, after which a new application must be submitted. The PHS Policy applies to all vertebrate animals, including those not regulated by the AWA (US Congress, 1985a).

Food and Drug Administration

In the United States, the development of new drugs and devices must undergo a rigorous oversight process. The US Federal Food, Drug and Cosmetic Act, initially passed in 1938, authorizes the FDA to oversee the safety of food, drugs, medical devices, and cosmetics. In 1987, passage of the Good Laboratory Practices (GLP) Act (21 CFR 58.90) required the FDA to regulate preclinical research conducted in direct support of new drugs or medical devices (US Congress, 1987). The GLP regulations ensure reproducibility and integrity of data used to support new drug or device applications. These regulations include minimum basic requirements for study conduct, personnel, facilities, equipment, written protocols, operating procedures, study reports, and the system of quality assurance oversight for each study. The GLP regulations govern nonclinical studies, including controlled in vivo and in vitro experiments to evaluate the safety of test articles (e.g., new drug or device) in validated animal and laboratory test systems (US Congress, 1987). These studies do not include clinical or field studies with human or animal subjects or basic exploratory studies.

The FDA approval process differs for drugs and devices. Clinical testing of a new drug in humans requires FDA approval of an Investigational New Drug (IND) application. The IND application contains data from nonclinical/preclinical laboratory studies, including toxicity testing, pharmacology, and pharmacodynamic studies. Nonclinical studies must include data from more than one species, typically one rodent and one nonrodent (e.g., rabbits, dogs, nonhuman primates) (21 USC, Section 314 and 316) (US Congress, 2019). Testing of the new drug in human volunteers and patients occurs only after approval of the IND and if successful is followed by submission of a New Drug Application (NDA) to request FDA approval of the new pharmaceutical for sale or marketing in the United States. The NDA includes data from preclinical studies and clinical Phase I, Phase II, and Phase III trials.

The approval process for new medical devices differs significantly from that for new drugs (US Congress, 2019). The FDA classifies medical devices by a risk-based system, with higher classes receiving increased regulatory control. Class I devices pose the least risk to consumers (e.g., oxygen masks, surgical tools) and require only the use of good manufacturing practices. Class II devices (e.g., wheelchairs, some pregnancy tests) pose more risk to consumers than Class I and require specific testing to assure safety and performance. Class III devices support or sustain life, are implanted in the body, or have the potential for significant risk of illness or injury (e.g., pacemakers, implanted defibrillators, heart devices) if defective or improperly used. Some implanted devices, e.g. orthopedic fracture fixation devices and joint replacement devices, are sometimes determined by the FDA to be classified as Class II. Class III devices require premarket application (PMA) approval to provide scientific evidence that the benefits to human health outweigh risks and that the device will significantly help a large portion of the target population.

Sponsors submit one of three types of applications for new medical devices. Class III devices require PMA approval unless they are similar to current marketed devices. The PMA must contain nonclinical GLP study results. The less-restrictive premarket notification or 501(k) requirement applies to Class I and Class II devices as well as to Class III devices similar to others on the market. Lastly, devices can be submitted under humanitarian device exemption where devices are used to treat or diagnosis a disease or condition that affects fewer than 4000 people (21 USC Part 314)

(US Congress, 2019). Additional information on medical device development and regulatory concerns can be found in Part 3 of this book.

Institutional Responsibilities

Productive and humane research animal care and use requires close coordination and support from multiple institutional entities. The three key components of the program are the Institutional Animal Care and Use Committee (IACUC), the attending veterinarian (AV), and the principal investigator (PI). The separate and interrelated roles of these entities are legally defined and described next.

Institutional Animal Care and Use Committee

The AWAR and the PHS Policy assign primary responsibility for an animal research program to the IACUC (US Congress, 2013, 1985b). The regulations require a minimum of three (AWAR) or five (PHS) members and must minimally include a veterinarian, a scientist, a nonscientist, and an unaffiliated member. The IACUC reviews and approves in advance all animal research protocols to ensure compliance with the relevant regulatory requirements. In addition, the IACUC regularly inspects the animal research facility, reviews the animal care and use program, designs and implements institutional policies, and investigates allegations of animal mistreatment.

Attending Veterinarian

The AV must have training/experience in the care and management of species used at the institution and has direct or delegated authority for animal activities at the facility (National Research Council, 2011; US Congress, 2013). Veterinarians offer important expertise to investigators using animals. Laboratory animal medicine is a subspecialty of veterinary medicine that involves additional training and acquisition of skills in the diagnosis and treatment of laboratory animal diseases, development of new experimental techniques, and provision of specialized preoperative, intraoperative, and postoperative care. Most large research institutions have at least one staff veterinarian trained and experienced in laboratory animal medicine. Smaller institutions may use consultant veterinarians. Other veterinary specialties of potential value in a biomaterials research program include surgery, anesthesia, pathology, and internal medicine.

Principal Investigator

The PI is responsible for proposing, designing, conducting, and/or implementing research involving animals. The PI must obtain advanced approval for all research procedures and assure proper training, oversight, and safety of laboratory members in the conduct of these studies. These study details are typically contained in the IACUC protocol. The PI must assure the IACUC that (1) procedures causing discomfort, distress, and pain are minimized, (2) alternatives to procedures that may cause pain or distress have been considered, (3) activities do not unnecessarily duplicate previous experiments, (4) procedures causing pain and distress will be alleviated with sedatives, analgesics, or anesthetics, except when they must be omitted for scientific reasons, (5) personnel conducting procedures are adequately trained, (6) no animal will undergo more than one major operative procedure without scientific justification, and (7) a veterinarian is consulted in the generation of the animal care protocol (National Research Council, 2011; US Congress, 2013).

Surgical Facility Design

Minimum functional components of the survival surgery suite include dedicated areas for surgery, animal preparation, surgeon's scrub, postoperative recovery, and surgical support. In the United States, federal regulations require the use of dedicated surgical suites for major survival surgery on USDA-regulated species other than rats, mice, and birds. Surgical suites must allow aseptic surgery, animal preparation, and surgeon scrub to occur in separate dedicated rooms, arranged to facilitate entry and exit of animals and staff and minimize unnecessary traffic. Animal recovery may occur in the same room as anesthesia induction and preparation. Institutions receiving federal funding (e.g., NIH) may permit rodent survival surgery in any procedure space provided necessary conditions for asepsis are present (National Research Council, 1980).

Many research institutions maintain centralized experimental surgery suites to maximize economies of scale and efficient use of equipment and skilled support staff. Support spaces in large surgical suites may be configured to allow two or more operating rooms to run simultaneously from shared animal and surgeon preparation rooms. Specialized facilities may be appropriate to accommodate unique experimental requirements such as imaging, cardiopulmonary bypass, specimen preparation, or postoperative intensive care and monitoring. Principles of research animal operating room design have been described (Hessler and Lehner, 2009; National Research Council, 1980).

Other functional areas commonly required in, at, or near the experimental surgery suite are: a pharmacy, including secure controlled substance storage; instrument cleaning and sterilization; and record keeping. Secure data collection and storage require network connections, and possibly other information technology capabilities. Radiography and other imaging modalities are often necessary in experimental surgical studies and may be conveniently located within or adjacent to the surgery suite.

Model Selection

A wide variety of animal models are used in biomedical research. Nonanimal models are an integral part of drug and device development, and include in vitro systems, computer simulations, and mathematical models. By definition,

a model serves as a surrogate and is rarely identical to the subject being modeled. Desired features of an animal model include (National Research Council, 1998):

1. The model is appropriate for its intended use, in that the specific disease model faithfully mimics the human disease AND/OR the model system is appropriate for the human system being modeled.
2. The model can be developed, maintained, and provided at reasonable cost in relation to the perceived or potential scientific values that will accrue from it.
3. The model is of value for more than one limited kind of research.
4. The model is reproducible and reliable, so results can be confirmed.
5. The model is reasonably available and accessible.

The essential characteristic of a useful animal model is that it has been validated through a formal, hypothesis-driven process to determine that significant similarities exist between the model and what is being modeled (Shapiro, 1998). For this reason, choice of the proper animal model is critical to successful development of novel technologies and scientific discoveries.

Cardiovascular Devices

Virtually all traditional research species have been used in cardiovascular research, including zebrafish, mice, rats, rabbits, dogs, sheep, pigs, and nonhuman primates. Each species differs in its specific advantages and disadvantages, including size, cost, ability to use genetic engineering, and similarity to human anatomy and physiology. However, due to similarity to humans, swine and sheep models are more commonly used for the testing of biomedical devices and cardiovascular tissue engineering.

Heart Valve Replacement

Heart valve repair historically has focused on replacing the defective or diseased heart valve with a mechanical or animal tissue-derived artificial valve. Valve repair via tissue engineering has been an active area of research but has not been clinically realized yet (Cheung et al., 2015; Kheradvar et al., 2015; Rashid et al., 2004; Sodian et al., 2000a,b; Stassen et al., 2017; Vesely, 2005). Research behind heart valve devices and replacements is covered in Section 2.5 of this book. Pigs, sheep, and dogs are typically used for preclinical safety and efficacy studies of novel prosthetic heart valves. The benefits to using these species include similarities in size, anatomy, and physiology of the heart. However, differences between pigs, sheep, and dogs must be considered when choosing an animal model. The following sections provide a brief overview of these animal models. For animal models of spontaneous and induced heart valve disease, readers are encouraged to review Kheradvar et al. (2017).

Swine heart valves are remarkably similar to those of humans with respect to mitral valve size, leaflets, and chordae tendinea configuration (Crick et al., 1998; Lelovas et al., 2014). The tricuspid valve of pigs has three leaflets, unlike the two leaflets of dogs (Evans and de LaHunta, 2010; Lelovas et al., 2014). The semilunar (aortic and pulmonary) valves of pigs also share significant similarities to those of humans. As with humans and unlike sheep and calves, pigs have a fibrous attachment to the noncoronary cusp of the aortic valve (Sands et al., 1969), although the fibrous continuity between mitral and aortic valve leaflets is less pronounced in humans (Crick et al., 1998; Lelovas et al., 2014). However, the relative geometry and size of the three aortic valve cusps to each other differ between pigs and humans (Sim et al., 2003).

The use of pigs in implantable heart or intravascular devices research requires careful consideration of the study goals and duration, as the growth of the cardiovascular system is rapid and substantial in many breeds of pigs, especially those bred for meat production (e.g., Yorkshire, Landrace). The growth of the swine heart from birth to sexual maturity at 4.5 months of age is analogous to the growth of the human heart from birth to mid-teenage years (Swindle et al., 2013). Therefore the use of animals whose adult body size is comparable to humans, like miniature pigs or sheep, is preferable for nonacute implantable cardiovascular device studies (Kheradvar et al., 2017). For example, one study demonstrates relatively long-term survival (20 weeks) of Bama miniature pigs implanted with prosthetic heart valves (Li et al., 2007).

Another challenge to the use of pigs in cardiac studies includes the sensitivity of the heart to anesthesia and surgical manipulation, which can cause intraoperative and postsurgical complications, including arrythmia and death (Kheradvar et al., 2017; Swindle and Smith, 2016). In addition, maintaining safe levels of the anticoagulant warfarin is challenging in swine mechanical heart studies as warfarin is associated with a high incidence of hemorrhagic complications (Grehan et al., 2000).

Given that pigs are unable to reliably maintain chronic implants, sheep are the accepted gold standard model for regulatory and investigative valve replacement studies (Ahlberg et al., 2013; Gallegos et al., 2005; Kheradvar et al., 2017). The size and anatomy of heart valves and valve orifices of adult sheep are similar to those of humans (DiVincenti et al., 2014; Sands et al., 1969). Standardization requires the use of animals of similar age and weight. The relatively large left and right atria of the sheep facilitate the surgical approach to the valves. In addition, normal cardiovascular physiological parameters of sheep approximate normal human values for blood pressure, heart rate, cardiac output, and intracardiac pressure (Barnhart et al., 1982; Gallegos et al., 2005).

Historically, dogs were common in cardiac valve research due to their slow growth, cooperative temperament, and similarity to human cardiac anatomy and adult body size. Imaging and cardiac monitoring are also simpler in dogs compared to pigs and sheep. However, dog tricuspid valves have two leaflets, as opposed to three in humans, pigs, and sheep (Evans and de LaHunta, 2010). In addition, dogs exhibit variability in the number and position of papillary

muscles (Ahlberg et al., 2013; Kheradvar et al., 2017). These factors and public sensitivity to the use of dogs in biomedical research have reduced the use of this model for cardiac valve research and development.

Ventricular Assist Devices

For patients in end-stage heart failure or suffering from acute myocardial infarction, ventricular assist devices (VADs) are a useful bridge-to-transplant therapy when donor hearts for transplantation are unavailable. Recent advances have expanded the role of VADs to provide long-term, chronic support (Monreal et al., 2014). The VAD is a blood pump system designed to palliate severe congestive heart failure and is composed of inflow and outflow cannulae, connectors, and controllers.

VAD technology has been advanced by a variety of animal models. Preclinical testing of VADs typically uses healthy large animals. However, the human recipients of VADs are almost always in end-stage heart failure, making the healthy animal an imperfect model. There are multiple experimental models of heart failure. Sustained rapid pacing produces severe biventricular systolic dysfunction (Shinbane et al., 1997). Myocardial infarction can be performed in a minimally invasive manner by catheter-induced coronary embolization or by coronary artery ligation via thoracotomy (reviewed in Monreal et al., 2014). Additional large animal models of heart failure are reviewed in Dixon and Spinale (2009), Gallegos et al. (2005), and Chapter 10 in Gross (2009).

The calf (juvenile cow or bull) is the most commonly used VAD model (Litwak et al., 2008). Calves are used to study the function, biocompatibility, and efficacy of VAD. The bovine blood-contacting surfaces are procoagulant and activate blood clotting, therefore a device that resists thrombosis in a calf model will reduce the possibility of adverse events in human trials. The calf model also allows simulation of common clinical complications such as thrombosis, obstructions, or kinks, and mechanical, electrical, or software failures. The large thoracic cavity and large peripheral vessels facilitate vascular access and further contribute to the value of the calf model. Four- to six-month-old calves (70–100 kg) model average human body size. Much like swine, calves grow rapidly to a size not suited to long-term studies (Monreal et al., 2014).

Sheep are also common in VAD research. Sheep do not have a significant coronary collateral network, and in this respect are similar to humans and pigs (DiVincenti et al., 2014; Schaper et al., 1972). This characteristic makes sheep useful as a model in myocardial infarction. However, unlike right-side dominant humans and pigs, sheep hearts receive blood from the left coronary artery (DiVincenti et al., 2014). Adult sheep are compatible in body size and temperament for long-term studies.

Orthopedic Devices

Orthopedic devices and implants are very diverse, including wires, pins, screws, plates, spinal fixation devices, internal and external fixation, bone grafts, and joint replacements. These devices treat a variety of orthopedic injuries and diseases, including fractures, bone loss, and immune-related or degenerative joint conditions. Virtually every major laboratory animal species has been used in orthopedic research, including zebrafish, mice, rats, rabbits, guinea pigs, goats, sheep, dogs, cats, pigs, and horses. Dogs, sheep, and pigs are the most commonly used models for preclinical testing.

Animal model choice must weigh several factors, including, but not limited to, the nature of the device/implant, study timeline, species-specific bone characteristics (microstructure, bone composition, bone modeling/remodeling characteristics, etc.), animal size, and regulatory requirements (Pearce et al., 2007). Scientists interested in reviewing the bone differences between species and the appropriateness of common disease models should consult Nunamaker (1998), Pearce et al. (2007), Li et al. (2015), and Wancket (2015).

However, some innate characteristics of animals pose challenges in translating orthopedic animal studies to humans. All mammalian research animals except nonhuman primates are quadrupeds. The resulting differences in weight bearing and mechanical load on the musculoskeletal system will alter the load that orthopedic devices and implants experience, as compared to humans. In addition, the inability to control weight bearing and joint motion postoperatively pose additional challenges (Rodeo, 2017). For example, sheep and dogs that undergo rotator cuff repair will uniformly retear in the early postoperative period unlike humans undergoing the same procedure (Derwin et al., 2007, 2018; Rodeo et al., 2007).

Bone Defect Models

Bone grafts are one of the most commonly used surgical methods to augment bone regeneration. There are four common induced bone defect animal models: calvarial defect, long bone or segmental defect, partial cortical defect, and cancellous bone defect (reviewed in Bigham-Sadegh and Oryan, 2015; McGovern et al., 2018). Important in all bone defect animal models is the size of the defect.

An important but controversial concept in bone defect research is that of the "critical size defect." The purpose of the critical size defect is to create a reliable, repeatable, and translatable model that represents a "stringent test of a material's ability to induce or augment bone growth." ASTM International (2014), an organization that develops recognized standard consensuses for preclinical testing, defines critical size defect "as the minimum defect dimension that the animal in incapable of repairing without intervention. The dimensions of critical defects generally differ for each species and should be considered carefully when designing the implant dimensions and method of fixation." The length of the defect should at least be equal to 1.5 times the diameter of the selected bone but may exceed 2.5 times this diameter (Gugala et al., 2007; Lindsey et al., 2006). The recommended critical size defect will vary based on species, strain, bone used, age, weight, and metabolic condition of

the animal (Bigham-Sadegh and Oryan, 2015; Lammens et al., 2017). Since the interaction of these variables is complex and the dimensions are often not reported in publications, some consider critical size defect models unreliable for translational studies (Cooper et al., 2010; Lammens et al., 2017; Reichert et al., 2009b).

The rat calvaria model is one of the most common preclinical bone defect models. After incising the skin, the surgeon uses a trephine to create a standardized full thickness circular bone defect between 5 and 8 mm in diameter, using saline irrigation to prevent thermal damage to surrounding bone (Cooper et al., 2010; Vajgel et al., 2014). Experimental tissue-engineered materials in scaffold are then applied to the bone defect (Bigham-Sadegh and Oryan, 2015; McGovern et al., 2018).

The sheep tibia is the most common model for segmental long bone defects (McGovern et al., 2018). Some of the advantages of using sheep include body size, bone dimensions, and healing characteristics similar to adult humans (Pearce et al., 2007; Reichert et al., 2009a; Wancket, 2015). In addition, the mechanical loading in sheep hind limbs is well documented and approximately half that in humans during the walking phase (Taylor et al., 2006). Reported sheep critical size defects range from 2 to 3 times the diameter of the bone (Christou et al., 2014; Gugala et al., 2007; Lammens et al., 2017; Lindsey et al., 2006). Sheep cortical bone is primarily plexiform through 7–9 years of age, unlike human cortical bone, which is lamellar (Wancket, 2015). In addition, during winter, sheep undergo seasonable bone loss, which may impact bone healing (Bonucci and Ballanti, 2014). Adult sheep trabecular bone tends to be stronger and more dense than human bone. Immature sheep, however, have weaker, low-density trabecular bone that is highly flexible (Nafei et al., 2000; Wancket, 2015).

Vascular

Animal models are used in vascular biomaterials research to investigate biocompatibility and strategies to increase resistance to stenosis and thrombosis. Considerations for animal model selection include size, availability, and specific biological requirements of the model, including size and accessibility of the vasculature. The regulatory requirements for preclinical assessment of synthetic vascular conduits have been described and require consideration of the diameter and length of the target vessel and intended clinical application (Byrom et al., 2010).

The unique biological characteristics of a particular species should guide model selection and interpretation (Byrom et al., 2010). In some cases, a more stringent model is indicated to provide a better margin for safety in translating results to the human clinical application. For example, pigs and dogs are relatively hypercoagulable compared to humans, so a vascular conduit resistant to thrombosis in these species may be more likely to resist thrombosis in humans. Of the common laboratory animal species, the coagulation systems of the rabbit and baboon coagulation systems are considered the most similar to humans (Byrom et al., 2010).

Large animal models in vascular biomaterials research include sheep, swine, dogs, and baboons (Ahmed et al., 2014; Brennan et al., 2008; Bhattacharya et al., 2000; Byrom et al., 2010). Small animal models include mice, rats, and rabbits. Swine are widely preferred for the development and assessment of intravascular stents, because of their size and the ability to assess devices in the setting of common human comorbid conditions such as atherosclerosis, which is easily induced in this species (Swindle et al., 2012). Rapidly growing animals such as juvenile sheep (Brennan et al., 2008) and swine (Robotin-Johnson et al., 1998) have been used to evaluate the ability of grafts to grow with the host. Aged sheep have been used to assess tolerability of vascular grafts in the senescent model (Ahmed et al., 2014).

Anesthetic and analgesic management of animals in these studies is comparable to other applications. Since thrombosis prevention by modification of the luminal surface or the use of drug-eluting grafts is often a key scientific goal of the study, supplemental antithrombotic drugs are not common. In other cases, antithrombotic medications such as aspirin are appropriate (Bélanger and Marois, 2000). Care is required to prevent prolonged ischemia when inserting interposition grafts to avoid neuromuscular damage and paralysis. Rabbits are relatively susceptible to this complication following abdominal aorta interposition grafts, whereas sheep are relatively resistant following common carotid artery grafts (Byrom et al., 2010).

Ophthalmology

Animal models serve an important role in the development of ocular biomaterials. The eye is sensitive to painful stimuli, prone to inflammation, and most procedures require specialized skill and instrumentation. Failure or infection of an implant may cause chronic pain or blindness. Therefore all implants must demonstrate biocompatibility and durability in an animal model before being applied to humans. Animal models allow the additional advantage of histologic assessment of implants for stability and biocompatibility.

The pig and rabbit are the most commonly used animal model species for ocular research. Both species are readily available and have globes of comparable size to humans. The rabbit eye is especially prone to inflammation, which may complicate experimental manipulation but provides an important indicator of biocompatibility. Although the large size of the rabbit eye makes it attractive for surgical and drug therapy trials, important differences include a thinner cornea, larger lens, and relatively poorly vascularized retina. The rabbit is the model of choice for the assessment of intraocular lenses and other ophthalmic devices and solutions (Werner et al., 2006). Cats and nonhuman primates are less commonly used in ophthalmologic model studies but may have value for certain applications (Steinert and Jain, 2013).

Anesthesia for ocular animal model research is similar to other procedures, with several important caveats. The

oculocardiac vagal response is pronounced in many species, leading to potentially fatal profound bradycardia or asystole during surgical manipulation of the globe. Monitoring of the heart rate is therefore essential during ocular procedures. This effect is less common during ketamine anesthesia compared to propofol and can be largely prevented with the use of topical proparacaine (Singh et al., 2010). Systemic glycopyrrolate effectively treats vagal bradycardia. However, routine preoperative use of anticholinergic agents may predispose to arrhythmias and is not advised.

The eye often deviates away from the central position under general anesthesia. Neuromuscular blocking agents may be a useful aid to proper positioning of the globe for intraocular procedures. Mydriasis is often required for procedures on the lens and to prevent postoperative adhesions. Effective mydriasis can be achieved with topical 1% cyclopentolate hydrochloride and 2.5% phenylephrine; 0.3% scopolamine combined with 10% phenylephrine; 1% atropine; or a combination of 1% atropine and 10% phenylephrine (Gelatt, 2011a; Werner et al., 2006). Since eye position and pupil size are important indicators of anesthetic depth, the surgeon must assure adequate anesthetic depth when using these agents. Instrumentation for intraocular surgery has been described in Gelatt (2011b).

Skin

Rodents and swine are the most commonly used experimental models for wound healing and biomaterial studies. Rodents are inexpensive and readily available in well-defined inbred and transgenic strains and outbred stocks. Limitations to the use of rodents include small size, limiting the size of implants, opportunity for sequential biopsy, dense fur coat, and thin dermis and epidermis. Swine are more comparable to humans because of sparse body hair, and similar epidermal thickness, microscopic anatomy, and collagen composition. Pigs further resemble humans because both species lack the panniculus carnosus present in most loose-skinned animals. As a result, cutaneous wounds in pigs heal primarily through reepithelization rather than by contraction as occurs in rodents (Sullivan et al., 2001).

Anesthetic and analgesic requirements for wound healing and biomaterials studies in rodent and swine models are similar to those for other applications. Procedures are typically brief and lend themselves to injectable anesthetic technique. The potential for pain following excisional procedures or subcutaneous implantation through a skin incision is minor and can be readily treated with short-term systemic nonsteroidal antiinflammatory agents or opioid analgesics. Extensive wounds or partial thickness injuries have greater potential for pain and typically require analgesic treatment for several days.

Dressing of cutaneous wounds requires special care and ingenuity to prevent infection and physical disruption of the healing wound through scratching and grooming by cage or pen mates. Adhesive dressings should be applied so as not to impair mobility or access to food and water, and to facilitate removal and wound inspection.

Animal Management and Care of Animals

The remainder of the chapter will review species-specific considerations for rodents, ruminants, swine, and rabbits, including animal selection, anesthesia, analgesia, and preoperative and operative considerations. While PIs must consult a veterinarian in the design of animal studies, it is common for investigators and animal users to perform procedures without continuous veterinary support. Therefore it is important for animal users to be familiar with these considerations.

Rodent

Animal Selection and Preoperative Preparation

Specific pathogen-free (SPF) rodents should be used for all surgical procedures to reduce experimental variability and morbidity and mortality from chronic respiratory disease. Infectious agents may cause severe clinical disease and mortality, or even when subclinical may alter immune function, impair detoxification of anesthetic or experimental drugs, or introduce other experimental variables.

Many institutions will implement a stringent rodent health program and restrict the sources of animals to approved vendors. Several commercial vendors supply common strains and stocks of laboratory rodents free from the majority of rodent infectious agents. These are known as SPF rodents. The specific panel of excluded agents may vary according to the vendor. Animals sourced from academic or other institutions may harbor excluded agents. Animals from these suppliers commonly require quarantine or rederivation before entry to the clean vivarium. SPF animals introduced to rooms with enzootic viral infection may rapidly acquire and succumb to severe clinical disease. A conditioning period of at least 3 days after purchase is advised to assure animals have recovered from dehydration and other shipping stress.

General Anesthesia

Most surgical procedures in rodents are brief. Small body size and limited vascular access complicate anesthesia and intraoperative support of rodents. Nevertheless, skilled operators with appropriate instrumentation can accomplish delicate vascular surgery and other procedures in rats and mice with minimal postoperative mortality. Endotracheal intubation and positive pressure ventilation are also possible and require the use of customized equipment (Gaertner et al., 2008).

Rodents do not vomit, and preoperative fasting is not recommended. When fasting is required the duration should be kept to a minimum (2–3 h) to avoid hypoglycemia and shock (Flecknell et al., 2015).

Several anesthetic combinations are appropriate for brief, noninvasive procedures in rodents. Intraperitoneal (IP) injection of ketamine (40–100 mg/kg) and xylazine (3–10 mg/kg) provides 20–60 min of surgical anesthesia with good muscle relaxation in most rodents. Medetomidine (1 mg/kg IP) may be substituted for xylazine. Anesthetic duration

varies in a dose-dependent manner. If necessary, supplemental administration of half doses of ketamine will prolong anesthesia. Ketamine volumes commonly required for rats and mice require division of an intramuscular (IM) dose between two or more sites if the IP route is contraindicated. Atipamezole (1 mg/kg IP) will reverse medetomidine or xylazine-associated sedation and speed recovery from anesthesia but will also likely reverse residual xylazine-induced analgesia (Janssen et al., 2017). Side effects of general anesthesia in rodents may include hypercarbia, hypoxemia, and hypotension although these effects are less evident with ketamine and xylazine in comparison with older agents such as sodium pentobarbital.

Isoflurane provides safe and effective anesthesia in rats and mice. This agent is suitable both for brief restraint and for procedures of up to several hours' duration. Isoflurane requires the use of a precision vaporizer to maintain consistent anesthetic concentration. The "drop method" of placing a rodent in a closed chamber with an isoflurane-soaked gauze is strongly discouraged for survival surgery because the unregulated and large resulting anesthetic dose may cause unacceptably high mortality. Rapid induction of anesthesia follows placement of animals into an induction chamber containing 3%–4% isoflurane in oxygen. Most animals awaken 1–2 min after removal from the chamber, which is sufficient time for blood sampling or tail biopsy. To maintain anesthesia for longer periods, place the animal's head and nose into a customized nose cone connected to a nonrebreathing anesthetic circuit and scavenger. Concentrations of 2%–3% isoflurane are commonly used for maintenance. The absence of the pedal withdrawal reflex confirms adequate anesthetic depth. Rodent nose cones are easily fashioned from funnels or disposable syringe barrels. For procedures requiring positive pressure ventilation, endotracheal intubation is easily accomplished. Techniques for endotracheal intubation for rodents have been described (Gaertner et al., 2008).

Analgesia

Buprenorphine is the most widely used opioid analgesic in rodents. Buprenorphine is a mixed mu agonist/antagonist and a kappa receptor agonist with approximately 25–40 times the analgesic potency of morphine. The relative activity at each receptor may be dose dependent. The standard buprenorphine hydrochloride formulation agent provides safe and effective analgesia for 4–8 h after dosing. The current recommended dose of buprenorphine hydrochloride for most rodent indications is 0.03–0.05 mg/kg IP or subcutaneous (SQ) (Lee-Parritz, 2007; Curtin et al., 2009). Sustained-release buprenorphine (SR-Lab, https://wildpharm.com/) provides effective analgesia up to 72 h after a single administration (1.0–1.2 mg/kg SQ rat; 0.5–1.0 mg/kg mouse).

For procedures under isoflurane, buprenorphine is given at least 1 h before incision. The anesthetist should be aware of the anesthesia-sparing effects of buprenorphine and be prepared to reduce the isoflurane vaporizer setting by 30%–50% as necessary or reduce the amount of injectable anesthetic needed (Brunson, 2008). Preoperative administration of buprenorphine or other narcotics at standard ketamine/medetomidine or xylazine doses may cause unpredictable increases in anesthetic depth (Roughan et al., 1999; Lee-Parritz, 2007). Local infusion of the surgical site with lidocaine (up to 1 mL/kg of 1.0% lidocaine or 0.25% bupivacaine) before incision will provide additional intraoperative and postoperative analgesia (Lee-Parritz, 2007; Wenger, 2012).

Clinically significant side effects of buprenorphine include consumption of bedding (pica), and excessive licking or biting of the limbs and cage, which may also be directed to the surgical incision. These effects are more common in rats that receive high doses (0.1–0.3 mg/kg) and can often be managed through temporarily placing animals on a wire grid during surgical recovery or substitution of a synthetic for a natural bedding substrate. A generalized increase in activity and a reduction of ventral grooming may also occur. These effects most likely represent a direct effect of the drug, and do not necessarily indicate the presence or absence of pain (Lee-Parritz, 2007).

The nonsteroidal antiinflammatory drugs (NSAIDs) ketoprofen, carprofen, and meloxicam are the next most widely used analgesics. These drugs block the formation of inflammatory mediators associated with surgical injury, and also act centrally to inhibit secondary allodynia. The current recommended dose for meloxicam is 1 mg/kg PO (per os or orally) or SQ in rats, and up to 10 mg/kg in mice. The dose for ketoprofen and carprofen in rats is 5 mg/kg SQ. The dose interval for these agents has not been critically evaluated in rodents but is 12–24 h in other species. Sustained-release meloxicam protects against mechanical hypersensitivity but thermal hypersensitivity up to 96 h after administration in the rat (Seymour et al., 2016). NSAIDs are highly effective preemptive analgesics when administered 1 h or more before surgery, and isoflurane vaporizer settings or injectable anesthetic doses typically do not require adjustment (Lee-Parritz, 2007).

There are few reported adverse side effects associated with NSAIDs in rodents. Diffuse intestinal ulceration may occur at high doses, especially in animals with concurrent disease. Most NSAIDs inactivate platelet function to some extent through cyclooxygenase-mediated inactivation of thromboxane. This may slightly prolong the bleeding time, but rarely causes adverse clinical effects in humans even when administered preoperatively (Lee-Parritz, 2007).

Ruminants (Sheep, Goats, Calves)

Animal Selection and Preoperative Preparation

Sheep and goats are desirable research animals, because the adult body weight is comparable to humans and they are hardy, inexpensive, and have a calm disposition. Calves (immature cattle) are also readily available and of suitable size and disposition when young. Sheep are particularly useful for reproductive research because investigators may

easily obtain cohorts of pregnant animals with known gestational age and hysterotomy, and fetal manipulation is possible with a low postoperative abortion rate.

The quality of sheep and goats used in research often depends on the source. Surgical and transportation stress will reduce resistance to disease. A conditioning and quarantine period after arrival allows recovery from shipping stress, acclimation to the facility, and reduces transmission of infectious diseases to resident animals (Underwood et al., 2015).

Facilities should adopt measures to prevent transmission of zoonoses from sheep and goats. Silent infection with *Coxiella burnetti*, the causative agent of human Q fever, is common in sheep. Fetal membranes and amniotic fluid from infected animals carry large numbers of hardy organisms. Human infection occurs from direct contact with infected materials or from fomites. Signs of Q fever infection in humans range from subclinical disease to severe flu-like symptoms, pneumonia, endocarditis, and death. Diagnosis of subclinical infection in sheep is difficult and false-negative results are common because animals may shed large numbers of organisms in the absence of detectable antibody. Contagious ecthyma ("orf") is a poxvirus-induced papular disease of sheep and goats. Infected animals frequently have lesions on the mucocutaneous junctions of the head, which can spread to humans by direct contact. Affected animals and humans develop long-lasting immunity and usually recover in 10–14 days. Effective vaccines for sheep and goats are available but provide only short-term protection and pose some hazard to humans. No human vaccine is available (Fox et al., 2015). For these reasons, researchers should always wear gloves and other personal protective equipment and report unexpected illness to a physician familiar with specific occupational risks associated with animals.

Careful preoperative preparation of the rumen is required for safe anesthesia of sheep and goats. Adult animals require withdrawal of food and water for at least 8–12 h and no longer than 24 h before surgery to reduce rumen size and digestive activity. Rumen distension and hypoventilation are common when positioning animals in dorsal or lateral recumbency. Preoperative passage of a 1–2 cm diameter thick-walled stomach tube into the rumen allows intraoperative decompression and aspiration of gas if required. Removal of large amounts of fluid is typically unnecessary and may impair return of normal gut motility. Placement of a cuffed endotracheal tube should immediately follow anesthetic induction to prevent aspiration pneumonia. Aspiration pneumonia can be fatal after regurgitation because rumen fluid contains numerous anaerobic bacteria. Infant ruminants (<30 days of age) lack a functional rumen and should not be fasted longer than 8–12 h if at all (Flecknell et al., 2015).

Most anesthetic and analgesic drugs are used off-label in small ruminant species. Therefore animals that receive these drugs in research may not enter the food supply through rehoming, slaughter, or compost (Flecknell et al., 2015).

Brief Restraint

Sheep and goats are docile and rarely require sedation for blood sampling, dressing changes, or other routine procedures. For more invasive procedures, animals may be sedated for 10–20 min with a low dose of xylazine (0.02–0.04 mg/kg intravenous [IV] or IM) or medetomidine (0.01–0.02 mg/kg IV). Atipamezole (0.02–0.06 mg/kg IM) reverses xylazine or medetomidine sedation when necessary. Research staff should be mindful of the much lower xylazine dose required for ruminants compared to other species. By contrast, the dose of medetomidine in ruminants is similar in most laboratory animal species. Animals in late pregnancy should not receive xylazine to avoid fetal hypooxygenation secondary to depressed maternal cardiac output. The benzodiazepines diazepam (0.25 mg/kg IV) and midazolam (1.3 mg/kg IV) produce muscle relaxation and sedation in sheep and goats, with less depression of cardiac output than is seen with medetomidine (Flecknell et al., 2015).

General Anesthesia

Isoflurane is the anesthetic of choice for general anesthesia of sheep and goats. Anesthesia is induced by premedication with a low dose of xylazine (0.03 mg/kg IM) followed 10–15 min later by ketamine (5 mg/kg) and diazepam (0.3–0.5 mg/kg IV to effect) to produce light anesthesia of 10–20 min duration suitable for endotracheal intubation (Flecknell et al., 2015). Propofol (4.0–6.0 mg/kg IV to effect) is a suitable induction agent and may be suitable as a sole agent for brief procedures, or by continuous rate infusion (0.5 mg/kg/min) for longer procedures (Flecknell et al., 2015).

Profuse salivation follows the administration of most anesthetic drugs in ruminants. Administration of anticholinergic drugs is not recommended in ruminants, because these agents may increase salivary viscosity and impair gastrointestinal motility. Anesthetized ruminants should be positioned with the head down to encourage drainage of saliva away from the airway (Flecknell et al., 2015).

Endotracheal intubation requires a laryngoscope with a 20–30 cm blade. Vinyl- or silicone-cuffed tubes 10–16 mm in diameter are suitable for most sheep and goats. An assistant positions the animal in sternal recumbency, extends the neck, and holds the mouth open. The anesthetist visualizes the epiglottis with the laryngoscope and intubates the trachea during inspiration. Prior application of 2% lidocaine spray to the vocal cords prevents laryngospasm. The use of a stylet may help deflect the tip of the tube into the larynx. A mouth gag is often necessary to prevent damage to the tube by sharp molar teeth. After inflation of the cuff, secure the tube with gauze to the mandible. Isoflurane vaporizer settings of 0.75%–1.0% are often sufficient to maintain general anesthesia in sheep and goats. Absence of chewing motions and the palpebral reflex in response to stimulation indicates an adequate surgical plane. Eye position is not a reliable indicator of anesthetic depth in sheep and goats. Intermittent positive pressure ventilation

is recommended to prevent hypoventilation from positioning and pressure from abdominal viscera (Flecknell et al., 2015).

Analgesia

Signs of pain in ruminants may be subtle and limited to lethargy, reduced appetite, and rumination. Signs of severe pain include rolling, moaning, grunting, and grinding of the teeth (bruxism). The general anesthetics isoflurane and propofol provide minimal analgesia, therefore effective preemptive and postoperative analgesia is essential.

NSAIDs are highly effective in small ruminants and recommended for first-line treatment unless scientifically contraindicated. Flunixin (1.1–2.2 mg/kg), ketoprofen (2–3 mg/kg), carprofen (4 mg/kg), and meloxicam (0.5 mg/kg IV or 1 mg/kg PO) provide effective analgesia for up to 24 h after dosing. All NSAIDs should be administered parenterally in small ruminants. The intravenous route is preferred for animals with severe acute pain, but the subcutaneous and intramuscular routes have been widely reported.

Opioid analgesics may be indicated as a supplement or as primary analgesics in some cases. The epidural space is easily accessed in small ruminants. Epidural morphine (0.1 mg/kg diluted in sterile saline) administered in the lumbosacral or sacrocaudal spaces provides up to 12 h of analgesia (Riebold, 2017). The transdermal fentanyl patch (50 µg/h) produces effective blood levels in sheep for up to 72 h, but may be unpredictable in goats. Buprenorphine (0.005–0.01 mg/kg) is effective in calves and sheep but requires administration every 4–6 h for effective analgesia. Buprenorphine causes excitation in goats and is not recommended (Flecknell et al., 2015).

Local anesthetics are effective agents in multimodal analgesic protocols for thoracotomy and other painful procedures. The long-acting local anesthetic bupivacaine may be administered by diffusion catheter at the incision site (0.25%, 5–12 mL q8h). Ruminants are more sensitive to systemic effects of local anesthetics than other species. The maximum suggested dose of lidocaine for sheep and goats is 0.5 mL/kg of a 2% solution. For wide infiltration, 2% lidocaine may be diluted to 1%. Signs of systemic local anesthetic overdose include seizures, respiratory depression, bradycardia, hypotension, and collapse (Flecknell et al., 2015).

Rabbit

Animal Selection and Preoperative Preparation

The most common respiratory pathogen in conventional rabbits is *Pasteurella multocida*; however, most laboratory animal vendors provide animals free of this agent. *P. multocida* infection may be clinically inapparent or cause severe mucopurulent nasal discharge ("snuffles") and/or middle ear disease resulting in head tilt. Rabbits do not vomit, and aspiration pneumonia is therefore not a concern. Adult rabbits will tolerate an overnight fast without difficulty, and the resulting reduction in stomach contents may help maintain adequate oxygenation during spontaneous respiration under anesthesia. Rabbits weighing less than 2 kg should not be fasted, as hypoglycemia and metabolic acidosis may be significant (Lipman et al., 2008). Prolonged fasting may cause dehydration and subsequent intestinal motility disorders (Flecknell et al., 2015; Lipman et al., 2008). Traumatic lower-back fracture is common when inexperienced staff handle rabbits. The best way to handle rabbits is to grasp the scruff of the neck with one hand while supporting the rump and hind legs with the other. Sudden onset of flaccid paraplegia in rabbits is almost always the result of lower-back fracture and warrants immediate euthanasia for humane reasons (Nowland et al., 2015). Never lift, move, or restrain rabbits by the ears.

Brief Procedures

Combined administration of ketamine (35–50 mg/kg IM) and xylazine (5–10 mg/kg IM) provides excellent anesthesia for a variety of applications in the rabbit. General anesthesia lasts for 30–60 min and provides adequate analgesia and restraint for procedures of moderate intensity. Supplemental use of a narcotic analgesic such as buprenorphine (0.05 mg/kg IM) prolongs anesthesia and improves analgesia. Propofol administered by intravenous bolus or constant rate infusion produces light anesthesia suitable only for intubation or nonpainful procedures such as imaging. Telazol should not be used for survival procedures in rabbits, because renal tubular damage is a common complication even at standard anesthetic dosages (Flecknell et al., 2015; Lipman et al., 2008).

General Anesthesia

The intramuscular ketamine/xylazine combination suggested for brief procedures is also an excellent induction agent prior to endotracheal intubation for inhalation anesthesia. Intravenous administration of ketamine and xylazine through the ear vein will achieve rapid induction, but care is required to minimize skin irritation from perivascular infiltration. Mask induction is rarely indicated because apnea, breath holding, bradycardia, and struggling are common when unsedated rabbits are exposed to isoflurane, and because operator exposure to waste anesthetic is difficult to avoid in this setting (Flecknell et al., 2015).

Propofol (10–20 mg/kg IV) is an effective rabbit anesthetic induction agent that produces significantly faster postoperative recovery than ketamine/xylazine in animals maintained on sevoflurane or isoflurane. By contrast, anesthetic recovery following ketamine/xylazine or ketamine/medetomidine may require up to 120 min. Animals should receive preoperative analgesics and be preoxygenated by mask before propofol administration.

The initial propofol dose of 10 mg/kg should be administered slowly over 60 s (~0.17 mg/kg/s), with additional small increments as required to allow endotracheal intubation. Respiratory arrest may occur, particularly following rapid infusion (>0.25 mg/kg/s) (Allweiler et al., 2010).

Endotracheal intubation of the rabbit may be difficult because of several distinctive anatomic features. Prominent incisor teeth, a long oropharynx, and limited mobility of the temporomandibular joint hinder direct visualization of the larynx from the front. Lidocaine spray on the vocal cords is necessary to prevent further narrowing of the larynx through laryngospasm. Benzocaine spray (Cetacaine) produces methemoglobinemia in rabbits and should be avoided. Supine, prone, or lateral positions are all suitable for endotracheal intubation. Hyperextension of the neck will straighten the larynx and facilitate proper tube placement. Blind intubation of the trachea is easily accomplished with practice. Studies have shown that using supraglottic airway devices (e.g., v-gel) offers some benefits over blind intubation, including faster placement and less trauma to the airway (Engbers et al., 2017; Zeeland and Schoemaker, 2012).

Anesthetic maintenance with isoflurane usually requires a vaporizer setting of 1%–4%. Absence of the pinna withdrawal reflex is the best indicator of a surgical anesthetic plane in the rabbit. Many rabbits retain the corneal and pedal withdrawal reflexes even under very deep anesthesia (Flecknell et al., 2015; Lipman et al., 2008).

If an anticholinergic agent is required, investigators should be aware that approximately 50% of rabbits produce atropinesterase (AtrE) as a genetically determined trait. Glycopyrrolate resists AtrE and is therefore recommended over atropine for rabbits. Glycopyrrolate prevents xylazine-associated bradycardia in rabbits (Flecknell et al., 2015; Lipman et al., 2008).

Analgesia

The most frequently recognized signs of pain and discomfort in rabbits include anorexia, an unkempt appearance due to failure to groom, and reduced activity. Untreated anorexia can create serious secondary disease, including generalized gastrointestinal stasis, rapid weight loss, and fatal hepatic lipidosis (Flecknell et al., 2015; Lipman et al., 2008). The recent validation of a facial grimace score, which assesses orbital tightening, cheek flattening, nose shape, and changes in whiskers, has facilitated the diagnosis and management of pain in rabbits (Hampshire and Robertson, 2015; Keating et al., 2012).

The best indicator of gastrointestinal health in the rabbit is the quantity and consistency of fecal pellets. Dehydration and anorexia result in a reduced number of firm dry pellets. Treatment of anorexic postoperative rabbits should be directed to relief of underlying pain if present and toward restoration of normal gastrointestinal function. A high-fiber supplement such as Oxbow Critical Care or blenderized rabbit chow is preferred over low-fiber nutritional gels such as Nutrical to restore normal gut motility. Aggressive analgesia, fluid therapy, and force feeding may be necessary in some cases.

Narcotic analgesics are preferred for the treatment of moderate to severe postoperative pain in rabbits. Buprenorphine (0.01–0.05 mg/kg SQ twice or three times a day) is the narcotic of choice, because it provides effective analgesia at a convenient dosing interval and is generally well tolerated. The fentanyl patch (25 µg/h) is an alternative narcotic analgesic option that provides continuous analgesia up to 72 h without the requirement for regular injections (Flecknell et al., 2015).

NSAIDs are also highly effective in rabbits, particularly for musculoskeletal pain or coadministered with narcotics for multimodal analgesia. Flunixin (1.1 mg/kg SQ q24h), carprofen (4 mg/kg SQ q24h), and meloxicam (0.3 mg/kg PO q24h) all demonstrate good clinical efficacy in rabbits (Lipman et al., 2008). Meloxicam oral suspension (Metacam, 1.5 mg/mL) has recently undergone pharmacokinetic evaluation in rabbits. Oral administration of 0.3 mg/kg once a day produced blood levels comparable to those shown to be clinically effective in other species for up to 24 h. Although rabbits demonstrate more rapid metabolism of meloxicam than other species, delayed gastrointestinal absorption of the drug allows maintenance of effective blood levels throughout the dose period (Carpenter et al., 2009; Fredholm et al., 2013; Turner et al., 2006).

Swine

Animal Selection and Preoperative Preparation

Swine are commonly used in experimental surgery because of many anatomic and physiologic similarities to humans. Advantages to the use of pigs in the laboratory include low cost, ready availability, and ease of acclimation to the laboratory. Disadvantages include the uncooperative nature of pigs with respect to most clinical procedures, limited number of intravenous access sites, and relative difficulty of endotracheal intubation.

Because animals larger than 100 kg are difficult to handle in the laboratory, selective breeding has produced several types of miniature swine for research. The Gottingen minipigs and the Yucatan micropigs achieve a maximum bodyweight of 35–55 kg at 2 years of age. The Hanford and Yucatan minipigs are somewhat larger and weigh 70–90 kg at 2 years of age. By contrast, adult crossbred farm pigs weigh 90–110 kg at 6 months of age, and 200–300 kg at 2 years of age (Bollen Hansen et al., 2000; Swindle and Smith, 2016). Juvenile crossbred farm pigs are less expensive than minipigs or micropigs, and are often used for short-term surgical studies. Juvenile farm pigs gain 2–4 kg/week and require larger pens as they grow to maintain facility compliance with the Guide (National Research Council, 2011).

Careful evaluation of the vendor health program is required to reduce experimental morbidity from unrelated clinical conditions. Chronic respiratory disease is common in commercial swine operations. Although subclinical infections are common, transportation, anesthesia, and surgery may activate latent infections and result in excess morbidity and mortality. Many commercial breeders of laboratory minipigs and micropigs maintain specific SPF herds free from infection with common pathogens.

Malignant hyperthermia (MH) is an autosomal recessive trait that causes affected animals to develop marked

hyperthermia (rectal temperature >41°C), and extensor muscle rigidity and necrosis after exposure to environmental extremes or halothane or isoflurane anesthesia. The disease has been described only in farm animals bred for rapid growth, including but not limited to the Landrace, Yorkshire, Duroc, Pietrain, and Poland China breeds. MH is increasingly rare as commercial breeders identify and cull carrier pigs but may still be encountered sporadically when farm pigs are used for experimental surgery. The condition has not been described in minipigs or micropigs or other species. Treatment of animals that develop MH during an experimental procedure requires immediate termination of anesthesia and supply of 100% oxygen, whole body cooling, and administration of corticosteroids, sodium bicarbonate, and dantrolene sodium (3–5 mg/kg IV) (Helke et al., 2015; Swindle and Smith, 2016; Swindle et al., 2012).

Food and contact bedding must be removed 6–8 h prior to general anesthesia. Water may be offered until 2 h before anesthesia. The presence of food in the stomach frequently results in gastric distension, hypoventilation, and tachycardia during prolonged general anesthesia, requiring prompt decompression through orogastric intubation (Swindle and Smith, 2016).

Brief Restraint

Pigs may be easily trained to accept handling for physical examination, blood collection through a vascular access port, and dressing changes. The acclimation period following arrival to the facility before study initiation is an appropriate training time. Uncooperative pigs may require chemical restraint for minor clinical procedures. Slings and hammocks are available that will allow restraint of calm pigs up to 50 kg for up to several hours (Swindle and Smith, 2016). The Panepinto sling was specifically designed for veterinary practice and laboratory environments and is easy to operate and sanitize. Sedation may be necessary to facilitate initial placement of animals into the sling. Azaperone (4 mg/kg IM) is a useful agent for this purpose. For more invasive procedures, a mixture of Telazol (4.4–6.6 mg/kg IM), xylazine (2.2 mg/kg IM), and atropine (0.05 mg/kg) provides approximately 30 min of anesthesia suitable for minor surgery, followed by smooth recovery. Endotracheal intubation for subsequent maintenance on isoflurane is also possible after Telazol and xylazine induction (Bollen Hansen et al., 2000; Swindle and Smith, 2016).

General Anesthesia

Prolonged or invasive procedures are best conducted under isoflurane anesthesia. Endotracheal intubation is warranted for general anesthesia in swine to protect the airway and allow for controlled ventilation when required. Endotracheal intubation is possible with the pig in dorsal, ventral, or lateral recumbency. Two anatomic characteristics can complicate the procedure. First, the soft palate is long and must be displaced dorsally for visualization of the larynx. Second, the laryngeal diverticulum distal to the larynx may "trap" the tip of the endotracheal tube unless the tube is gently twisted as it passes over the epiglottis. After intubation, maintenance anesthesia usually requires an isoflurane vaporizer setting of 1.5%–2.5% in oxygen. The actual concentration of isoflurane will vary according to the anesthetic induction regimen, type of procedure, and concurrent use of other narcotic and sedative agents. Administration of Telazol and xylazine for anesthetic induction has a substantial isoflurane-sparing effect that may last for the first 30–60 min of anesthesia. Adequate surgical anesthesia is indicated by the absence of the pedal withdrawal reflex, minimal jaw tone, and stable heart rate and blood pressure (Flecknell et al., 2015; Smith and Swindle, 2008).

TABLE 2.3.6.1 Recommendations of Animal Models by Clinical Application (Byrom et al., 2010)

Species	Indication
Sheep	Vascular conduits 4–6 mm diameter
Baboon	Thrombogenicity
	Tissue-engineered conduits
Rabbit	Vascular conduits 1–4 mm diameter

Analgesia

Diagnosis of pain in swine may be challenging. Pain scoring systems reported by some investigators have not been validated in large-scale studies. Withdrawal to palpation of painful areas, for example, is the most obvious sign of pain in pigs. Although an indirect measure, depressed appetite is a common indicator of pain in postoperative pigs. In addition, depending on the nature of the pain, pigs may exhibit reduced or increased activity and depressed attitude compared to normal pigs (Flecknell et al., 2015; Ison et al., 2016).

Narcotics are commonly used postoperative analgesics in swine. Buprenorphine is the most widely used narcotic and provides excellent analgesia at a convenient dose interval with few side effects. The fentanyl patch (5 µg/kg/h) is effective in swine and reduces the need to handle animals during the immediate postoperative period, when struggling may increase pain at the incision line or predispose to dehiscence. Fentanyl patches should be applied in the dorsal midscapular region to prevent accidental dislodgement and ensure consistent absorption (Harvey-Clark, 2000; Malavasi et al., 2005; Osorio Lujan et al., 2017). Group-housed pigs may remove and consume patches applied to cage mates and develop acute narcotic overdose.

NSAIDs are highly effective analgesics in swine. Carprofen (2 mg/kg SQ or PO q24h), meloxicam (0.4 mg/kg SQ q24h), and flunixin (1–4 mg/kg SQ or IM q24h) have been used as sole agents or in combination with opioid local anesthetics. Gastric irritation has not been reported following short-term use, but may be a concern in animals that require chronic therapy (Smith and Swindle, 2008; Swindle and Smith, 2016) (Table 2.3.6.1).

CASE STUDY

You are a biomaterials engineer for a large pharmaceutical company. You wish to evaluate a novel material in an animal model for use in the repair of large segmental long bone defects. The test material contains human-origin stem cells in a proprietary matrix. You propose to use 100 nonhuman primates for the study. During protocol prereview, the attending veterinarian suggested you clarify the following questions in your IACUC protocol before submission for full committee review:

1. Provide scientific justification to use nonhuman primates for this model. Your answer should identify at least two other animal models in common use (species and bone):
   - *a. Scientific justification:*
     - *i. Nonhuman primates are bipedal, therefore mechanical loading is more similar to humans.*
     - *ii. Human-origin stem cells may be more likely to engraft in a nonhuman primate species than in other species.*
   - *b. Common models:*
     - *i. Sheep tibia*
     - *ii. Rat calvarium*
2. What are the advantages and disadvantages of the common models over the nonhuman primate model?
   - *a. Advantages:*
     - *i. Lower cost and increased availability, reduced biohazard concern.*
     - *ii. Large experience base and consensus acceptance of these species as standard models compared to primates.*
   - *b. Disadvantages:*
     - *i. Quadrupedal locomotion.*
     - *ii. Different microscopic anatomy.*
     - *iii. Rapid rejection of xenogeneic tissue.*
3. What postoperative complications should you be prepared for (provide at least two) and what would you do to detect and treat these if they occur?
   - *a. Complications:*
     - *i. Pain from creation of the defect.*
     - *ii. Infection or inflammation associated with the implant.*
     - *iii. Collapse or pathologic fracture of the bone.*
   - *b. Detection and treatment:*
     - *i. Postoperative monitoring for poor appetite, increased attention to wound, redness, swelling, or discharge.*
     - *ii. Treatment.*
       1. *NSAID and/or narcotic analgesic for at least 3 days or longer as needed.*
       2. *Consultation with facility veterinarian:*
          - *a. Warm compresses, antibiotics, analgesics, or other treatments as directed.*
          - *b. Euthanasia if complication causes untreatable pain or disability or if treatment will introduce unacceptable study variables.*
4. Clarify, reevaluate, and revise your protocol considering the "three Rs" (replacement, reduction, refinement) as an ethical imperative. For example, replacement is demonstrated by replacing animals with a computer model.
   - *a. Replacement:*
     - *i. Evaluate potential of embryonic stem cells to stimulate bone formation in an in vitro model (cells in culture, "organ on a chip," ex vivo model).*
     - *ii. Before proceeding to nonhuman primate studies, demonstrate proof of concept in a smaller number of rodents using the rodent calvarium model with either rodent-origin stem cells or in an immune-compromised rodent (nude rat, severe combined immunodeficient mouse) with human-origin cells. This is also an example of refinement since the calvarium model is arguably less painful than a segmental defect model because the calvarium is not weight bearing.*
   - *b. Reduction:*
     - *i. Perform power analysis to justify animal numbers used by fully describing control and treatment groups, expected treatment effect, and inherent variability of the animal model.*
     - *ii. Consider using one control group for multiple treatment groups.*
   - *c. Refinement:*
     - *i. Evaluate and optimize an analgesic, surgical, and postoperative care regimen in a small pilot study before proceeding to full 100 primate study.*
     - *ii. Assure adequate staffing and budget to provide needed monitoring and care.*

Chapter Study Questions

1 What characteristic of coronary circulation of the pig heart makes it a better cardiac animal model than dogs and sheep?
   a Answer: Pigs' hearts are supplied primarily by the right coronary artery, much like humans. Sheep and dogs are supplied primarily by the left coronary artery.

2 What are the four common bone defect models in animals and which is most commonly performed in rodents? Which is the most common in sheep?
   a Answer: Calvarial defect (rodent most common), long bone or segmental defect, partial cortical defect, and cancellous bone defect.
   b Answer: The sheep tibia is the most common segmental long bone defect model.

3 A new graduate student in your lab is responsible for handling rabbits on your studies. The student has experience with mice and was briefly trained on rabbit care by the outgoing graduate student. The facility veterinarian notifies you that one of your rabbits has complete paralysis in the back legs. The student acknowledged the rabbit struggled and kicked during the previous day's physical examination. What is the likely diagnosis and treatment? What could have prevented this from occurring?
   a Answer: It is likely that this rabbit experienced lower back fracture during handling by the inexperienced researcher. The seventh lumbar vertebra is considered the most frequent site of fracture. This occurs when the hindquarters of the rabbit are not supported, allowing for the powerful hind limb muscles to damage the relatively light and fragile skeleton. Radiologic examination can confirm the diagnosis; however, these clinical signs are characteristic. The injury is painful and not treatable. The animal requires emergency euthanasia for humane reasons.
   b Answer: Training and a calm unhurried approach are critical for successful handling of any animal in research. Although the facility veterinary staff typically provides training and technical support by request, the PI is ultimately responsible to assure all staff have training and experience in research procedures, including handling and restraint.

4 What nerve mediates the oculocardiac reflex, which can cause bradycardia and death during surgical procedures on the eye? What drugs are recommended for prevention and treatment?
   a Answer: The vagus nerve mediates the oculocardiac reflex.
   b Answer: Topical proparacaine reduces the incidence and severity of the reflex. Glycopyrrolate is effective for treatment.

5. What injectable anesthetic combination is recommended for short-term surgical procedures in rats? What drug is recommended to speed recovery by antagonizing one of the drugs in the combination?
   a. Answer: Ketamine combined with either xylazine or medetomidine provides 15–30 min of surgical anesthesia.
   b. Answer: Atipamezole reverses xylazine or dexmedetomidine.

6. Which injectable analgesic provides 72 h of postoperative pain control in rats?
   a. Answer: Sustained-release buprenorphine.

7. Which opioid analgesic provides effective pain control for 48–72 h when applied as a topical patch?
   a. Answer: Fentanyl.

8. What are the three separate functional components required to perform survival aseptic surgery in dogs, pigs, and other USDA "regulated species"?
   a. Answer: Animal preparation.
   b. Answer: Surgeon preparation.
   c. Answer: Surgery room.

9. Which common research animal resembles the human because it lacks the panniculus carnosus causing cutaneous wounds to heal by reepithelialization rather than by contraction?
   a. Answer: Swine.

10. What anatomic features complicate endotracheal intubation in the pig?
   a. Answer: Long soft palate.
   b. Answer: Laryngeal diverticulum.

2.4.1 Introduction: The Body Fights Back–Degradation of Materials in the Biological Environment

BUDDY D. RATNER[1], WILLIAM R. WAGNER[2]

[1]Bioengineering and Chemical Engineering, Director of University of Washington Engineered Biomaterials (UWEB), Seattle, WA, United States

[2]Departments of Surgery, Bioengineering & Chemical Engineering, McGowan Institute for Regenerative Medicine, University of Pittsburgh, Pittsburgh, PA, United States

The biological environment, seemingly a mild, aqueous salt solution at 37°C, is, in fact, surprisingly aggressive and can lead to rapid or gradual breakdown of many materials. Some mechanisms of biodegradation have evolved over millennia specifically to rid the living organism of invading foreign substances—these same mechanisms now attack our contemporary biomaterials. Other breakdown mechanisms have their basis in well-understood chemical and physical principles and will occur in a living organism or in a beaker on a laboratory bench. After this introduction, four chapters (2.4.2–2.4.5) directly address degradation, where the emphasis is on processes working against the intent of the material or device design. The first three of these chapters consider breakdown in the biological environment for polymers, metals, and ceramics, respectively. These chapters build upon the fundamental principles associated with these broad classes of materials as covered in Section 2.3. Not specifically addressed in this section is the range of biodegradation processes for biologically derived materials. In some cases, these biological materials will not be modified or processed to resist natural degradation mechanisms (as is the case with decellularized tissues) and the principles of wound healing and tissue remodeling apply. In other cases where there has been cross-linking or fixation of the material, the intent is often to reduce immunogenicity and impart degradation resistance. An example of such processing occurs with commercial bioprosthetic heart valves. For these processed tissues a common concern is another type of degradation, calcification, which can lead to device failure and can exacerbate other degradation mechanisms. Chapter 2.4.4 describes the issue of pathological calcification in detail.

In addition to the chapters of Section 2.4, several textbook chapters address biomaterial degradation in other contexts. Chapter 1.3.2F reviews the chemistry of polymers designed to be biodegradable, while Chapter 1.3.3D addresses the rapidly growing area of intentionally degradable metallic materials. Chapter 2.6.3 on scaffolds for tissue engineering demonstrates how degradation processes can be engineered into more complex systems intended to provide improved tissue-based outcomes. Chapter 3.1.9 addresses device failure, with multiple examples where unintentional degradation or mechanical failure occurred clinically, and many of the device-focused chapters of Section 2.5 consider degradation issues.

Careful consideration of the working environment for many implanted medical devices highlights why degradation is a fundamental biomaterial design consideration. The biomaterials of medical devices are usually exposed to varying degrees of cyclic or periodic stress (humans ambulate and the cardiovascular system pumps). Abrasion and flexure may also take place. Particularly challenging are designs where biomaterials must cyclically articulate with one another, or surrounding tissue, under high loads (e.g., hip

and knee prostheses). Such mechanical loading occurs in an aqueous, ionic environment that can be electrochemically active to metals and plasticizing (softening) to polymers. It is well known that a material under mechanical stress will degrade more rapidly than the same material that is not under load.

Specific biological mechanisms are also invoked. Proteins adsorb to the material and can enhance the corrosion rate of metals. Cells (especially macrophages) adhere to materials via interfacial proteins, and can be activated to secrete powerful oxidizing agents and enzymes intended to digest or dissolve the material. The secreted, potent degradative agents are concentrated in the space between the adherent cell and the biomaterial upon which they act, undiluted by the surrounding aqueous medium. Also, bacteria, bacterial biofilms (Chapter 2.2.8), and yeast, and the local immune response to these infections, can markedly enhance degradation and corrosion rates.

To understand the biological degradation of implant materials, synergistic pathways must be considered. For example, cracks associated with stress crazing in polymers open up fresh surface areas to reaction. Swelling and water uptake can similarly increase the number of sites for reaction, and provide an access route for degradative agents into the bulk of the biomaterial. Amorphous material at metal grain boundaries can degrade more rapidly, leading to increases in surface area and localized stresses. Degradation products can alter the local pH, catalyzing further reaction. Hydrolysis of hydrophobic polymers can generate hydrophilic species, leading to polymer swelling and an increased propensity for degradation reactions. Cracks might also serve as sites for the initiation of calcification.

Biodegradation is a term that is used in many contexts. It can be used for reactions that occur over minutes or over years. It can be engineered to happen at a specific time after implantation or it can be an unexpected long-term consequence of the severity of the biological environment. Implant materials can solubilize, crumble, tear, become rubbery, or become rigid with time. The products of degradation may be toxic or irritating to the body or they may be designed to stimulate a desirable local cellular response.

Calcification, a process we strive for in bone healing, is undesirable in most soft tissue contexts. Calcific mineral can interfere with the mechanical function of devices, induce cracking in polymers and tissues, and embolize, leading to complications downstream. Implants based on natural tissue are particularly subject to calcification, but calcification is reasonably common in synthetic polymer devices.

Below are some comments and questions on biomaterial degradation issues that are meant to stimulate further thinking on this subject in conjunction with the chapters in this section:

- Consider strategies used to create materials that degrade at controlled rates versus strategies for synthesizing biostable materials intended for long-term performance in the body.
- Consider the degradation of materials commonly used in medicine that do not have well-defined breakdown mechanisms. Some examples include poly(ethylene glycol), hydroxyapatite, and some polysaccharides. How does the body deal with these common materials?
- Classes of biomaterials have been designed that degrade on cue. The cue might be thermal, photonic, or enzymatic. Ingenious chemical design principles are being applied to create such materials, but how might the body react to the products generated by a sudden breakdown of the structure?
- Learn about new strategies to stabilize materials against degradation. For example, for orthopedic polymers the loading of vitamin E or the development of new types of cross-linked materials for articulating surfaces. For elastomers, the incorporation of polyisobutylene or other degradation-resistant segments into block copolymer designs.
- Endovascular stents are among the most widely used of all medical devices (Chapter 2.5.2B). New designs of biodegradable stents have entered clinical testing and been approved in some regions. Some have been removed from the market. Whether these degradable devices will take substantial market share from nondegradable stents is not yet clear. Consider the biocompatibility concerns associated with biodegradable poly(lactic acid) or magnesium, iron, or zinc (Chapter 1.3.3D) in the complex intravascular environment.
- For a medical device intended for years of service, especially a device where failure can lead to death, how can we test and qualify the device for the expected period of service? Are there useful in vitro tests? What accelerants might be brought to bear? Are there relevant and justified animal models?
- Consider medical device failure, past and present, associated with degradation, and how these unintended complications will lead to better medical devices. A few examples include the degradation of polyurethane pacemaker leads, the breakdown of a protective sheath on the tailstring of the Dalkon Shield intrauterine device, and the wear debris associated with the oxidation of ultrahigh molecular weight polyethylene in hip prostheses or the failure of metal-on-metal hip designs (see Chapter 3.1.9).

Degradation in biological environments is seen with metals, polymers, ceramics, and natural materials. Undesired degradation is observed to some degree in most long-term implants, and even in some medium- and short-term implants. Often, its initiation, mechanisms, and consequences are incompletely defined. Biodegradation as a subject is broad in scope, and critical to device performance. It rightfully should command considerable attention for the biomaterials scientist. The intent of this section is to provide a basis for further study and insight into this complex but essential subject.

2.4.2

Chemical and Biochemical Degradation of Polymers Intended to Be Biostable

ARTHUR J. COURY

Northeastern University, Boston, MA, United States

Introduction

Biodegradation is the chemical breakdown of materials by the action of living organisms that leads to changes in physical properties. It is a concept of vast scope, ranging from decomposition of environmental waste involving microorganisms to host-induced deterioration of biomaterials in implanted medical devices. It is a precise term, implying that specific biological processes are required to effect such changes (Williams, 1989). This chapter, while grounded in biodegradation, addresses other processes that contribute to the often-complex mechanisms of polymer degradation even before communicating with tissue (see Table 2.4.2.1). While minor attention is paid to physical breakdown, its focus is the unintended chemical breakdown in the body of synthetic, solid-phase polymers. (See Chapter 1.3.2F for a description of systems designed to break down in the body). The factors impacting the undesired biodegradation of polymeric implants are largely well-defined, moreover, some recent progress (to be noted) has been made in mitigating such degradation.

Polymeric components of implantable devices are designed to be reliable for their intended lifetimes. Careful selection and extensive preclinical testing of the compositions, fabricated components, and devices generally establish functionality and durability. However, with chronic, indwelling devices, it is not feasible during qualification (typically short-term testing) to match all implant conditions in real time for years or decades of use.

The accelerated in vitro aging, animal implants, limited clinical trials and statistical projections employed cannot expose all of the variables that may cause premature deterioration of performance. The ultimate measure of the acceptability of a material for a medical device is its acceptable performance for the device's intended lifetime as ascertained in human postimplant surveillance (Coury, 1999). No polymer is totally impervious to the chemical processes and mechanical action of the body. Generally, polymeric biomaterials degrade because body constituents attack the biomaterials directly or through other device components, sometimes with the intervention of external factors. The seeds for biodegradation may be sown prior to implantation by compositional or processing issues.

Polymer Degradation Processes

Preimplant Degradation

Numerous operations are performed on a polymer from the time of its synthesis to its use in the body (see Table 2.4.2.2). Table 2.4.2.2 lists states and stages in the history of a polymeric biomaterial leading to its implantation which, alone or in concert, may predispose it to degradation when implanted (Brauman et al., 1981; Greisser et al., 1994; Ling et al., 1998). A prominent example of biomaterial degradation caused by preimplant processing is the gamma irradiation sterilization of ultrahigh-molecular-weight polyethylene used in total joint prostheses. The process generates free radicals within the material that react with oxygen to produce undesirable oxidation products. Chain oxidation, scission, and cross-linking can occur for periods of months to years, causing loss of strength and embrittlement with limited shelf-life (Furman and Li, 1995; McKellop et al., 1995; Weaver et al., 1995; Daly and Yin, 1998; Blanchet and Burroughs, 2001; Kurtz et al., 2005; Rimnac and Pruitt, 2008). Recent attempts to mitigate degradation effects by gamma sterilization in inert atmospheres instead of air and the use of antioxidants such as vitamin E have provided some improvement in the long-term in vivo performance of polyethylene joint components (Booth, 1995; Medel et al., 2009; Crowninshield and

TABLE 2.4.2.2 Typical Operations on an Injection-Moldable Polymer Biomaterial

Polymer: Synthesis, extrusion, pelletizing

Pellets: Packaging, storage, transfer, drying

Components: Injection-molding, postmold finishing, cleaning, inspecting, packaging, storage

Device: Fabrication, storage (presterilization), cleaning, inspecting, packaging, storage (packaged), sterilization, storage (sterile), shipment, storage (preimplant), implantation, operation in body

Muratoglu, 2008). Polypropylene and polytetrafluoroethylene are also notable as polymers that are predominately, but not entirely (Liebert et al., 1976), chemically stable in the body, but can be severely degraded during processing by sterilization with ionizing radiation (Williams, 1982; Portnoy, 1997). Gamma irradiation may also cause optical changes such as darkening of poly(methyl methacrylate) intraocular lenses (Hoffman, 1999). It is crucially important, therefore, that appropriate and rigorous processing and characterization protocols be followed for all operations (Coury et al., 1988; Shen et al., 1999).

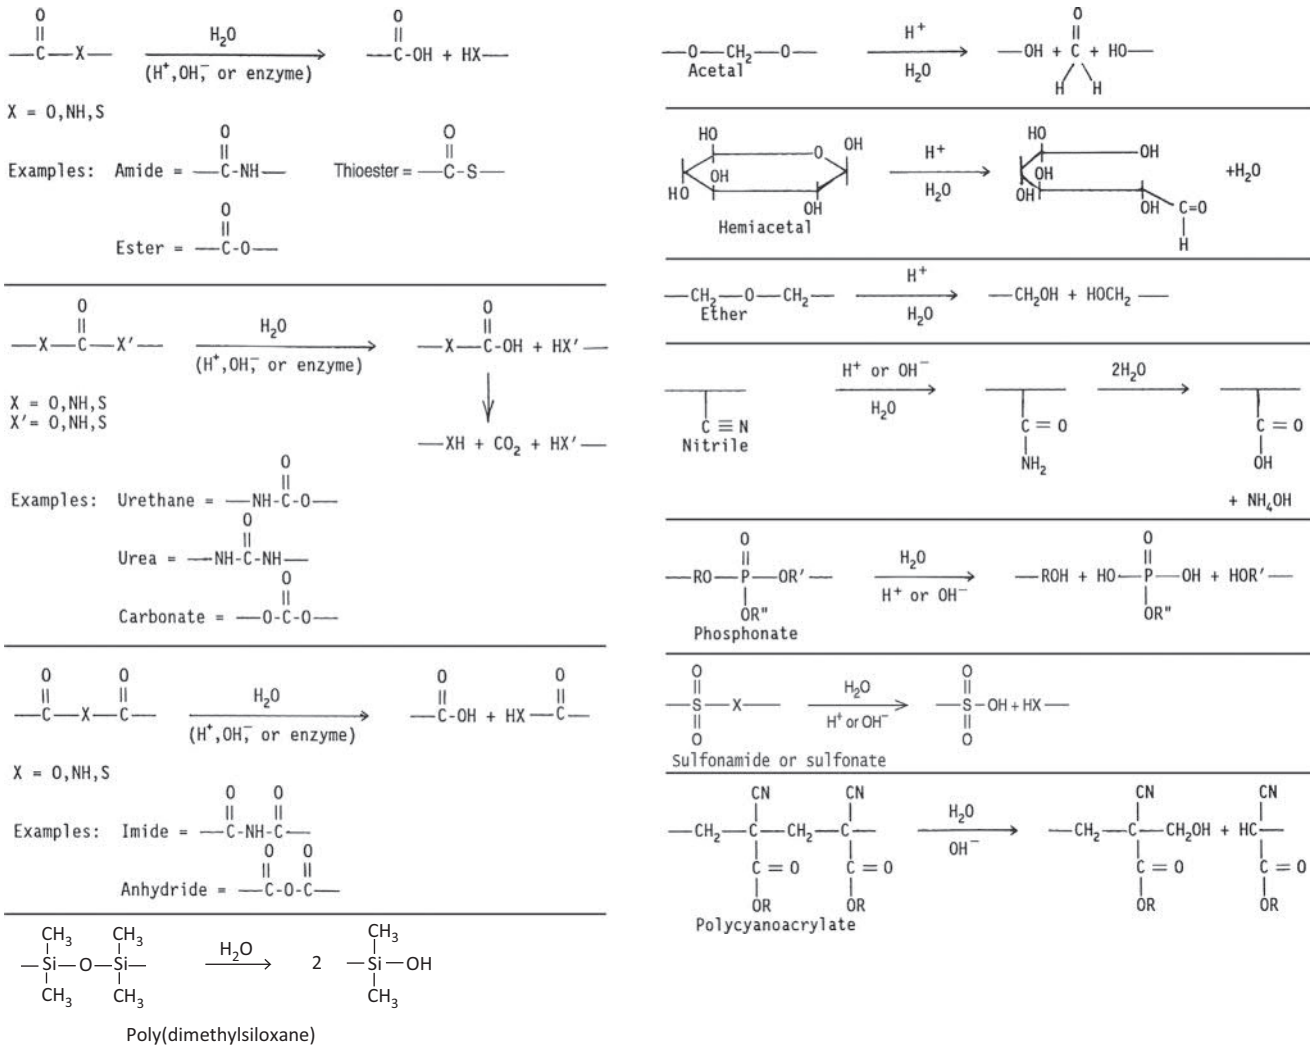
Postimplant Degradation Forces

After a device has been implanted, adsorption and absorption processes occur. Polymeric surfaces in contact with body fluids immediately adsorb proteinaceous components, and the bulk begins to absorb soluble components such as water, ions, proteins, and lipids. Cellular elements subsequently attach to the surfaces and initiate chemical processes. With biostable components, this complex interplay of factors is of little functional consequence. At equilibrium fluid absorption, there may be some polymer plasticization causing dimensional and mechanical property changes (Coury et al., 1988). On the surface, a powerful acute attack by cells and humoral chemical agents, including oxidants and enzymes, will have been substantially withstood, although inconsequential, superficial changes may occur. Over days to weeks, with the resolution of this acute inflammatory phase, a fibrous capsule will likely have formed over the device, and the rate of release of powerful chemicals from activated cells will have markedly decreased. For those polymers subjected to chemical degradation in vivo, few if any reports have comprehensively described the sequential processes and interactions that produce the deleterious effects. Rather, explant analysis and occasionally metabolite evaluation are used to infer reaction pathways. Analysis of chemically degraded polymers has almost always implicated either hydrolysis or oxidation as an essential component of the process. Device fouling by mineralization and thrombosis is not addressed within the scope of this chapter, but the processes are covered in Cauich-Rodriguez et al. (2013) and in Chapters 2.3.5 and 1.4.3A, B. Regarding rates of degradation of polymers used in implantable devices, a publication by Lyu and Untereker (2009) elegantly describes propensities and rate equations for predominant polymer hydrolytic and oxidative degradation mechanisms which have high predictive values for choosing polymer biomaterials.

Hydrolytic Biodegradation

Structures of Hydrolyzable Polymers

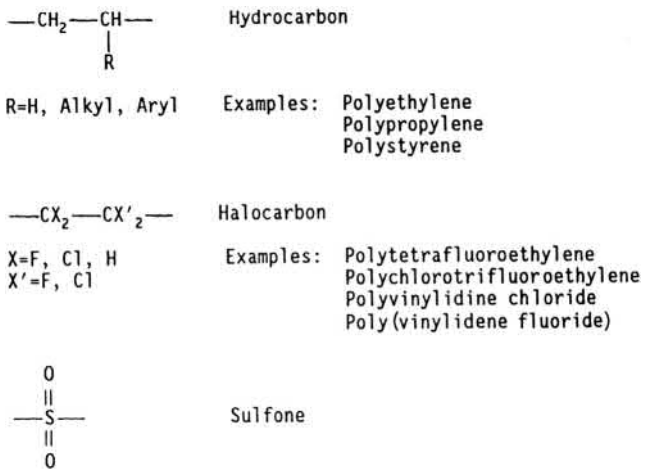
Hydrolysis is the scission of susceptible molecular functional groups by aqueous attack. Hydrolysis may be catalyzed by acids, bases, salts, or enzymes. It is a single-step process in which the rate of chain scission is directly proportional to the rate of initiation of the reaction (Schnabel, 1981). A polymer's susceptibility to hydrolysis is the result of its chemical structure, its morphology, its mass and dimensions and the body's environment. In a commonly used category of hydrolyzable polymeric biomaterials, functional groups consist of carbonyls bonded to heterochain elements (O, N, S). Examples include esters, amides, urethanes, carbonates, and anhydrides (Fig. 2.4.2.1). Other polymers containing groups such as ether, acetal, nitrile, phosphonate, sulfonate, sulfonamide, or active methylenes hydrolyze under certain conditions (Fig. 2.4.2.1). Hydrolytically susceptible groups exhibit differing rates of degradation which are dependent



• **Figure 2.4.2.1** Hydrolyzable groups in polymer.

on the intrinsic properties of the functional group and on other molecular and morphological characteristics. Among carbonyl polymers with oxygen heteroatoms attached, anhydrides display the highest hydrolysis rates followed, in order, by esters and carbonates. Polymers containing such groups, in fact, comprise many of the intentionally resorbable devices (Chapter 1.3.2F). Other carbonyl-containing groups such as urethane, imide, amide, and urea can demonstrate long-term stability in vivo if contained in a hydrophobic backbone or highly crystalline morphologic structure. Groups that are normally very stable to hydrolysis are indicated in Fig. 2.4.2.2.

The rate of hydrolytic degradation tends to increase with one or more of the following: a high proportion of hydrolyzable groups in the main or side chain; other polar groups which enhance hydrophilicity; low crystallinity; low or negligible cross-link density; a high ratio of exposed surface area to volume; and, in some cases, mechanical stress. Porous hydrolyzable structures undergo rapid property loss relative to monolithic structures, because of their large surface area. Factors that tend to suppress hydrolysis rate include hydrophobic molecular moieties (e.g., hydrocarbon



• **Figure 2.4.2.2** Groups highly stable to hydrolysis.

or fluorocarbon); cross-linking; high crystallinity due to chain order, thermal annealing or orientation; low stress and compact shape (low surface-to-volume ratio). While the molecular weight of linear polymers per se may not have a great effect on the hydrolysis-induced degradation rate,

physical property losses may be retarded for a given number of chain cleavage events with relatively high-molecular-weight polymers. Property loss caused by chain cleavage is more pronounced in polymers with weak intermolecular bonding forces.

Host-Induced Hydrolytic Processes

The body is normally a highly controlled reaction medium. Through homeostasis, the normal environment of most implants is maintained at isothermal (37°C), ~neutral (pH 7.4), aseptic, and photo-protected aqueous steady state. By in vitro standards, these conditions may appear mild. However, complex interactions of humoral and cellular components of body fluids involving activators, receptors, inhibitors, etc., produce aggressive responses to any foreign bodies through the processes of cell adhesion, cell activation, chemical attack, and particulate transport.

Several scenarios leading to hydrolysis in the host can be considered. For all scenarios, hydrolysis can only occur at a site other than the surface of a polymer mass after water permeates to the site. The first scenario considers water at pH 7. Water is capable of hydrolyzing certain polymers (e.g., polyglycolic acid), intended to degrade, at a significant rate (Chapter 1.3.2F and Zaikov, 1985). However, this simple hydrolysis mechanism is unlikely to be significant in polymer compositions selected for long-term in vivo biostability.

Next, ion-catalyzed hydrolysis offers a likely scenario in body fluids. Extracellular fluids contain ions such as: H^+, OH^-, Na^+, Cl^-, HCO_3^-, PO_4^{3-}, K^+, Mg^{2+}, Ca^{2+}, and SO_4^{2-}. Organic acids, proteins, lipids, lipoproteins, etc., also circulate as soluble or colloidal components. It has been shown that certain ions (e.g., PO_4^{3-}) are effective hydrolysis catalysts, enhancing, for example, reaction rates of polyesters by several orders of magnitude (Zaikov, 1985). Ion catalysis may be a surface effect or a combined surface–bulk effect, depending on the hydrophilicity of the polymer. Very hydrophobic polymers (e.g., those containing <2% water of saturation) absorb negligible concentrations of ions. Hydrogels, on the other hand, which can absorb large amounts of water (>15% by weight) are essentially "sieves," allowing significant levels of ions to permeate and be absorbed with consequent bulk hydrolysis via acid, base, or salt catalysis.

Localized pH changes in the vicinity of the implanted device, which usually occur during acute inflammation or infection, can cause catalytic rate enhancement of hydrolysis (Zaikov, 1985). Organic components, such as lipoproteins, circulating in the bloodstream or in extracellular fluid, appear to be capable of transporting catalytic inorganic ions into the polymer bulk by poorly defined mechanisms.

Enzymes generally serve a classic catalytic function, altering the reaction rate (via ion or charge transfer) without being consumed by modifying activation energy, but not thermodynamic equilibrium. While enzymes function in extracellular fluids, they are most effectively transferred onto target substrates by direct cell contact (e.g., during phagocytosis). Hydrolytic enzymes or hydrolases (e.g., proteases, esterases, lipases, glycosidases) are named for the molecular structures they affect. They are cell-derived proteins which act as highly specific catalysts for the scission of water-labile functional groups.

Enzymes contain molecular chain structures and develop conformations that allow "recognition" of chain sequences (receptors) predominately found on biopolymers. Complexes form between chain segments of the enzyme and the biopolymer substrate which result in enhanced bond cleavage rates. Lacking the recognition sequences of susceptible natural polymers, most synthetic polymers are more resistant to enzymatic degradation than natural polymers. Nevertheless, comparative studies have shown some enhancement of hydrolysis rates by enzymes, particularly with synthetic polyesters and polyamides (Kopecek and Ulbrich, 1983; Zaikov, 1985; Smith et al., 1987). Apparently, the enzymes can recognize and interact with structural segments of the polymers, or more accurately, of the polymers coated with serum proteins, to initiate their catalytic action in vivo (Pitt, 1992).

Enzymes with demonstrated effects on hydrolysis rates can be quite selective in the presence of several hydrolyzable functional groups. For example, poly(ether urethane ureas) and poly(ester urethane ureas) exposed to hydrolytic enzymes (an esterase, cholesterol esterase, and a protease, elastase) were observed for rate of hydrolysis and hydrolytic site. Enzyme catalysis was clearly observed for the ester groups, while the hydrolytically susceptible urea, urethane, and ether groups did not show significant hydrolysis, as indicated by release of radiolabeled degradation products (Santerre et al., 1994; Labow et al., 1995, 2002a).

Many enzymes exert predominantly a surface effect because of their molecular size, which prevents absorption. Even hydrogels [e.g., cross-linked poly(acrylamide)], which are capable of absorbing certain proteins, have molecular weight cut-offs for absorption, and can exclude large enzymes. However, as the degrading surface becomes roughened or fragmented, enzymatic action may be enhanced as a result of increased surface area if the substrates remain accessible to phagocytic cells that express the active enzymes. Implanted devices that are in continuous motion relative to neighboring tissue can provoke inflammation, stimulating enzyme release.

Hydrolysis: Preclinical and Clinical Experience

A discussion of in vivo responses of several prominent polymer compositions known to be susceptible to hydrolysis follows. The structures of these polymers are described in Chapter 1.3.2.

Polyesters. Poly(ethylene terephthalate) (PET), in woven, velour, or knitted fiber configurations, remains a primary choice of cardiovascular surgeons for large-diameter vascular prostheses, arterial patches, valve sewing rings, etc. In extruded, drawn form, it is a strong, flexible polymer, stabilized by high crystallinity as a result of chain rigidity and

orientation, and is often considered to be biostable. Yet, over several decades, there have been numerous reports of long-term degeneration of PET devices in vivo, owing to breakage of fibers and device dilation. Proposed causes have been structural defects, processing techniques, handling procedures, and hydrolytic degradation (Cardia and Regina, 1989).

Systematic studies of PET implants in healthy dogs have shown slow degradation rates, which were estimated to be equivalent to those in humans. For woven patches implanted subcutaneously, a mean total absorption time by the body of 30 ± 7 years, with 50% deterioration of fiber strength in 10 ± 2 years was projected. In infections in dogs, however, where localized pH dropped to as low as 4.8, degradation was enhanced exponentially, with complete loss of properties within a few months (Zaikov, 1985). Human implant retrieval studies have shown significant evidence of graft infection (Gumargalieva et al., 1982; Vinard et al., 1991). Besides the obvious pathological consequences of infection, the enhanced risk of polymer degradation due to local pH and, perhaps, cell-derived oxidative agents is a cause for concern.

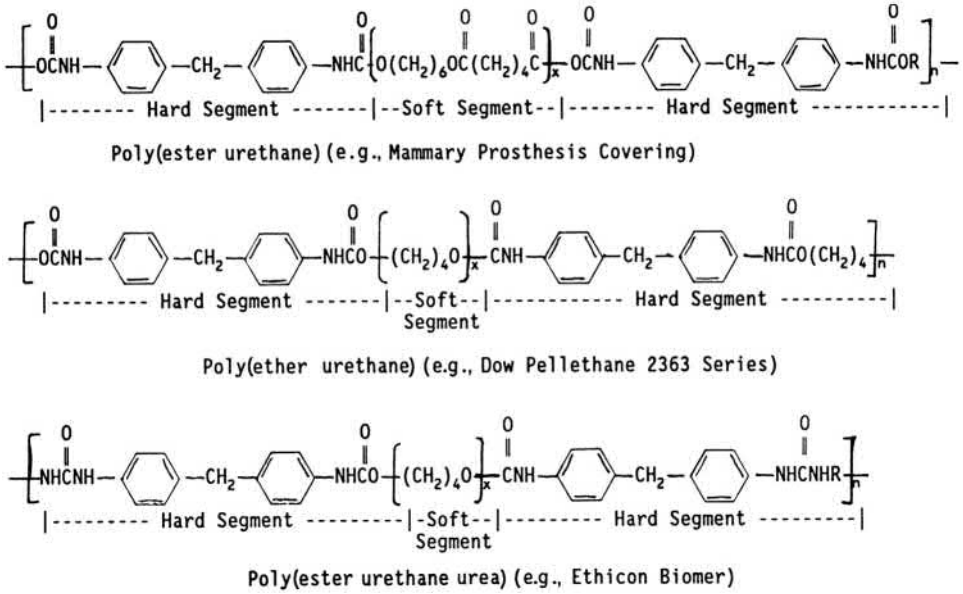
Aliphatic polyesters are most often intended for use as biodegradable polymers, with polycaprolactone, for example, undergoing a significant decrease in molecular weight, as indicated by a drop of 80%–90% in relative viscosity within 120 weeks of implant (Kopecek and Ulbrich, 1983).

Poly(Ester Urethanes). As an introduction to segmented polyurethanes in general, aromatic hard segments offer advantages over aliphatic ones for their higher physical properties and resistance to chemical degradation, and aromatic polyurethanes constitute the majority of polyurethanes used in long-term implants (Lamba et al., 1998). Whatever degradation is stated for aromatic polyurethanes, with the exception of discoloration, would be exceeded in the same tests for aliphatic polyurethanes.

The earliest reported implants of polyurethanes, dating back to the 1950s, were cross-linked, aromatic poly(ester urethane) foam compositions (Bloch and Hastings, 1972; Blais, 1990). Their use in plastic and orthopedic reconstructive surgery initially yielded promising results. Acute inflammation was low. Tissue ingrowth promoted thin fibrous capsules. However, within months they were degraded and fragmented, producing unsatisfactory chronic effects (Bloch and Hastings, 1972). Foci of initial degradation of those polymers are generally considered to be the polyadipate ester soft segments that undergo hydrolysis (Fig. 2.4.2.3). By comparison, corresponding poly(ether urethanes) are very resistant to hydrolysis, although more susceptible to oxidation (see Section Oxidative Biodegradation). Whether such hydrolytically degraded poly(ester urethanes) subsequently produce meaningful levels of aromatic amines (suspected carcinogens) by hydrolysis of urethane functions in vivo is an unresolved subject (Blais, 1990; Szycher and Siciliano, 1991).

An excellent analysis of historical references to the consideration of the carcinogenicity of aromatic polyurethanes was published by Pinchuk (1994). His literature search demonstrated that, among the few suspected human cases of device-related carcinogenicity at that time (Schoen, 1987), none were assigned to polyurethanes. However, "solid state tumors" can be induced preclinically as described in the following paragraph.

Several other points are noted. First, implantation of polyurethanes and other polymers in rodents leads to the formation of tumors as functions of their physical characteristics (size, shape, surface characteristics). Tumorigenesis, in such cases, is independent of the compositions of the polymers, as long as they reside in situ long enough to stimulate that response. Second, this effect, called the "Oppenheimer effect" (Oppenheimer et al., 1961) or "solid-state



• **Figure 2.4.2.3** Structure of implantable poly(ester urethane), poly(ether urethane), and poly(ester urethane urea).

tumorigenesis," which occurs in rodents, has not been shown to correlate with human implant studies. Finally, even studies of workers in polyurethane foam manufacturing plants experienced nonsignificant development of several types of neoplasms, all attributable to the free isocyanates (hydrolyzable to aromatic amines) with which they were working (Hagmar et al., 1993).

Therefore, the extensive use of aromatic polyurethanes in chronic implants continues with low concern for or observation of polyurethane carcinogenicity. It is noteworthy that poly(ester urethane) foam-coated silicone mammary implants had survived as commercial products for decades (Blais, 1990), despite the polyurethane's known propensity to degrade. Apparently, the type of fibrous capsules formed, initially by ingrowth into the degradable foam, was favored by some clinicians over those caused by smooth-walled silicone implants. In large devices not stabilized by tissue ingrowth, the frictional effects of sliding may cause increased capsule thickness and contraction (Snow et al., 1981), along with extensive chronic inflammation.

However, an important consideration recently published for mammary prostheses deserves brief mention. The FDA first published a warning of rare cancer incidence with textured implants above those of smooth implants in 2011 and updated it in 2019 (U.S. FDA, 2019). This update confirmed the greater, but not exclusive, occurrence of the rare lymphoma within the fibrous capsules of textured implants. It was noted that physical structure, not chemical composition, was the important variable.

Polysiloxane/Urethane Soft Segment Issues. This family of polymers is covered in the section on hydrolysis, as hydrolysis is postulated to be the major chemical mechanism of biodegradation. In 2006, the first new polyurethane biomaterial composition in decades was introduced as pacemaker/defibrillator lead insulation with improved biostability. It is an aromatic polyurethane with soft segments of mixed polysiloxane/polyether composition and a compatibilizing amount of poly(hexamethylene oxide) (Simmons et al., 2004; Padsalgikar, 2015). It demonstrated physical properties superior to silicone elastomers (Parmar, 2012). Some studies showed improved, but not total, degradation resistance of this polymer family when compared to softer (Shore 80 A hardness) poly(ether urethanes) formerly introduced as pacing lead insulation (St. Jude Medical, Inc., 2012). Consequently, since cardiac leads can be implanted for decades, a history of commercial use is being accumulated.

Literature of the marketer (formerly St. Jude Medical, now Abbott) of this "silicone/urethane" copolymer indicates that longevity performance of leads insulated with this copolymer in human implants is comparable to the highest performing poly(ether urethanes) (Shore 55D hardness) in similar applications (St. Jude Medical, 2012). These harder poly(ether urethanes), although considered by some as being stiffer than optimal for use in endocardial pacing leads, have been well adapted by design innovations for such purposes. Abbott's (2019) product performance publication indicates satisfactory survival probability for its silicone/urethane-based bradycardia and defibrillator leads. The latter, having insulation more susceptible to degradation, demonstrates a 10-year survival probability range of 78%–98% (Abbott, 2019).

Regarding the mechanisms of failure of the silicone/urethane pacing lead insulation, two hypotheses have been presented, one based on physical, the other based on chemical, degradation. Articles published by cardiologists indicate that abrasion of the insulation leads to breaches and failures (Hauser et al., 2013). This may be due to the "hybrid" structure of silicone/urethanes, incorporating components of both low (silicones) and high (polyurethanes) abrasion resistance where intermediate abrasion resistance and, therefore, toughness, may be hypothesized. The second hypothesis of failure of silicone/urethanes is susceptibility of linear poly(dimethyl siloxane), i.e., silicone, moieties to hydrolysis. Studies involving accelerated aging of the silicone/urethanes in aqueous environments indicated such a mechanism (Chaffin et al., 2012). This phenomenon is known for linear silicones' environmental degradation (Griessbach and Lehmann, 1999; Graiver et al., 2003). The hydrolysis mechanism seems rational since, as, for other hydrolyzable functional groups stated above, siloxanes are formed by the dehydration of silanols which should be reversible by hydrolysis. To conclude this subsection, silicone/urethane copolymers constitute a viable alternative to other polyurethane compositions, but, for defibrillator lead insulation in particular, they display some characteristics that allow some level of biodegradation. That said, all major pacemaker manufacturers have experienced defibrillator lead recalls for various reasons (Thomas, 2012), emphasizing the ongoing and specifically serious biodegradation problems for this important device component.

Polyamides. Nylon 6 (polycaproamide) and nylon 6,6 [poly(hexamethylene adipamide)] contain a hydrolyzable amide connecting groups, as do proteins. A significant use for polyamides is as "nonabsorbable" sutures (Chen et al., 1993). These synthetic polymers can absorb 9%–11% water, by weight, at saturation. It is predictable, then, that they degrade by ion-catalyzed surface and bulk hydrolysis (Fig. 2.4.2.1). In addition, hydrolysis due to enzymatic catalysis leads to surface erosion (Zaikov, 1985). Quantitatively, nylon 6,6 lost 25% of its tensile strength after 89 days, and 83% after 726 days in dogs (Kopecek and Ulbrich, 1983). An example of polyamide degradation of particular consequence involved the in vivo fragmentation of the nylon 6 tail string of an intrauterine contraceptive device. This string consisted of a nylon 6-sheath around nylon 6 multifilaments. The combination of fluid absorption (>10%) and hydrolysis was claimed to produce environmental stress cracking. The cracked coating allegedly provided a pathway for bacteria to travel from the vagina into the uterus along the filaments, resulting in significant pelvic inflammatory disease (Hudson and Crugnola, 1987).

Degradation of a poly(arylamide) intended for orthopedic use (the fiber-reinforced polyamide from *m*-xylylene

diamine and adipic acid) was also shown in a rabbit implant study. Although the material provoked a foreign body reaction comparable to a polyethylene control, surface pitting associated with resolving macrophages was noted at 4 weeks and became more pronounced by 12 weeks. This result was not predicted, since poly(arylamides) are very resistant to solvents and heat (Finck et al., 1994).

Polyamides with long aliphatic hydrocarbon chain segments [e.g., poly(dodecanamide), Nylon 12] (Duke Extrusion.com, Copyright, 2019) such as that used for intraarterial balloon catheters are more hydrolytically stable than shorter-chain nylons, and correspondingly degrade slower in vivo.

Poly(Alkyl Cyanoacrylates). This class of polymers used as tissue adhesives is noteworthy as a rare case in which carbon–carbon bonds are cleaved by hydrolysis (Fig. 2.4.2.1). This occurs because the methylene ($–CH_2–$) hydrogen in the polymer is highly activated inductively by electron-withdrawing neighboring groups. Formation of the polymer adhesive from monomers is base catalyzed, with adsorbed water on the adherend being basic enough to initiate the reaction.

Catalysts for equilibrium reactions affect the reverse, as well as the forward, reaction. Therefore, water associated with tissue can induce poly(cyanoacrylate) hydrolysis by a "reverse Knoevenagel" reaction (Fig. 2.4.2.1). More basic conditions and (as suggested by in vitro cell culture or implant studies) enzymatic processes are much more effective at inducing hydrolysis. In chick embryo liver culture (a rich source of a variety of enzymes), poly(methyl cyanoacrylate) degraded much faster than in cell culture medium alone. In animal implants, poly(methyl cyanoacrylate) was extensively degraded within 4–6 months (Kopecek and Ulbrich, 1983). Higher alkyl (e.g., butyl) homologs degraded slower than the methyl homolog, and were less cytotoxic (Hegyeli, 1973; Vauthier et al., 2003). Octyl cyanoacrylate polymer, introduced to the device field as a dermal tissue adhesive (Singer et al., 2008), promises to be the most stable cyanoacrylate device composition to date, based on increased hydrophobicity. Preclinical and clinical studies have yielded promising results with the use of octyl cyanoacrylate as a surgical sealant (Barbarini Ferraz et al., 2009; Carr, 2011), and, more recently, a composition containing the monomers octyl cyanoacrylate and butyl lactoyl cyanoacrylate was FDA (US Food and Drug Administration) approved as a blood vessel anastomotic sealant (US FDA, 2010).

Polymers Containing Hydrolyzable Pendant Groups

Certain polymers intended for long-term implantation consist of biostable main chain sequences and hydrolyzable pendant groups. Poly(methyl methacrylate) (PMMA) used in bone cements and intraocular lenses is an example of a hydrophobic polymer with a stable hydrocarbon main chain and hydrolyzable ester side groups. It has been proven, over decades of use, to provide reliable, stable service, with hydrolysis rates being so slow as to be inconsequential.

Another polymer system with a hydrocarbon backbone, poly(methyl acrylate-*co*-2-hydroxyethyl acrylate) also contains hydrolyzable ester side groups. This polymer, which forms hydrogels in an aqueous environment, has been used as a "scleral buckling" device for retinal detachment surgery. Basically, the dry polymer, shaped as a band or ring, placed as a "belt" around the sclera, expands through hydration to create an indentation in the zone of the retinal detachment to reestablish retinal contact. The device is left in place as a permanent implant (or "exoplant" as it is sometimes called because it is external to the sclera) (Braunstein and Winnick, 2002). This hydrogel device, introduced into clinical practice in the 1980s (Refojo and Leong, 1981; Colthurst et al., 2000), apparently performed satisfactorily for years as an approved product. However, in the 1990s, reports of long-term complications of these hydrogel scleral buckles began to surface (Hwang and Lim, 1997; Roldan-Pallares et al., 1999). The hydrogel structures resumed swelling, sometimes with fragmentation, after maintaining stable dimensions for years. One report described a difficult explantation 13 years after implantation (Braunstein and Winnick, 2002). An article described three unique complications from hydrogel scleral buckle use: orbital cellulitis mimicry; fornical shortening with orbital prosthetic intolerance; and orbital pseudotumor (Bernardino et al., 2006). Those buckles remained in place for 7–15 years, with a mean time of 10.7 years. In a study of 15 patients with 17 scleral buckles, all reported complications within 4–14 years (Figs. 2.4.2.4–2.4.2.6). Removal of the buckles was technically difficult and postoperative complications were significant, although immediate palliative relief was experienced after surgery. Pressure applied to the eye by the swelling has led to blindness and loss of the eyeball. Hydrogel scleral buckles are no longer used in retinal surgery (Watt, 2001).

• **Figure 2.4.2.4** A subconjunctival and subpalpebral hydrogel explant interferes with ocular motility, especially on attempted gaze up and to the right. (From Kearney, J.J., Lahey, J.M., Borirakchanyavat, S., Schwartz, D.M., Wilson, D., et al., 2004. Complications of hydrogel explants used in scleral buckling surgery. Am. J. Ophthalmol. 137 (1), 96–100.)

Very little speculation has been provided in published articles about the mechanism of failure of acrylate scleral buckling devices other than that chemical degradation has occurred (Roldan-Pallares et al., 1999). I suggest that a likely mechanism involves hydrolysis of the ester side groups enhanced by the hydrophilic nature of the polymer (as contrasted to hydrophobic polymers such as PMMA). Hydrolysis of either of the two acrylate esters in the polymer chain provides an acrylic acid moiety. Linear poly(acrylic acid) is fully water soluble, and each hydrolytic event renders the polymer more hydrophilic and subject to enhanced swelling. This process is slow but inexorable in the case of the scleral buckling device. The valuable lesson is that devices with intrinsically susceptible groups can eventually degrade by predictable mechanisms. This may take longer than is required for pivotal preclinical qualification studies (typically two-year animal implants). In fact, Bernardino et al. (2006), in discussing long-term hydrogel implants, warn: "Patients with newer uses of hydrogel, such as orbital expanders, should also be observed for long-term complications." If late degradation is suspected, therefore, accelerated aging studies should be performed in vitro with correlations made to in vivo studies. Such efforts give valuable, if not completely trustworthy, information (see Section Polymer Degradation Processes).

The sponge was removed at the same surgical sitting as the hydrogel explant. (From Kearney, J.J., Lahey, J.M., Borirakchanyavat, S., Schwartz, D.M., Wilson, D., et al., 2004. Complications of hydrogel explants used in scleral buckling surgery. Am. J. Ophthalmol. 137 (1), 96–100.)

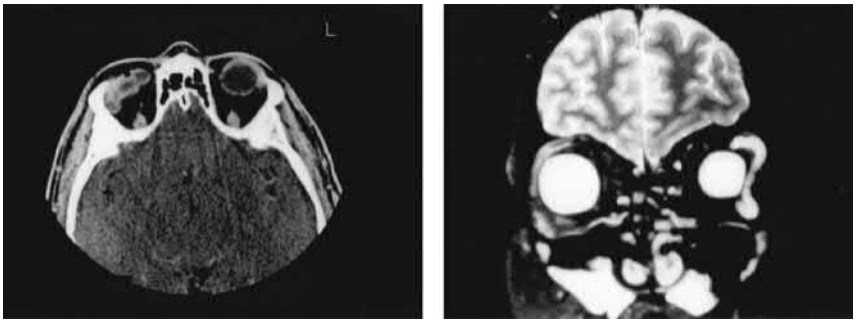
Oxidative Biodegradation

Oxidation Reaction Mechanisms and Polymer Structures

While much is known about the structures and reaction products of polymers susceptible to oxidative biodegradation, confirmation of the individual reaction steps has not yet been demonstrated analytically. Still, mechanistic inferences are possible from extensive knowledge of physiological oxidation processes and polymer oxidation in vitro.

The polymer oxidation processes to be discussed may be consistent with a homolytic chain reaction or a heterolytic mechanism. Species such as carbonyl, hydroxyl, and chain scission products are detectable in these types of processes. Classic initiation, propagation, and termination events for homolysis and ionic heterolytic processes are detailed in Fig. 2.4.2.7.

The principles of polymer degradation resistance stated in the section on hydrolyzable polymers (e.g., group frequency, crystallinity, hydrophobicity) are valid for predicting relative oxidation resistance of polymers, except where particularly oxidation-susceptible groups are present. Sites favored for initial oxidative attack, consistent with a homolytic or heterolytic pathway, are those that allow abstraction of an atom or ion and provide resonance stabilization of the resultant radical or ion. Fig. 2.4.2.8 provides a selection of readily oxidized groups and the atom at which initial attack occurs. In Fig. 2.4.2.9, examples of radical and ion stabilization by resonance in ether and branched hydrocarbon structures are provided. Peroxy, carbonyl, and other radical intermediates are stabilized by similar resonance delocalization of electrons from the elements C, O, H, or N. Within Fig. 2.4.2.9, a coupling reaction which can lead to polymer cross-linking as a consequence of oxidative degradation is shown. Fig. 2.4.2.10



• **Figure 2.4.2.6** (Left panel) Computed tomography scan showing a hydrogel implant in the anterior orbit of the right eye. (Right panel) Magnetic resonance image of the left orbit shows an expanded hydrogel explant. (From Kearney, J.J., Lahey, J.M., Borirakchanyavat, S., Schwartz, D.M., Wilson, D., et al., 2004. incorporates the points made in the previous three figures and illustrates the general sequence of oxidative degradation of an ether function by cleavage at the carbon–oxygen bond which would lead to chain scission of polyether-containing polymers.

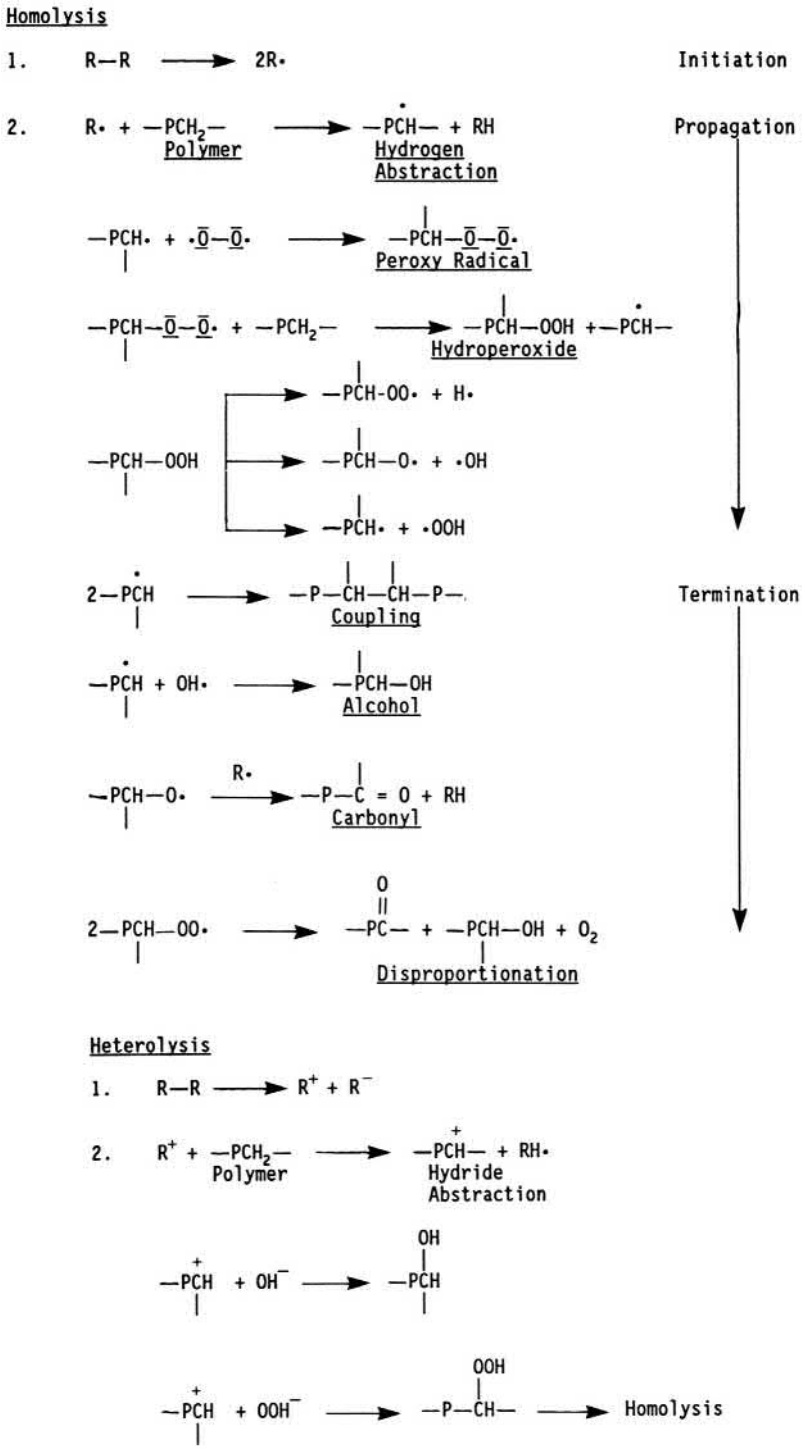
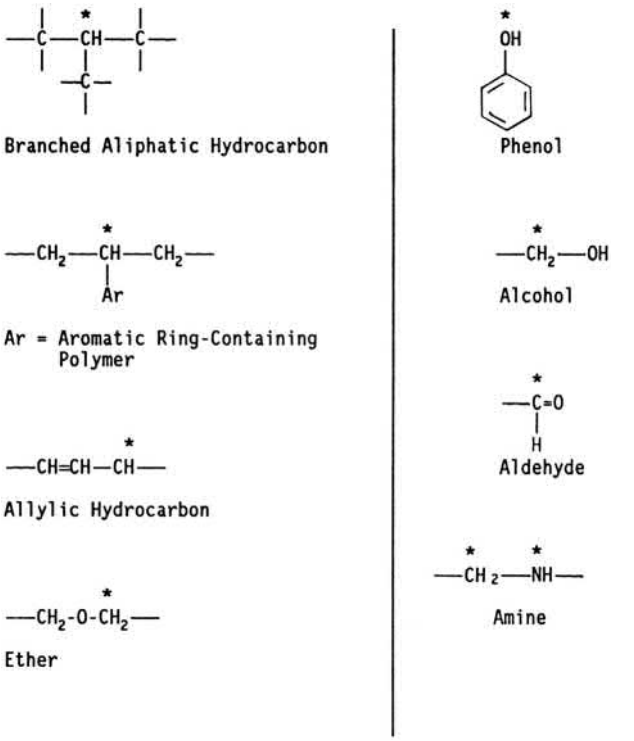
Two general categories of oxidative biodegradation, based on the source of initiation of the process, are direct oxidation by the host and external environment-mediated oxidation.

Direct Oxidation by Host

In these circumstances, host-generated molecular species effect or potentiate oxidative processes directly on the polymer. Current thinking, based on solid analytical evidence, is that such reactive molecules are derived from activated phagocytic cells responding to the injury and the properties of the foreign body at the implant site (Zhao et al., 1991). The two major types of these cells are the neutrophils



• **Figure 2.4.2.7** Proposed homolytic chain reaction and heterolytic oxidation mechanisms.



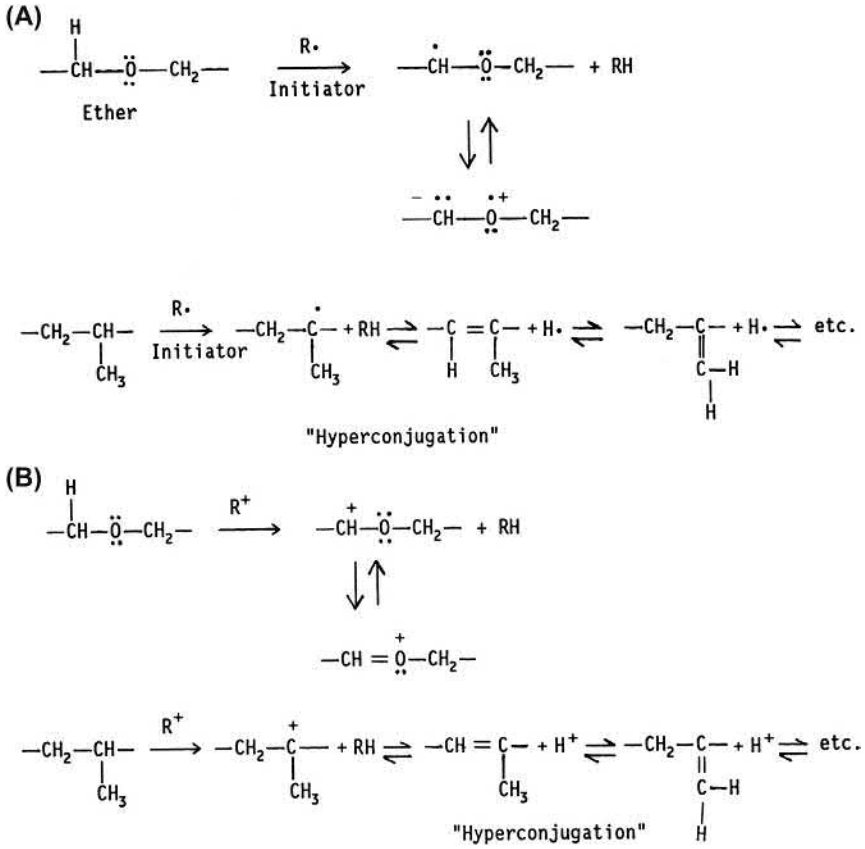
• **Figure 2.4.2.8** Readily oxidizable functional groups (* is the site of homolysis or heterolysis).

(polymorphonuclear leukocytes, PMNs) and the monocytes. The latter, which are found in circulation, can differentiate upon attachment to tissue and divide into macrophage and foreign-body giant cell (FBGC) phenotypes (see Chapter 2.2.2) (Ziats, 1988).

Much work is under way to elucidate the sequence of events leading to phagocytic oxidation. Certain important processes of wound healing in the presence of biologically derived foreign bodies such as bacteria and parasites have shown some relevance to biomaterial implants (Northup, 1987).

Neutrophils, responding to chemical mediators at the wound site, mount a powerful but transient chemical attack within the first few days of injury (Test and Weiss, 1986; Northup, 1987). Chemically susceptible biomaterials may be affected if they are in close apposition to the wound site (Sutherland et al., 1993). Activated macrophages subsequently multiply and subside within days at a benign wound site or in weeks if stimulants such as toxins or particulates are released at the site. Their fusion products (FBGCs) can survive for months to years on the implant surface. Macrophages also remain resident in the collagenous foreign-body capsule for extended periods.

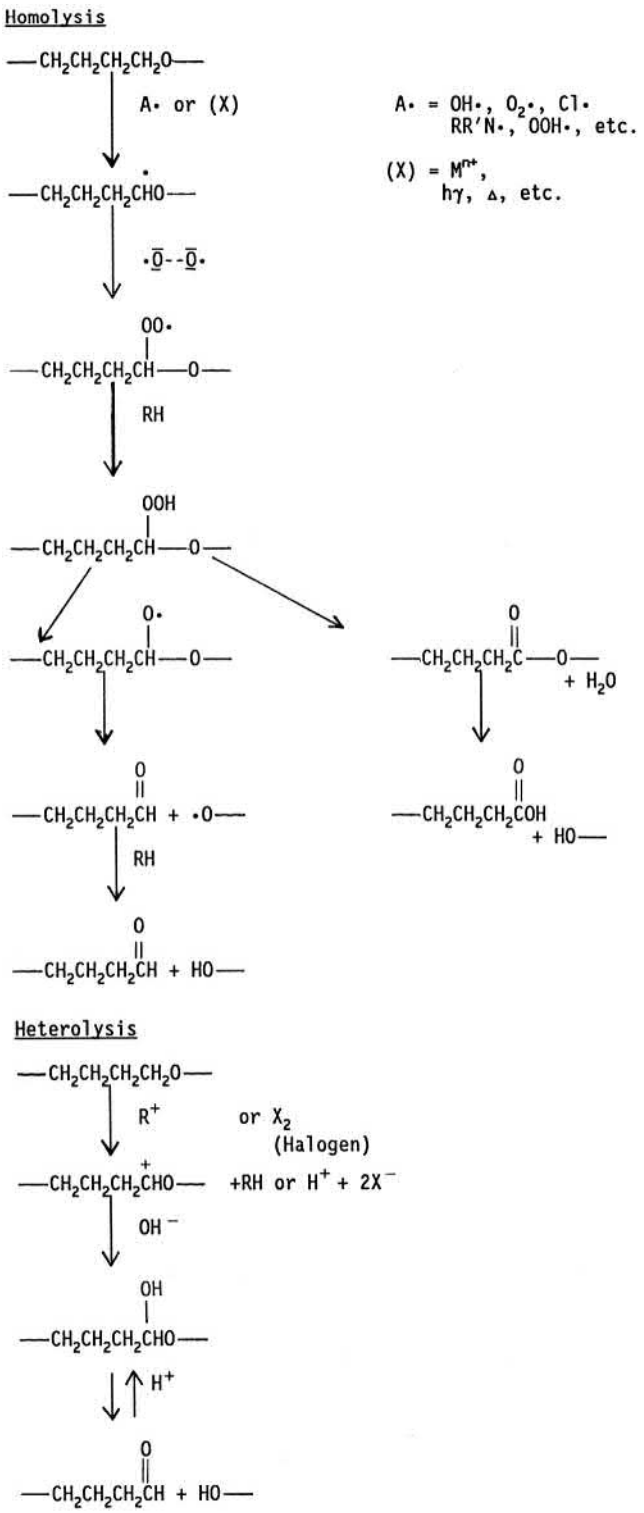
While it is recognized that the complete mechanism of cellular attack and oxidation of biomaterials is as yet



• **Figure 2.4.2.9** (A) Resonance stabilization of ether and hydrocarbon radicals; (B) resonance stabilization of ether and hydrocarbon cations.

unconfirmed, the following discussion attempts to provide logical biological pathways to powerful oxidants capable of producing known degradation products.

Both PMNs and macrophages metabolize oxygen to form a superoxide anion ($O_2^{\bullet -}$). This intermediate can undergo transformation to more powerful oxidants, and conceivably can initiate homolytic reactions on the polymer. Superoxide dismutase (SOD), a ubiquitous peroxidase enzyme, can catalyze the conversion of superoxide to hydrogen peroxide which, in the presence of myeloperoxidase (MPO) derived from PMNs, is converted to hypochlorous acid (HOCl). A potent biomaterial oxidant in its own right (Coury et al., 1987), hypochlorite $(ClO^-)_2$ can oxidize free amine functionality (e.g., in proteins) to chloramines which can perform as long-lived sources of chlorine oxidant (Test and Weiss, 1986; Figs. 2.4.2.11 and 2.4.2.12). Hypochlorite can oxidize other substituted nitrogen functional groups (amides, ureas, urethanes, etc.) with potential chain cleavage of these groups.



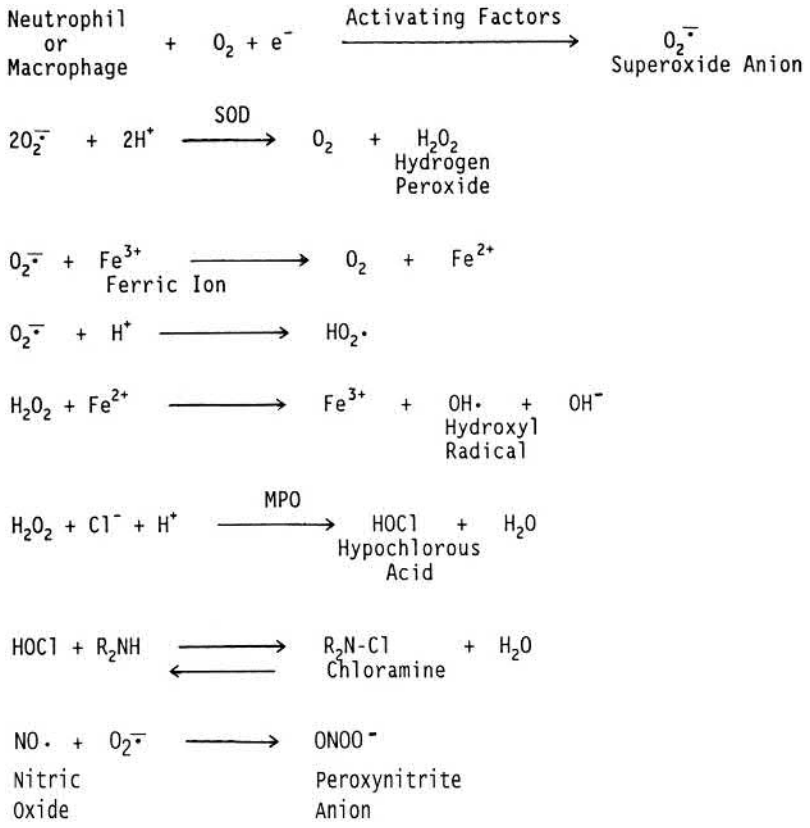
• **Figure 2.4.2.10** Pathways for oxidative fragmentation of polyethers.

The following paragraphs describe potential cooperative reactions involving acquired peroxidase and free ferrous ions. Macrophages contain essentially no MPO, so their hydrogen peroxide is not normally converted to HOCl. However, PMN-derived MPO can bind securely to foreign-body surfaces (Locksley et al., 1982), and serve as a catalyst reservoir for macrophage- or FBGC-derived HOCl production. If free ferrous ion, which is normally present in negligible quantities in the host, is released to the implant site by hemolysis or other injury, it can catalyze the formation of the powerfully oxidizing hydroxyl radical via the Haber–Weiss cycle (Klebanoff, 1982; Fig. 2.4.2.10).

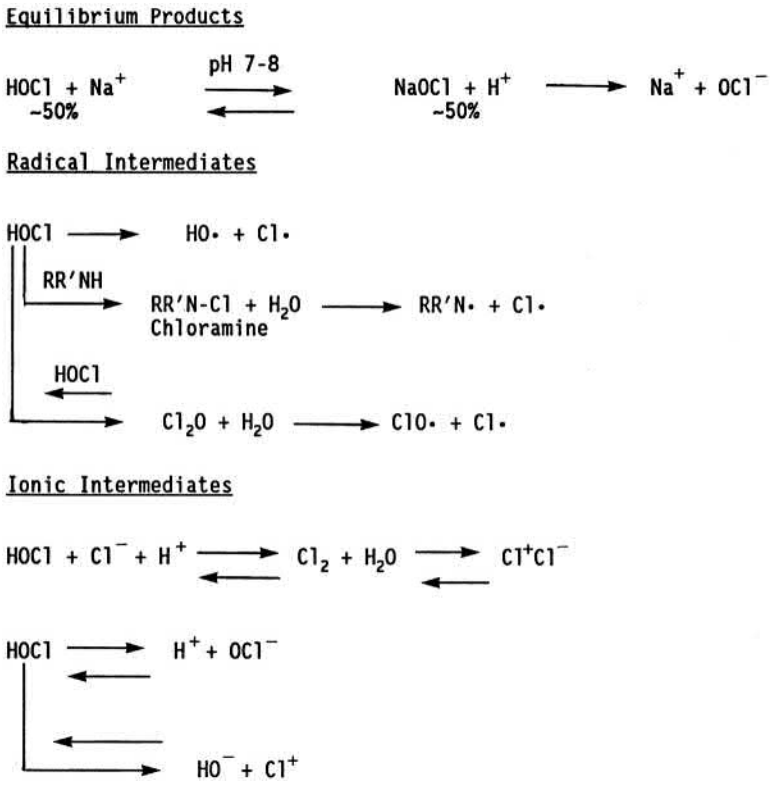
Fig. 2.4.2.11 shows radical and ionic intermediates of HOCl that may initiate biomaterial oxidation. Fig. 2.4.2.12 is a diagram showing a leukocyte phagocytic process that employs endogenous MPO catalysis of HOCl formation. In a more general sense, the MPO may come from within or outside of the cell.

The foregoing discussion of sources of direct oxidation is focused primarily on acute implant periods in which bursts of PMN activity followed by macrophage activity normally resolve within weeks. However, since the foreign body subsequently remains implanted, a sustained if futile attempt to phagocytose an implanted device provides a prolonged release of chemicals onto the biomaterial. This phenomenon, called exocytosis, occurs over months to possibly years (Zhao et al., 1990), and results primarily from the macrophage-FBGC line. It can contribute to long-term chemical degradation of the polymer. The oxidation processes induced by phagocytes are the result of oxidants produced by the general foreign-body response (innate immune response), not direct receptor–ligand catalysis by oxidase enzyme (adaptive immune response). Attempts to degrade oxidatively susceptible polymers by direct contact with oxidase enzymes have produced short-range or limited effects (Sutherland et al., 1993; Santerre et al., 1994).

Macrophages mediate other processes, such as fibrous capsule formation, around the device. Their release of cellular regulatory factors stimulates fibroblasts to populate the implant site and produce the collagenous sheath. Any knowledge of the effects of factors such as fibroblasts or fibrous capsules on rates and mechanisms of polymer degradation is, at this time, incompletely understood.



• **Figure 2.4.2.11** Generation of potential oxidants by phagocytic processes.



• **Figure 2.4.2.12** Hypochlorous acid: formation and potential reaction intermediates.

Stress Cracking

An important category of host-induced biodegradation with an oxidative component is stress cracking as manifested in poly(ether urethane) elastomer implants. It differs from classic environmental stress cracking (ESC), which involves a susceptible material at a critical level of stress in a medium that may permeate and swell the polymer but does not dissolve the polymer. Classic ESC is not accompanied by significant chemical degradation (Stokes, 1988). In contrast, stress cracking of polyurethanes is characterized by surface attack of the polymer, and by chemical changes induced by relatively specific in vivo or in vitro oxidizing conditions. Conditions relevant to stress cracking of certain poly(ether urethane) compositions are stated in Table 2.4.2.3.

Experimental information on the stress cracking of poly(ether urethanes) and poly(ether urethane ureas) (e.g., the polymers described in Fig. 2.4.2.3) has provided insights which may be valid for these and other compositions that can be oxidized, for example, polypropylene (Liebert et al., 1976; Altman et al., 1986) or polyethylenes (Wasserbauer et al., 1990; Zhao et al., 1995).

Poly(ether urethane) compositions containing low polyether content, which are resistant to degradation in vivo, are used as connectors (also called "headers"), insulators, and adhesives for cardiac pacemakers and neurological stimulators (Fig. 2.4.2.13). They have performed with high reliability in chronic clinical applications since 1975. Certain poly(ether urethane) pacing leads have displayed surface cracks in their insulation after residence times in vivo of months to years. These cracks are directly related in frequency and depth to the amount of residual stress (Figs. 2.4.2.14 and 2.4.2.15) and the ether (soft segment) content of the polyurethane (Coury et al., 1987; Martin et al., 2001).

Morphologically, the rough-walled cracks display regular patterns predominately normal to the force vectors, occasionally with "tie fibers" bridging the gaps, indicative of ductile rather than brittle fracture (Figs. 2.4.2.16 and 2.4.2.17). Infrared (IR) analysis indicates that oxidation does not take place detectably in the bulk, but only on the surface where extensive loss of ether functionality (as seen in the ether IR stretch, 1110 cm^{-1}) and enhanced absorption in the hydroxyl and carbonyl regions are observed (Stokes et al., 1987). Possible mechanisms for the oxidative degradation of ethers are

TABLE 2.4.2.3 Characteristics of Poly(Ether Urethanes) That Cracked In Vivo

Components contained residual processing and/or applied mechanical stresses/strains
Components were exposed to a medium of viable cellular and extracellular body constituents
Polymers had oxidatively susceptible (aliphatic ether) groups
Analysis of polymers showed surface oxidation products

presented in Fig. 2.4.2.18. The participation of molecular oxygen in the degradation mechanism is supported by studies which showed that poly(ether urethane urea) degradation in vitro correlated with oxygen diffusion into the polymer bulk after surface oxidation was initiated by hydrogen peroxide/cobalt chloride (Schubert et al., 1997a,b).

In a seminal study, Zhao et al. (1990) placed polyurethane tubing under strain in cages permeable to fluids and cells (therefore under high initial stress, which was subject to subsequent stress relaxation), and implanted them in rats. In certain cases, antiinflammatory steroids or cytotoxic polymers were coimplanted in the cages. Implants of up to 15 weeks were retrieved. The only prestressed samples to crack were those that did not reside in the cages with the cytotoxic coimplants. The authors concluded that adherent cells caused the stress cracking, and cell necrosis or deactivation inhibited crack induction.

Subsequently, viable phagocytic cells were implicated as a cause of crack initiation in vivo (Zhao et al., 1991). By removing adherent foreign-body giant cells after 10-week implantation of a curved poly(ether urethane urea) film in a wire cage, exposed foreign-body cell "footprints" showed localized surface cracking in the order of several microns deep and wide.

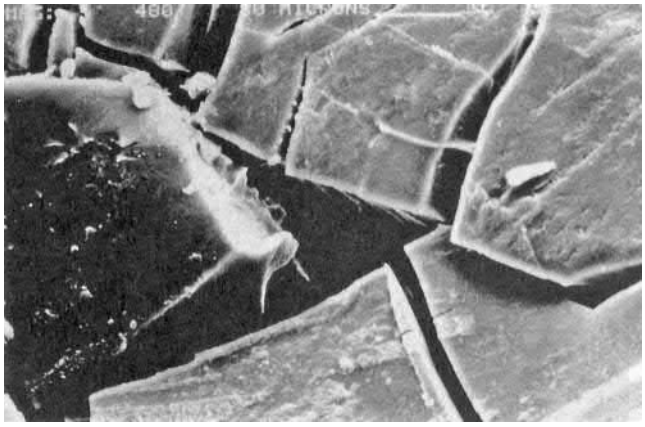
Adjacent areas of polymer which were devoid of attached cells were not cracked. Owing to relatively low stresses in the implanted film, deep crack propagation was not observed.

In vitro studies of strained (Stokes, 1988) and unstrained poly(ether urethane) films (Phua et al., 1987; Ratner et al., 1988; Bouvier et al., 1991; Wiggins et al., 2003) using oxidants, enzymes, etc., have sought to duplicate in vivo stress cracking. Although some surface chemical degradation with products similar to those seen in vivo was demonstrated, stress crack morphology was most closely matched in vitro in two studies. A test which involves immersing stressed poly(ether urethane) tubing in a medium of glass wool, hydrogen peroxide, and cobalt chloride produces cracks which duplicate those produced in vivo, but with rate acceleration of up to seven times (Zhao et al., 1995). These investigators also showed that human plasma proteins, particularly alpha-2-macroglobulin and ceruloplasmin, enhance in vitro stress cracking by oxidants in patterns morphologically similar to those observed in vivo (Zhao et al., 1993). The potential of macrophages to contribute to stress cracking of poly(ether urethanes) was verified in an in vitro study which succeeded in potentiating macrophage oxidative effects with ferrous chloride, and inhibiting them with the antiinflammatory steroid dexamethasone (Casas et al., 1999). In another study, comparable crack patterns were produced when specimens of stressed tubing in rats were compared with those incubated with PMNs in culture (Sutherland et al., 1993). Moreover, this study revealed a difference in chemical degradation products with time of implants which correlated with products from oxidants generated primarily by PMNs (HOCl) and macrophages ($ONOO^-$). Early implant times, activated PMNs, and HOCl caused a preferential decrease in the urethane oxygen stretch peak, while longer implant times and $ONOO^-$ caused selective loss of the aliphatic ether stretch peak (by infrared spectroscopy).

Taken together, the foregoing observations are consistent with a hypothesized two-step mechanism for stress cracking in vivo. In the first step, surface oxidation induces very shallow, brittle microcracks. The second step involves propagation of the cracks in which specific body fluid components act on the formed cracks to enhance their depth and width, without inducing major detectable bulk chemical reactions. Should this hypothesis prove correct, the term "oxidation-initiated stress cracking" would be reasonably descriptive.

The above description of stress cracking has generally considered static stress, such as that entrained in polymers during the cooling of molten parts, or the assembly of components. Dynamic stresses and strains such as those occurring during cooling with stretching as with extruded tubing or by the operation of diaphragm or bladder heart pumps or artificial joints can cause related cracking in areas of high flex. The cracking has been purported to increase with time of device operation, but to display only minor surface chemical changes (Tomita et al., 1999; Wu et al., 1999).

The stress cracking related to entrained stress in the polymer has been controlled by reducing residual stress, isolating the polymer from cell contact (Tang et al., 1994), protecting the polymer from stress-cracking media, or using stress crack-resistant polymers (e.g., in the case of polyurethanes, ether-free compositions) (Coury et al., 1990; Takahara et al., 1994; Tanzi et al., 1997), and use of antioxidants such as hindered phenols (e.g., vitamin E, Monsanto Santowhite powder) (Schubert et al., 1997a,b). Stress cracking is next compared with another type of degradation, metal ion-induced oxidation.



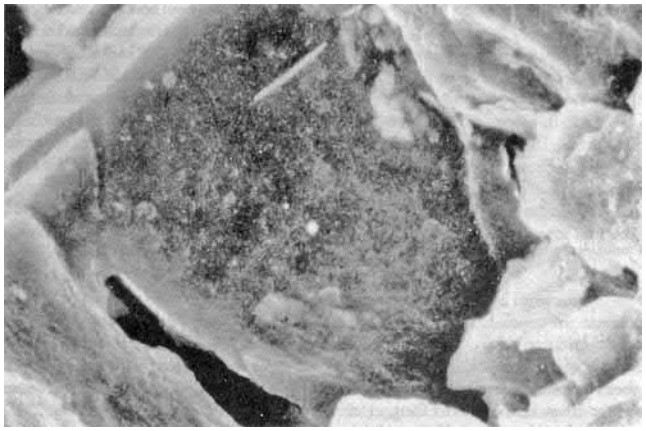
• **Figure 2.4.2.19** Random crack pattern of Pellethane 2363-80A lead insulation caused by metal ion-induced oxidation (×480).

Particularly alpha-2-macroglobulin and ceruloplasmin, enhance in vitro stress cracking by oxidants in patterns morphologically similar to those observed in vivo (Zhao et al., 1993).

Device- or Environment-Mediated Oxidation

Metal Ion-Induced Oxidation. A process of oxidative degradation that has, thus far, primarily been reported clinically for poly(ether urethane) pacemaker leads, requires, as does stress cracking, a very specific set of conditions. The enabling variables and fracture morphology are quite different from stress cracking, although oxidative degradation products are similar. Biodegradation of implanted devices through stress cracking always occurs on polymer surfaces exposed to living cells and provides characteristic rough-walled fissures (indicative of ductile fracture) oriented perpendicular to the stress vector (Figs. 2.4.2.14–2.4.2.17). Metal ion-induced oxidation initiates on the enclosed inner surfaces of pacing lead insulation near corroded metallic components and their entrapped corrosion products. Smooth crack walls and microscopically random crack orientation is indicative of brittle fracture (Figs. 2.4.2.19 and 2.4.2.20). Macroscopically, crack patterns that track metal component configurations may be present (Fig. 2.4.2.21). Degradation products that may be found deeper in the bulk than with stress cracking are again indicative of brittle fracture.

This phenomenon, called metal ion-induced oxidation (MIO), has been confirmed by in vitro studies, in which poly(ether urethanes) were aged in metal ion solutions of



• **Figure 2.4.2.20** Smooth crack wall indicative of brittle fracture caused by metal ion-induced oxidation (×830).

• **Figure 2.4.2.21** Crack pattern on inner lumen of poly(ether urethane) lead insulation tracking coil imprint indicative of metal ion-induced oxidation (×100).

different standard oxidation potentials. Above an oxidation potential of about +0.77, chemical degradation was severe. Below that oxidation potential, changes in the polymer that are characteristic of simple plasticization were seen (Coury et al., 1987, Table 2.4.2.4). This technique also showed that metal ion-induced oxidation was proportional to the ether content of the polyurethane (Table 2.4.2.5).

The effect of various metals on oxidation in vitro and in vivo has also been studied. Different metallic components of pacing lead conductors were sealed in poly(ether urethane) (Dow Pellethane 2363-80A) tubing and immersed in 3% hydrogen peroxide at 37°C for up to 6 months (Stokes et al., 1987) or implanted in rabbits for up to 2 years (Stokes et al., 1990). Both techniques resulted in corroded metals and degraded tubing lumen surfaces under certain conditions within 30 days. In particular, the in vivo interaction of body fluids with cobalt and its alloys resulted in oxidative cracking of the polymer.

The metal ion-induced oxidation process clearly involves corrosion of metallic elements to their ions, and subsequent oxidation of the polymer. In operating devices, the metal ion may be formed by solvation, galvanic or electrolytic corrosion, or chemical or biochemical oxidation (Fig. 2.4.2.22).

TABLE 2.4.2.4 Effect of Metal Ion Oxidation Potential on Properties of Poly(Ether Urethane) (Pellethane 2363-80A)[a]

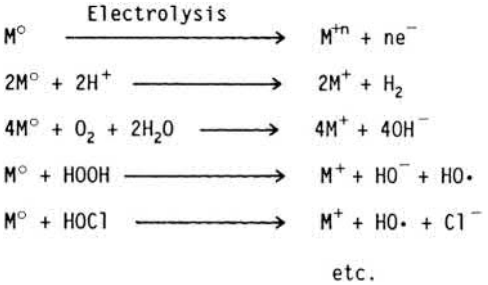
Aqueous Solution	Standard Oxidation Potential	Change in Tensile Strength (%)	Change in Elongation (%)
$PtCl_2$	~ +1.2	–87	–77
$AgNO_3$	+0.799	–54	–42
$FeCl_3$	+0.771	–79	–10
Cu_2Cl_2	+0.521	–6	+11
$Cu_2(OAc)_2$	+0.153	–11	+22
$Ni(OAc)_2$	–0.250	–5	+13
$Co(OAc)_2$	–0.277	+1	+13

[a]Conditions: 0.1 M solutions/90°C/35 days versus controls aged in deionized water; ASTM (D-1708) microtensile specimens; specimens were tested wet.

TABLE 2.4.2.5 Effect of Ether Content of Poly(Ether Urehane) on Susceptibility to Metal Ion-Induced Oxidation[a]

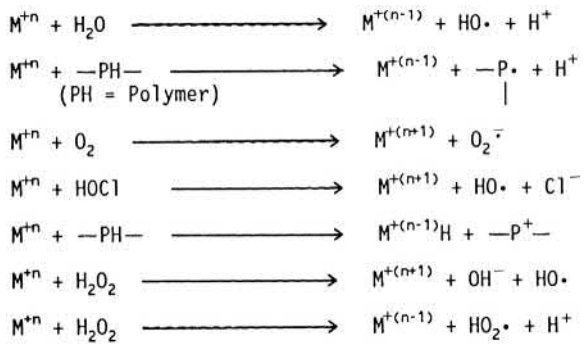
Poly(Ether Urethane)	Polyether Content	Change in Tensile Strength (%)	Change in Elongation (%)
Pellethane 2363-80A	High	–54	–42
Pellethane 2363-55D	Low	–23	–10
Model segmented polyurethane	None	+9	+3

[a]Conditions: 0.1 M $AgNO_3$/90°C/35 days versus controls aged in deionized water; ASTM (D-1708) microtensile specimens.



• **Figure 2.4.2.22** Formation of metal ion from metal.

In turn, these metal ions develop oxidation potentials that may well be enhanced in body fluids over their standard half-cell potentials. As strong oxidants, they produce intermediates or attack the polymer to initiate the chain reaction (Fig. 2.4.2.23). Metal ion-induced oxidation is, therefore,



• **Figure 2.4.2.23** Initiation of oxidation pathways by metal ions.

the result of a highly complex interaction of the device, the polymer, and the body.

Should metal ion-induced oxidation, specifically, be a possibility in an implanted device, several approaches are available to control this problem. They are not universally applicable, however, and should be incorporated only if functionality and biocompatibility are retained. Potentially useful techniques include using corrosion-resistant metals, "flushing" corrosive ions away from the susceptible polymer, isolating the metals and polymer from electrolyte solutions, incorporating appropriate antioxidants, and using oxidation-resistant polymers.

Chemical Structure Strategies to Combat Oxidation

To address oxidation susceptibility, polyurethane elastomers with enhanced oxidation stability have been developed. They should be ester-free and ether-free or deficient, and generally contain unconventional soft segments, including, for example, hydrogenated polybutadiene, polyisobutylene, polydimethylsiloxane (subject to hydrolytic consideration, above), polycarbonate, and dimerized fatty acid derivatives (Coury et al., 1990; Pinchuk et al., 1991; Takahara et al., 1991, 1994; Kato et al., 1995; Mathur et al., 1997; Hernandez et al., 2007; Kang et al., 2010; Desai et al., 2011). In implant tests, they have shown reduced tendency to stress crack oxidatively, and some have shown high resistance to metal ion oxidants in vitro. Early attempts to stabilize polyurethanes by laminating more biostable polymers (such as silicone rubbers) to tissue-facing surfaces have met with limited success in dynamic applications, due to the delamination tendencies Pinchuk (1992).

Other approaches to stabilizing polyurethanes to oxidative attack in situ have involved the use of surface modifying ("blooming") macromolecules (SMMs) (Santerre et al., 2000), surface-modifying end groups (SMEs) (Ward et al., 1995, 1998), and, more recently, self-assembling monolayer end groups (SAMEs) (Ward, 2008). SMMs, typically fluorocarbon-based polymers, are blended with the polyurethanes during processing, and migrate to the surface prior to implantation. SMEs are moieties (typically polysiloxane) bonded to polyurethane as end groups. SAMEs are formed from molecules appended to the backbone of polymers during synthesis. Such molecules consist of three components: a chemically reactive group for conjugation to the polymer as it is being made; typically, a hydrophobic spacer chain, to provide self-assembly at the surface of the formed article; and a head group from a variety of surface chemistries to provide specific bioactivity. One potential function is to stabilize the polymer against biodegradation (Ward, 2008).

The covalently modified polyurethanes may be used in bulk or as additives to conventional polyurethanes. Both approaches have provided enhanced in vivo stability for polyurethane implants; however, the long-term effects of these treatments are not, as yet, confirmed. SMMs have been covalently modified with bioactive agents, such as antioxidants, to provide further degradation resistance (Ernsting et al., 2002).

All of the "barrier" strategies to protecting polyurethanes described above appear to have validity, at least for protecting polyurethanes in the short term. The long-term (multiyear) benefits of these approaches remain to be seen in light of issues such as surface dynamics, interfacial interactions, and coating durability.

All of these polyurethane modifications, while potentially providing enhanced resistance to biodegradation, still allow susceptibility to attack by biological components, often at a slow rate.

Oxidative Degradation Induced by External Environment

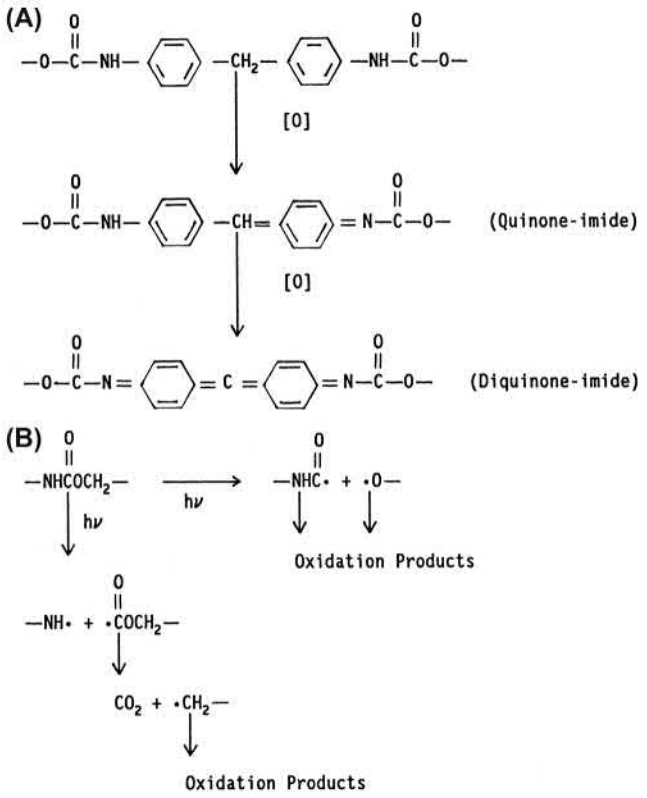
Under very limited circumstances, the body can transmit electromagnetic radiation that may affect the integrity of implanted polymers. For example, the cornea and vitreous humor of the eye, as well as superficial skin layers, allow the passage of long-wave (320–400 nm) "ultraviolet A" radiation. Absorption of ultraviolet radiation causes electron excitation that can lead to photooxidative degradation. This process has been suggested in the breakdown of polypropylene components of intraocular lenses (Altman et al., 1986; Jongebloed and Worst, 1986).

In maxillofacial exo- and very likely endoprostheses, elastomers may undergo undesirable changes in color and physical properties as a consequence of exposure to natural sunlight-frequency radiation (Craig et al., 1980). Photooxidation mechanisms involving the aromatic units and the urethane of aromatic poly(ether urethanes) or poly(ester urethanes) are shown in Fig. 2.4.2.24. Antioxidants and ultraviolet absorbers provide limited protection for these materials.

Emerging Long-Term Elastomer Applications

Polyurethanes

Three polyurethane families are now elaborated, the first for its broad-based popularity as an alternative to poly(ether



• **Figure 2.4.2.24** Photooxidative reactions of aromatic polyurethanes. (A) Formation of quinone-imide from aromatic polyurethane. (B) Photolytic cleavage of urethane link. (From Coury, A.J., Slaikeu, P.C., Cahalan, P.T., Stokes, K.B., Hobot, C.M., 1988. Factors and interactions affecting the performance of polyurethane elastomers in medical devices. J. Biomater. Appl. 3, 130–179. (B) From Brauman, S.K., Mayorga, G.D., Heller, J., 1981. Light stability and discoloration of segmented polyether urethanes. Ann. Biomed. Eng. 9, 45–58.)

urethanes), sometimes perhaps, unwarranted. The second is one that uses a large proportion of hydrocarbon soft segment with a lesser amount of polyether soft segment. The third elastomer family comprises polymers and copolymers that are completely hydrocarbon-based. Poly(carbonate urethanes) are specially elaborated in this section because their in vivo use has both oxidative and hydrolytic implications. Their mechanical properties rival the best poly(ether urethanes) and are favorite compositions for short-term implantable catheters with consideration for chronic use (Wright, 2006). In some studies, they have shown superior oxidation resistance to poly(ether urethanes) in several studies (Mathur et al., 1997; Tanzi et al., 1997). In other studies, however, these compositions were shown to be susceptible to oxidation (Christenson et al., 2004). Additionally, in aqueous media in vitro and in vivo, slow degradation attributable to simple hydrolysis was also detected (Zhang et al., 1997). The body fluid environment provides a relatively stable long-term hydrolytic medium, generally less subject to cellular "respiratory bursts" that strongly enhance oxidative processes. Although phagocytic processes may also produce hydrolytic enzymes, their effects on synthetic polymers are specific and limited (Labow et al., 2002a). Simple hydrolysis, therefore, may be expected to take place continuously, in the body buffer, with poly(carbonate urethane) integrity also susceptible to a combination of mechanical stress and vigorous oxidizing conditions (Faré et al., 1999; Labow et al., 2002b). A 3-year implantation study indicated detectable degradation (Seifalian et al., 2003). Only long-term implant studies (e.g., 5 years or greater) would ascertain the acceptability of poly(carbonate urethanes) or, for that matter, other new polymers having potentially susceptible groups. Unfortunately, financial constraints dictate that these extended studies would only be feasible as postmarket surveillance.

One of the most promising polyurethane families for use as tough, biostable polyurethane elastomers is in development by Boston Scientific Corporation, Formerly Cardiac Pacemakers, Inc., now Abbott Corporation (Desai et al., 2014, 2015). This polyurethane family employs poly(isobutylene diol) as a major soft segment component along with a lesser, reinforcing amount of poly(ether diol) soft segment and conventional methylene dianiline diisocyanate/short chain diol hard segment. Studies predictive of high biostability have been executed (Cozzens et al., 2010).

Hydrocarbon Elastomers

In 1987, Carl McMillin published a pioneering article on a set of elastomers intended for long-term flex fatigue resistance in medical devices such as artificial heart diaphragms (McMillin, 1987a,b). For simple flex life in an in vitro setup, Hexsyn [cross-linked poly(1-hexene)] rubber stood out. It was used in early artificial heart designs under the name of "Bion" rubber. A communication from Dr. McMillin indicated that its lack of adequate tear strength inhibited its successful use, but it may be a very valuable material for dynamic use not subject to cuts and abrasions.

A final very promising hydrocarbon rubber enjoying clinical use is the triblock copolymer, poly(styrene-isobutylene-styrene) (SIBS), spearheaded by (Pinchuk et al., 2007). It is reported to be stable in the body without degradation, long term, and causes a minimal host response. Its early use was as a drug carrier for the Boston Scientific TAXUS coronary artery stent. An advanced current clinical application is as a glaucoma drainage conduit (Pinchuk et al., 2015). The previous two uses were basically static implants. For dynamic applications, it is noted that SIBS is not as tough as polyurethanes and has not been reported for pacemaker lead insulation. In animal studies for heart valve leaflets, the leaflets failed, from "material failure and calcification" (Wang et al., 2010). However, subsequent studies of these copolymers, in cross-linked form to enhance toughness, have shown indications of greater durability while maintaining favorable host response for synthetic heart valves (Sheriff et al., 2015).

Conclusions

Polymers that are carefully chosen for use in implanted devices generally serve effectively for their intended lifetimes if they are properly selected, processed, and

device–material–host interactions are adequately addressed. In certain limited circumstances, excessive hydrolytic or oxidative biodegradation occurs. This may be induced by direct attack by the host or by nonbiological factors in the environment surrounding the implant. With susceptible polymers, protective measures can be taken to ensure extended efficacy, although new, biodegradation-resistant polymers that are on the horizon may require less protection. Knowledge of biodegradation mechanisms and the employment of appropriate countermeasures such as proper material selection or modification, optimal component design, protection from environmental attack, and careful processing, handling, and implantation procedures will promote continued progress in the development of polymers as long-term implantable biomaterials.

Acknowledgments

The author is very grateful to Dr. R.C. Allen for providing the drawing on activated phagocyte redox metabolism. For their technical advice and contributions, I sincerely thank James Anderson, Ken Stokes, Jonathan Sears, John Eaton, Allan Hoffman, John Mahoney, Maurice Kreevoy, Grace Picciolo, Buddy Ratner, Bob Ward, SuPing Lyu, Darrel Untereker, and Len Pinchuk. For the preparation of the original manuscript, I am deeply indebted to my "computer wizard," Mrs. Jayne McCaughey. For help in updating original literature sources, I thank Ms. Mari Ferentinos.

Chapter Questions

- Hydrophobic polymer biomaterials designed both to degrade and to be stable in vivo may produce sub-micron particles during use. What are issues with the host responses that are common to the degradation of both types of polymers?
- Consider the degradation of materials commonly used in medicine that do not have well-defined breakdown mechanisms. Some examples include poly(ethylene glycol), hydroxyapatite, and some polysaccharides. How does the body deal with these common materials?
- A new class of biomaterials is now under development that degrades on cue. The cue might be thermal, photonic, or enzymatic. Ingenious chemical design principles are being applied to create such materials, but how might the body react to the products generated by a sudden breakdown of the structure?
- Learn about new strategies to stabilize materials against degradation, for example, vitamin E loading of orthopedic polymers, and incorporation of poly-isobutylene segments into elastomers.
- Endovascular stents are among the most widely used of all medical devices (Chapter 2.5.2B). A new generation of biodegradable stents is expected to have a huge impact on cardiovascular therapies. Consider how biodegradable poly(lactic acid) or magnesium or iron will perform in the complex intravascular environment.
- For a medical device intended for years of service, especially a device where failure can lead to death, how can we test and qualify the device for the expected period of service? Are there useful in vitro tests? Are there relevant and justified animal models?
- Henry Petroski and other authors have discussed the important role of failure in advancing engineering design. Consider medical device failure, past and present, associated with degradation, and how these unintended complications will lead to better medical devices. A few examples include the degradation of polyurethane pacemaker leads, the breakdown of a protective sheath on the tailstring of the Dalkon Shield IUD, and the wear debris associated with the oxidation of ultrahigh-molecular-weight polyethylene in hip prostheses.

2.4.3

Metallic Degradation and the Biological Environment

JEREMY L. GILBERT

Department of Bioengineering, Clemson University, Charleston, SC, United States

Introduction

Metallic biomaterials experience degradation in the biological environment with a rate, form, and extent of damage accumulation that depends on the alloy, its surface structure and properties, and the mechanical, chemical, and biological processes ongoing adjacent to the alloy surface. Some alloys (e.g., magnesium alloys) degrade rapidly and are under consideration as "biodegradable" alloys where the implant is designed to be temporary and is removed by electrochemical processes over time, while other alloys (e.g., stainless steel, titanium, and cobalt–chromium–molybdenum alloys) are not intended to degrade and are meant to survive for the life of the patient. Such distinctions are important to understand and consider when making medical devices out of medical alloys. Alloys intended for degradation, including magnesium, zinc, and others, are rapidly corroding metals, while those intended for lifetime performance in the human body are highly corrosion resistant. The materials factors dictating such differences in performance include the basic concepts of electrochemistry where both the thermodynamics of oxidation (i.e., the driving force for oxidation) and the kinetics of oxidation governed primarily by the presence of passive oxide films on the surface are important.

Generally, metal alloys are used in the body to provide mechanical support and to resist fatigue, wear, and corrosion processes in various medical device applications. In some circumstances, metals serve an electrical or electrochemical role (e.g., as an electrode). When considering degradation of metals in the body, the processes of most concern typically relate to tribology (wear processes), corrosion, and fatigue (Gilbert, 2017). This chapter will focus on the tribology–corrosion–biology interactions that may arise in a range of medical device applications where metals are used.

The biological system affects the potential forms of metal alloy degradation (tribology and corrosion) and is variable with location (skeletal tissue, cardiovascular, etc.). The effects of degradation on the biological system and the effects of the biological system on degradation are both important and central to the complex interplay that often results in failure of a medical device. The basic mechanisms of degradation of metal surfaces will be discussed and the conjoint interaction between processes, and the interplay between the biological system and the degrading alloy will be discussed in this chapter.

The Severe Biological Environment (Fatigue, Tribology, Corrosion, and Biology)

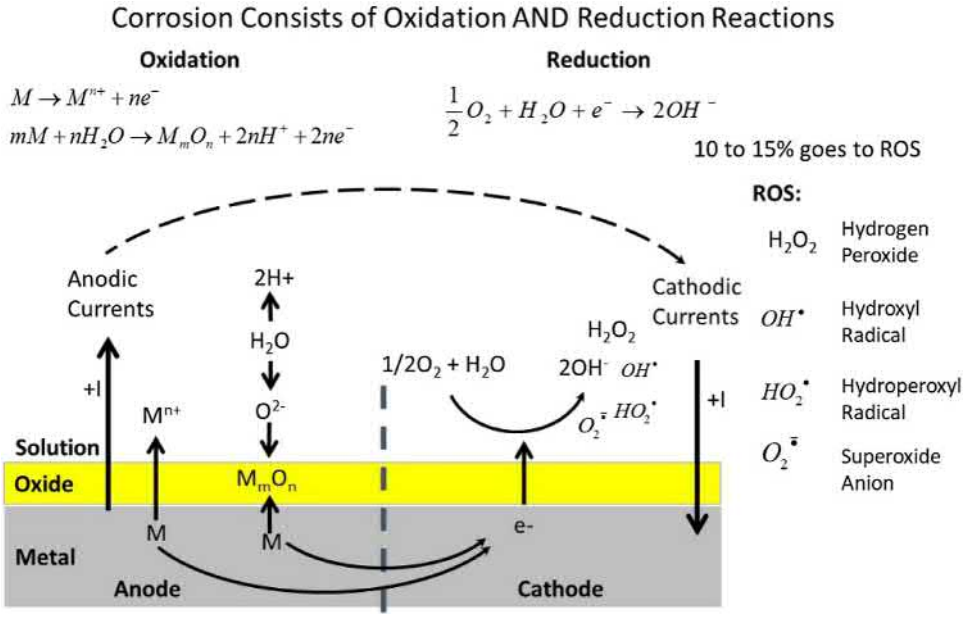
Metallic biomaterials are used in a wide range of applications where high cyclic stresses, tribological interactions, and exposure to body solutions, biological molecules, tissues, and cells are all present. This combination of factors is most easily recognized in total hip prostheses, where tribology, corrosion, and fatigue are experienced in a biological environment that can be inflamed and reactive. Typical hip implants used in the recent past (Fig. 2.4.3.1) have been comprised primarily of Ti–6Al–4V hip stems, CoCrMo necks and heads, CoCrMo acetabular liners, and Ti–6Al–4V acetabular shells. The combination of harsh body environment, comprised of local biological solutions, inflammation and inflammatory cells, and a range of proteins, enzymes, cytokines, etc., the large mechanical stresses due to activities of daily living, and the wear and corrosion mechanisms that arise can lead to large-scale, severe tribologically based and corrosion-based damage. In most cases these two combine to form a conjoint degradation mechanism known as mechanically assisted corrosion (MAC) and tribocorrosion (Gilbert et al., 1993; Swaminathan and Gilbert, 2012; Cao and Mischler, 2018; Mischler and Debaud, 1998).

Each aspect of this system (i.e., body environment, mechanical loading, tribology) can result in failure of the metal but it is more often the case that conjoint mechanisms arise leading to failure. That is, wear *and* corrosion *and* biological interactions often combine to result in more complex and severe failure modes than any one process might otherwise cause. Understanding such system-based failure modes is critical to understanding metallic biomaterials-based failures.

• **Figure 2.4.3.1** Several examples of metallic total hip prostheses that have been used in the recent past. These include implants with modular head/neck tapers, neck/stem tapers, modular body tapers, and acetabular tapers. The tapered metal–metal junctions in each of these locations have been known to be susceptible to mechanically assisted corrosion (Goldberg et al., 2002).

Basic Corrosion of Passive Oxide-Covered Alloys

It is well known that all metallic biomaterials exhibit some form of corrosion process, whether passive dissolution of ions through the passive film, or more aggressive corrosion damage that is linked to wear or crevice geometries or both. The basic corrosion interactions observed (Fig. 2.4.3.2) in vivo consist of oxidation and reduction reactions, where the oxidation processes take metal (zero valence) and increase its valence to make ions (cations) or oxides (or other solid oxidation products). These oxidation reactions occur at the passive oxide film surface, which is typically only a few nanometers thick. One of the potential reduction processes thought to be present takes water and oxygen and makes hydroxide ions and/or reactive oxygen intermediates (Fig. 2.4.3.2). However, there are many other biologically based molecules that are susceptible to redox processes and very little is known about these reactions, how the presence of oxidizing metals affects these species, or how biochemical species may alter oxidation of the metal or alteration of the oxide film. Little is known about such specific biological species and their role in corrosion of metallic biomaterials. The oxidation and reduction reactions are electrically connected through the metal and complete the circuit through



• **Figure 2.4.3.2** General summary of oxidation and reduction reactions that comprise corrosion of metallic biomaterials. Oxidation reactions, typically through the oxide film-covered surface, can form ions (in solution) or solid products like oxides or phosphates. Reduction reactions take oxygen and water in solution and make hydroxide ions and other reactive oxygen intermediates (e.g., reactive oxygen species [ROS]). (Used with permission from Gilbert, J.L., Kubacki, G.W., 2015. Oxidative stress, inflammation and the corrosion of metallic biomaterials: corrosion causes biology and biology causes corrosion. In: Dziubla, T.D., Butterfield, D.A. (Eds.), Oxidative Stress and Biomaterials. Elsevier Press (Chapter 3).)

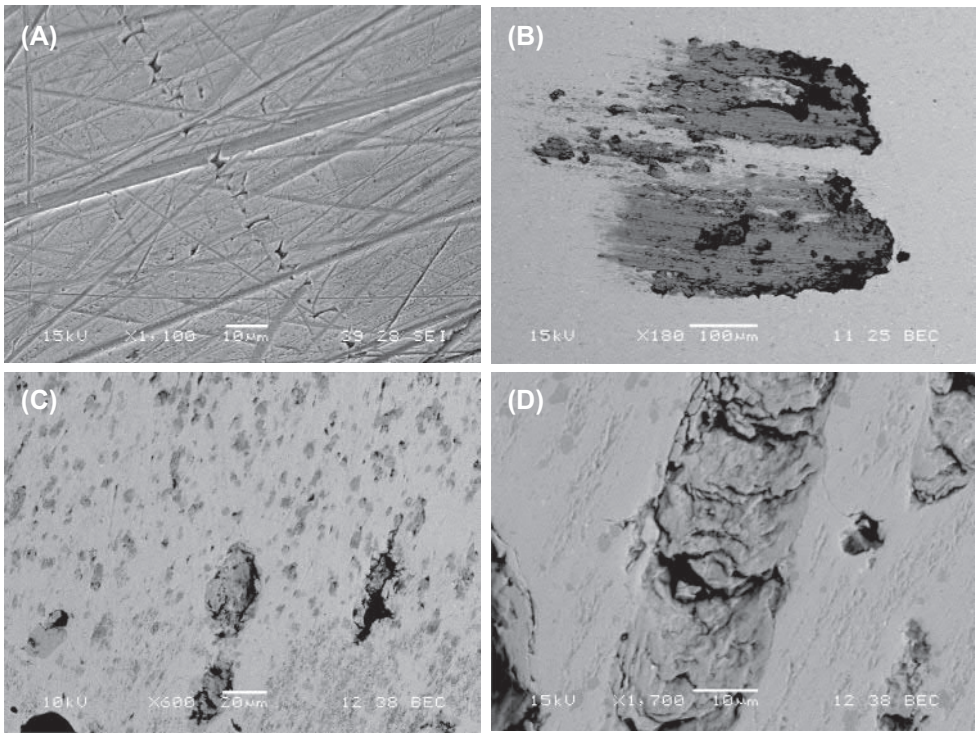
the solution, resulting in currents (electronic and ionic) through both phases.

Corrosion, in and of itself, does not define failure of the metallic implant. Failure, clinically, is more appropriately defined as the need to remove the device (metal) due to a clinically defined failure mode (e.g., pain, loosening, infection, adverse biological reaction, etc.). Thus while corrosion may be associated with failure, it is likely that other biologically based processes (e.g., adverse local tissue reactions) lead to the clinical conditions for revision. It is often difficult to determine the causal relationships between materials-based damage modes and biological processes leading to inflammation, pain, and ultimately revision. However, corrosion is a nearly universal observation in metallic biomaterials (i.e., all metals corrode to some extent). It is often the case that these metals, even though they are corroding, can perform their function and not lead to clinically significant failure modes. Indeed, biocompatibility is not the absence of degradation and even with such degradation processes (which are inevitable), the biomaterials can perform their function with an appropriate host response, making them biocompatible.

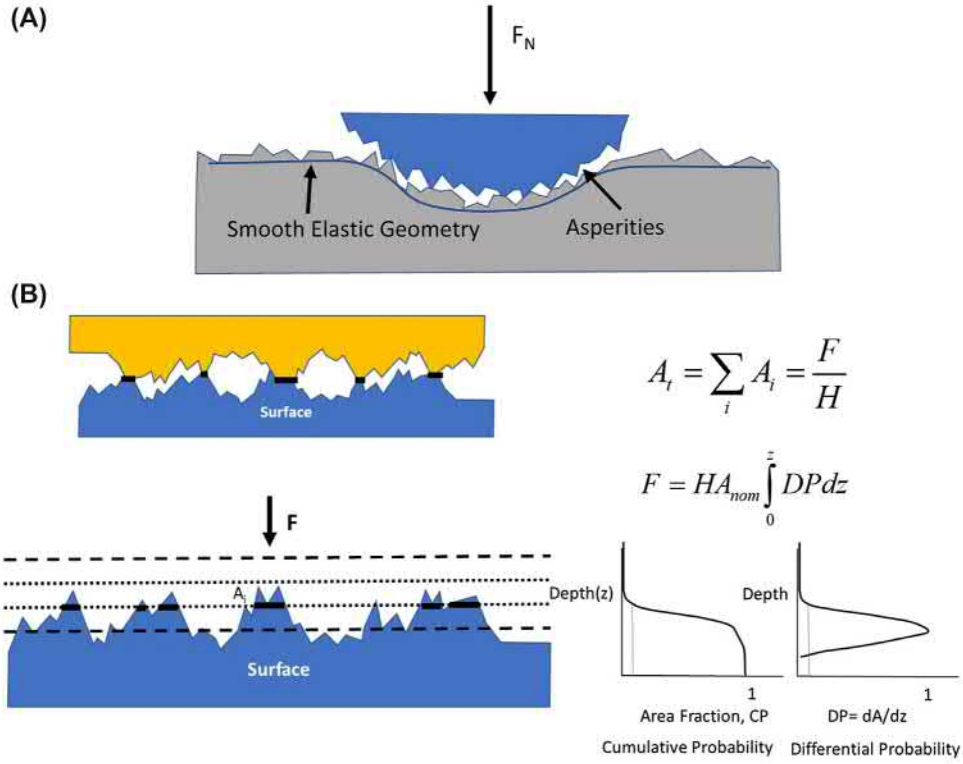
The biological environment adjacent to the metallic biomaterial may change with time from implantation, where highly inflammatory wound-healing mechanisms are at play, to chronic inflammatory conditions often associated with ongoing degradation processes. That is, there are feedback systems that may develop between the immune system response and the degradation mechanisms that can accelerate degradation of the metal and/or amplify the immune reaction. Such positive feedback systems and conditions are currently under active investigation for metallic biomaterial interactions with the living system (FDA, 2019).

Tribological Aspects of Metal-Hard Contact Degradation

From a tribological perspective, the contact and movement of metallic biomaterial surfaces relative to other surfaces can lead to wear processes of the metal (oxide) surface that include adhesive, abrasive (second and third body), and fatigue wear mechanisms (discussed in Chapter 1.2.4 of this text). Examples of CoCrMo alloy surfaces from retrieved total hip metal-on-metal implants, Fig. 2.4.3.3, show examples of abrasive, adhesive, and fatigue wear damage. When metals make contact with other metals or other hard contacting surfaces, the tribological interaction has a number of unique elements that require special consideration. This includes the fact that hard second-phase particles (e.g., oxides and carbides) may become free and serve as third body wear particles. These may roll or slide across the interface and imprint or scratch the surface (Fig. 2.4.3.3A). Adhesive wear interactions between CoCrMo and Ti–6Al–4V (Fig. 2.4.3.3B) are also possible where the



• **Figure 2.4.3.3** (A) Evidence of abrasive wear damage on a CoCrMo head-bearing surface. (B) Adhesive wear of Ti–6Al–4V debris (darker gray) onto CoCrMo femoral head (lighter gray). (C) and (D) Fatigue wear of CoCrMo metal-on-metal acetabular-bearing surfaces from retrieved total hip replacements. Note, evidence of abrasive wear (scratching) and of rolling hard particle imprinting in (A). In (B), the Ti alloy debris is a reacted oxide debris that came from entrainment of Ti alloy into the bearing surface from other components of the implant. In (C) and (D), fatigue wear arose from the high cyclic contact stresses near the edge of the acetabular component, the debris oxidized and partially refilled the region where the fatigue fracture occurred.



• **Figure 2.4.3.4** Schematic of an asperity–asperity contact between two hard surfaces. While the nominal stresses that arise may fall within the elastic range, the stresses at the asperity contact points rapidly reach the hardness or surface yield strength of the material and plastically deform.

titanium alloy and its degradation products can adhere to the CoCrMo surface in an oxidized form. Fatigue wear results from high cyclic contact stresses inducing fatigue fracture of the metal in the subsurface region and loss of alloy particles from the surface (Fig. 2.4.3.3C,D). The remnant holes can be partially refilled with oxidized tribocorrosion debris. In all wear cases that breach the oxide film in the body, there is a corresponding oxidation reaction that accompanies the wear damage resulting in repassivation of the oxide. Thus wear of these metals in the body is always associated with corrosion processes. It is important to note that not all tribological interactions of a metal surface result in breaching of the oxide film. It is only when the metal surface is abraded such that plastic deformation of the surface occurs that oxide films are disrupted. Thus wear against materials softer than the metal will not typically induce oxide film disruption. However, if there are hard particles (as hard as or harder than the metal surface) embedded within softer (polymeric) materials, then such third body particles can induce oxide film disruption and repassivation reactions on the alloy surface.

The three main nonbiodegradable alloy systems (titanium, cobalt–chromium–molybdenum, and stainless steel) are all passive oxide film-covered alloys. As such, contact of the metal surface involves these few nanometer-thick oxides and the immediately adjacent metallic grains contacting the opposing surface in an asperity–asperity contact condition. Even the smallest (nanometer or smaller) topographies give rise to localized asperities of the metal oxide surface, which will influence the contact conditions across the interface (Fig. 2.4.3.4). Thus the stress developed at these asperities quickly rises to the level of the yield stress (or hardness) of the surface and can induce localized plastic deformation. While the overall stress distribution may be nominally elastic, these local asperities experience plastic deformation and may cause disruption of the oxide film on these surfaces due to the local plastic deformation at and near the contacting asperities.

Metal-on-Metal (Hard) Surface Mechanics

In many circumstances, metal surfaces within the body come into contact with other hard surfaces (metals, ceramics, etc.). These metal–hard contact regions have several unique mechanical aspects to them that need to be clearly understood in terms of the contacting conditions and the associated corrosion and tribocorrosion processes that may arise. First, it has been generally acknowledged that the contact mechanics of metal–hard surfaces can be, to first approximation, modeled in terms of Hertzian elastic contact where geometrically smooth surfaces are in contact (e.g., sphere on sphere, flat on sphere, etc.). For two elastic spheres of radius R_1 and R_2, in contact with a force, F, there is elastic deformation of both spheres to develop a circular contact area, A, with radius of contact, a, where a is

$$a = \left(\frac{3FR}{4E^*}\right)^{1/3} \qquad (2.4.3.1)$$

where the effective radius, R, is

$$\frac{1}{R} = \frac{1}{R_1} + \frac{1}{R_2} \tag{2.4.3.2}$$

and the reduced modulus for the two materials is

$$\frac{1}{E^*} = \frac{1-\nu_1^2}{E_1} + \frac{1-\nu_2^2}{E_2} \tag{2.4.3.3}$$

The average stress, $\sigma = F/A$, and the stress across the contact is distributed as

$$\sigma = \sigma^{\max}\left(1 - \left(\frac{r}{a}\right)^2\right)^{1/2} \text{ and } \sigma^{\max} = \frac{3F}{2A} \text{ where } A = \pi a^2 \tag{2.4.3.4}$$

It is commonly thought that such analyses apply to metal–metal, or metal–hard contacts, and while the overall stress interaction is typically elastic when metals are in contact, there is an important role played by asperities (small-scale protruding features on the metal and other surfaces, see Fig. 2.4.3.4) that modify this conceptual framework. As shown in Fig. 2.4.3.4, when a hard sphere with asperities comes into contact with a metal surface also with small asperities present, the overall geometric deformation follows Hertzian contact; however, the local stresses at the peak asperities are more severe. At these asperities, the stresses quickly rise to the hardness (H) or yield stress of the metal surface and induce plastic deformation (dislocation motion) at and near the surface (Popov, 2010). When considering metal–hard surfaces, the true area of contact is dictated not by the Hertzian analysis, but rather by this asperity–asperity yielding process. This is shown schematically in Fig. 2.4.3.4B (bottom), where a smooth flat hypothetical surface is brought into contact with a random asperity-based surface. In this case, the highest asperities contact first and the contact stress in these asperities rises to the yield point, deforming the asperities plastically and allowing the next highest asperities to come into contact. This continues, with each asperity quickly reaching the yield stress of the surface, until the true area of contact is just the amount of asperity area needed to carry the applied load, F. That is, the true area of contact is given by $A = F/H$, where H is the hardness of the alloy that is yielding. Typically, the true area of contact of metal–hard surfaces is only a small fraction of the nominal (or even the Hertzian-based) contact area. The distribution of asperity heights in the surface can be defined by the cumulative probability (CP) function as the fraction of the area at a particular height, z, that is occupied by the material of the surface. This distribution varies from 0 to 1. The differential probability is simply the derivative of the CP and shows the height-based distribution of asperities. This differential probability function describes the area contact of two hard asperity–asperity contacting conditions (Fig. 2.4.3.4).

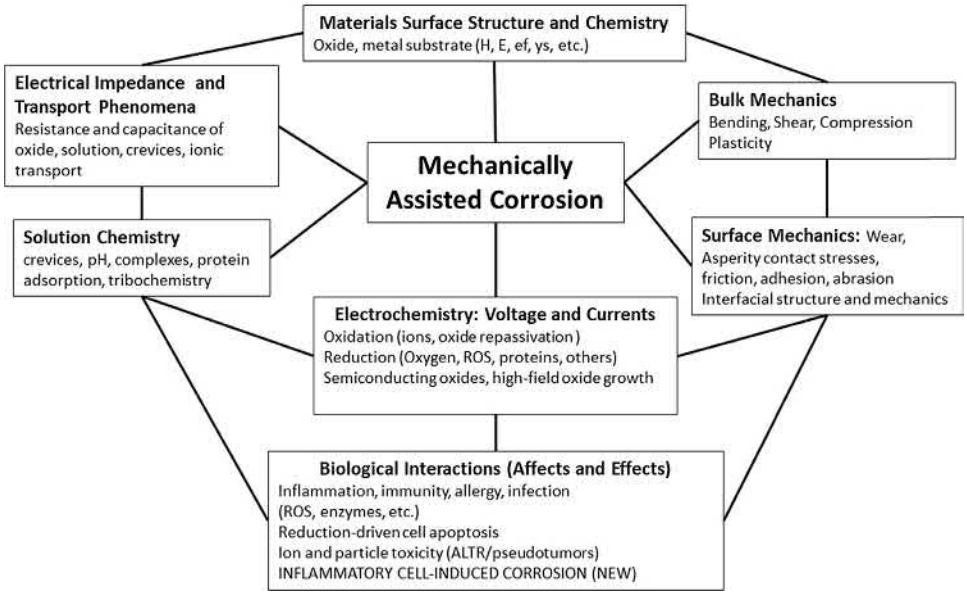
When tribological events occur (e.g., sliding of the two surfaces), it is the interaction of asperities that dominates the overall wear processes with the highest contacting regions experiencing damage and degradation. The oxide films on these interacting asperities will be disrupted by plastic deformation processes and the sliding will expose fresh metal to oxidation (releasing ions and repassivating the surface) and to generation of oxidized particles of debris.

Clinically Observed Mechanically Assisted Crevice Corrosion (Fretting Crevice Corrosion) In Vivo

One of the most studied and clearly identified degradation mechanisms associated with metallic biomaterials is a process known as mechanically assisted crevice corrosion (MACC, see Fig. 2.4.3.5 for a description of the complex multifactorial processes associated with this conjoint degradation mechanism). This term arose from the study of modular tapered junctions in total hip implants in the 1990s up to the present time. It is a degradation process that combines mechanical processes, particularly fretting, with corrosion processes and often involves crevice-like geometries where the local solution chemistry can be dramatically altered from the bulk environment by reactions at the surface. The biological system, its reaction to the alloy degradation, and its affect upon the degradation is also a critical aspect of this conjoint process.

MACC was first identified in modular tapered total hip replacements where the head of the prosthesis is attached to the stem by way of a conical tapered section called a modular taper junction. The surgeon assembles these parts during implantation surgery by impacting the head on to the neck. The junction between these two parts results in a crevice geometry into which body fluids can penetrate and fretting within the junction causes oxide abrasion/disruption at the asperity–asperity contacts leading to a tribocorrosion process. Such fretting crevice corrosion processes are also observed in other orthopedic implants, fracture fixation devices, dental implants, and any other cases where metal–metal contact is possible. The asperity–asperity nature of metal–metal junctions, described earlier, results in only a few percent of the nominal taper contact area being in actual contact, and the remaining space results in a crevice geometry into which solution can penetrate. During loading, high cyclic stresses induce fretting motion, asperity–asperity sliding, and fretting crevice corrosion.

Modular tapers often consist of different alloys coming into contact and concerns have been raised about the possibility of galvanic effects between, for example, Ti–6Al–4V and CoCrMo. However, these concerns are overstated. Typically, galvanic interactions occur between two alloys with significantly different electrode potentials (open circuit potential, OCP), where the more active (negative) potential alloy will experience an increased rate of corrosion, while the more noble (positive) potential alloy will be protected

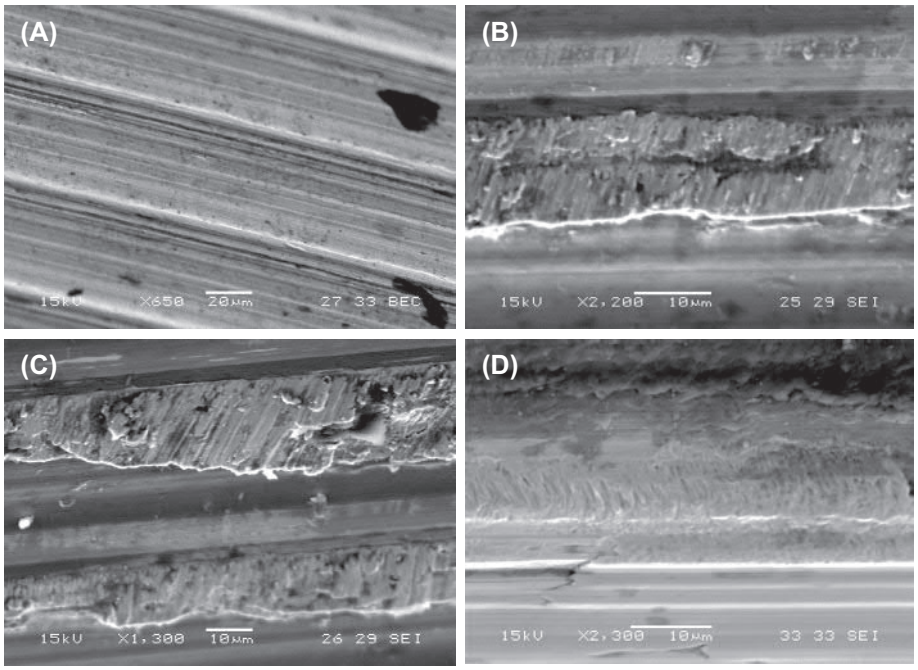


• **Figure 2.4.3.5** Schematic description of the interdisciplinary nature of mechanically assisted corrosion of metallic biomaterials. Knowledge across a range of disciplines is required to understand the in vivo interactions of metal surfaces, wear and corrosion-based degradation, and the biological environment. It includes materials science, bulk and surface mechanics, electrical and transport phenomena, and electrochemistry, all within a biological system that is both reactive to the degradation and contributing to the accelerated attack possible. *ALTR*, Adverse local tissue reaction; *ROS*, reactive oxygen species; *H*, hardness; *E*, Modulus; *ef*, fracture strain; *ys*, yield stress. (Used with permission from Gilbert, J.L., Sivan, S., Mali, S., 2015. Corrosion of modular tapers in total joint replacements: a critical assessment of design, materials, surfaces structure, mechanics, electrochemistry and biology. In: Greenwald, K., Lemons, M. (Eds.), ASTM Special Technical Publication on Implant Modularity, STP 1591. ASTM Int, 192–223.)

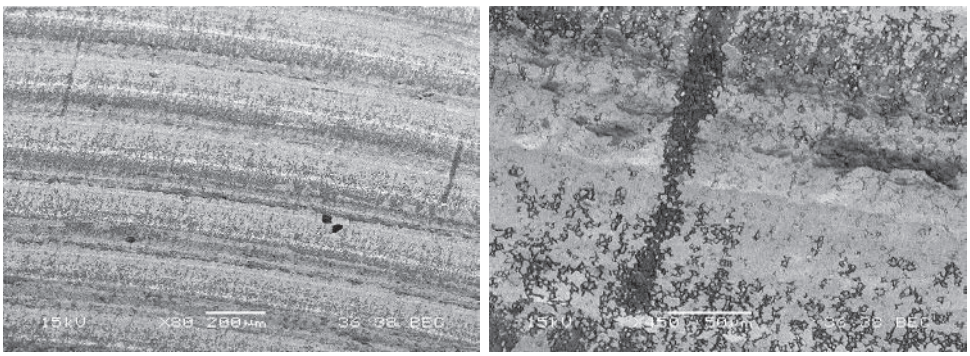
and will see a decreased rate of corrosion. Titanium and CoCrMo alloys, with passive oxide films intact, have very similar OCPs, thus little galvanic potential exists for increasing corrosion. In addition, if any difference in OCP exists, it is typically that Ti is more active and CoCrMo is more noble, thus it would be the titanium that would be accelerated in its corrosion. The passive oxide films also serve as a kinetic barrier to corrosion and limit galvanic effects (Jacobs et al., 1998). When modular tapers of Ti–6Al–4V and CoCrMo are examined, both the titanium and the CoCrMo are corroded and there is no evidence that either protects the other. Finally, MACC is observed in all possible alloy combinations and thus is not dependent on any galvanic effects. Therefore galvanic corrosion, while a mechanism that may play out in some circumstances (e.g., corrosion near carbides vs. bulk alloy, for example), does not contribute significantly to the MACC mechanism.

Examples of the type of damage resulting from MACC are shown in Figs. 2.4.3.6–2.4.3.8, where fretting damage, intergranular corrosion, direct oxide conversion, and pitting of CoCrMo and/or Ti–6Al–4V are all observed. Fig. 2.4.3.6 demonstrates the basic fretting damage that results in small parallel abrasion patterns due to asperity–asperity contact and cyclic micromotion. Examples of more severe fretting corrosion damage in Fig. 2.4.3.6 show generation of oxide debris that accumulates within the taper region. Fig. 2.4.3.6A is an undamaged region of a CoCrMo head taper after retrieval. Fig. 2.4.3.6B–D are examples demonstrating minor fretting damage resulting primarily from contact and motion.

Fig. 2.4.3.7 shows an example of the more severe corrosion that can arise in CoCrMo alloy modular tapers resulting from MACC where fretting corrosion within the crevice led to intergranular corrosion that is affiliated with the imprinting of the male trunnion. Intergranular corrosion at the grain boundaries of this high-carbon CoCrMo alloy surface is evident. Examples of corrosion damage in Ti–6Al–4V alloy modular taper junctions, Fig. 2.4.3.8, show the severe damage possible in vivo for these alloy systems. Fig. 2.4.3.8A is a scanning electron micrograph of a retrieved Ti–6Al–4V acetabular shell taper region (CoCrMo alloy was on the other side). Note the pitting and dissolution of the surface. Fig. 2.4.3.8B–D are scanning electron micrography (SEM) micrographs of sectioned regions through the taper junction of Ti–6Al–4V alloy modular body tapers (where Ti–6Al–4V was on both sides of the taper). These micrographs show the corrosion reaction leading to several hundred micron-thick oxide corrosion products (Fig. 2.4.3.8B), a sectioned region through a large (200 μm) pit in Ti–6Al–4V filled with oxide, and a section through a Ti–6Al–4V/Ti–6Al–4V alloy junction still intact (Fig. 2.4.3.8D), where about 10 μm of oxide formation has occurred at the taper junction. These images show that Ti alloys are susceptible to severe corrosion damage under MACC circumstances. The fretting corrosion aspects of MACC have been extensively



• **Figure 2.4.3.6** Evidence of fretting crevice corrosion in retrieved modular head/neck tapers of total hip replacements. (A) Undamaged machining ridges in a retrieved modular CoCrMo head taper. (B)–(D) Examples of minor fretting damage seen in retrieved CoCrMo head components.



• **Figure 2.4.3.7** Retrieved CoCrMo head taper with extensive intergranular corrosion damage associated with mechanically assisted crevice corrosion. studied and reproduced in device and basic pin-on-disk tests. However, the severe corrosion damage of both CoCrMo and Ti–6Al–4V alloys seen in these retrievals (e.g., intergranular corrosion of CoCrMo, thick oxide formation, and pitting in Ti–6Al–4V) has not been reproduced in any in vitro laboratory tests to date that represent the in vivo conditions, and the detailed conditions and mechanisms of generation of this type of damage are still under investigation.

Mechanically Assisted Corrosion Basics for CoCrMo and Ti–6Al–4V Alloys

MACC is a conjoint degradation process (Fig. 2.4.3.9) that combines mechanics, materials, surfaces, chemistry, and biology. A hard asperity makes contact with the metal oxide passive film-covered surface where the contact stresses reach the yield point of the substrate. This results in disruption (removal) of the oxide film covering the surface and generates oxide-based debris that can be released from the surface. Metal ions may be released into the solution from the regions where the oxide film has been removed; however, these regions rapidly repassivate (within milliseconds) and return the surface to a passive state. Because the contact stresses reach or exceed yielding, the substrate alloy undergoes plastic deformation (dislocation motion) of the near-surface region, which can work harden the outer alloy layer and develop very high dislocation densities. The corrosion reactions present are associated with both the ionic release of metal and the reaction of metal with oxygen and water for form metal oxides (repassivation). These reactions, because they involve the liberation of electrons, result in currents that can be detected and used to monitor the

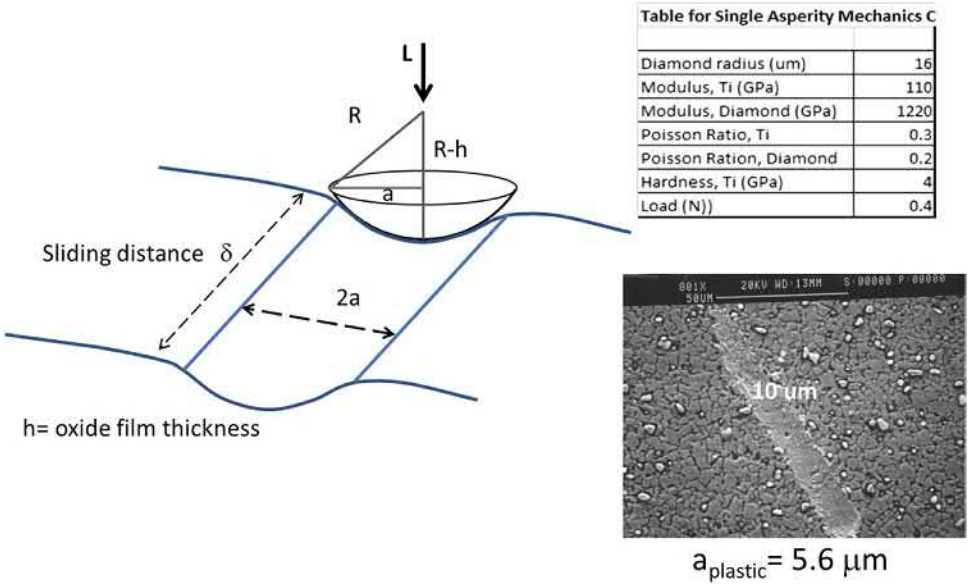
corrosion processes arising from mechanical disruption of the surface. Reduction reactions are also present, but can be remote from the site of abrasion.

Much has been learned about MACC from retrievals, but also from fundamental studies of oxide film disruption and repassivation tests that include high-speed single asperity scratch tests (Gilbert et al., 1996; Goldberg et al., 1997; Goldberg and Gilbert, 2004), to pin-on-disk fretting corrosion tests (Swaminathan and Gilbert, 2012, 2013), and in vitro implant tests (Goldberg and Gilbert, 2003; Gilbert et al., 2009 Jan; Mali and Gilbert, 2015). These tests have, for example, shown that during oxide



• **Figure 2.4.3.10** Schematic of the area abraded analysis based on plastic deformation. Scanning electron micrography micrograph is of a 16 µm radium diamond stylus scratching a high-carbon CoCrMo alloy surface under a controlled load (0.4 N). The width of the permanent scratch is determined by the hardness (4 GPa) and the normal load applied.

disruption, the corrosion reactions release free electrons into the metal (due to oxidation), which accumulate within the metal electrode and cause a negative excursion in potential. These electrons are eventually consumed in reduction reactions; however, it is well known that the open circuit potential of alloys engaged in MAC can drop significantly. The potential drop is limited by the potential where metal oxide films will begin to form (passivation potential). For titanium this potential is −1 V versus Ag/AgCl, while it is about −0.5 to −0.8 V for CoCrMo. The amount the potential drops in these cases depends on the rate of oxide abraded (and repassivated), the amount of available area for the reduction reactions to take place, and the kinetics of the reduction reaction. These effects are also reflective in the changes in impedance of the electrode where larger area electrodes have lower resistances and higher capacitances that will affect the extent of voltage change (Gilbert et al., 2016). In addition, the thickness of passive oxide film that repassivates depends primarily on the electrode potential above the passivation potential. This thickness is linearly dependent on the electrode potential difference (when within the passive range of the oxide). Thus the potential of the metal changes with MACC and the changing potential affects the repassivation processes, and these effects may have significant impacts on the nature of the corrosion damage observed (Figs. 2.4.3.6–2.4.3.8).

There are a number of models under development to describe the tribocorrosion behavior of passive film-covered alloys. These rely on the processes of oxide disruption and current arising from film growth (repassivation) and ionic dissolution (Gilbert et al., 1996; Goldberg et al., 1997). The mechanics of abrasion relate to asperity contact and sliding mechanics (Swaminathan and Gilbert, 2012). Here, a hard (rigid) spherical single asperity of some radius, R, indenting into a surface will penetrate to some load-dependent depth and will result in a contact area (Fig. 2.4.3.10) of

$$A_{\text{contact}} = \pi a^2 = \left(\frac{L}{H}\right) \text{ or } a_{\text{contact}} = \left(\frac{L}{\pi H}\right)^{1/2} \tag{2.4.3.5}$$

where a is the contact radius, L is the normal load, and H is the hardness of the metal. When this asperity slides some distance, δ, then the area abraded is twice the contact radius times the sliding distance:

$$A_{\text{abraded}} = 2a\delta = 2\delta\left(\frac{L}{\pi H}\right)^{1/2} \tag{2.4.3.6}$$

and the volume of oxide abraded (and repassivated) is

$$V_{\text{abraded}} = A_{\text{abraded}} h = 2\delta\left(\frac{L}{\pi H}\right)^{1/2} h \tag{2.4.3.7}$$

Since the repassivation rate is typically much faster than the rates of abrasion of the oxide, the sliding abrasion is the rate limiting step in the generation of currents resulting from MACC. The current due to film formation can be found by determining the volume of oxide film disrupted per unit time (which corresponds to the volume reformed) times the charge per unit volume of oxide created by the oxidation reactions. The volume of oxide abraded (disrupted) depends on the true contact area diameter times the sliding distance per unit time times the oxide film thickness:

$$I(t) = \frac{\rho n F}{Mw}\frac{dV}{dt} \tag{2.4.3.8}$$

TABLE 2.4.3.1 Physical Properties for TiO_2, CoCrMo, and 316L SS Oxides (Based on Alloy Composition)

	TiO_2	CoCrMo Oxide	316L SS	Units
ρ	4.45	6.06	5.81	g/cm^3
n	4	2.37	2.9	
M_w	79.9	76.91	130.09	g/mol
m	1.8	2.0	2.0	nm/V
E_o	–1,000	–500	–100	mV
$\rho nF/M_w$	21,498	18,020	12,498	C/cm^3

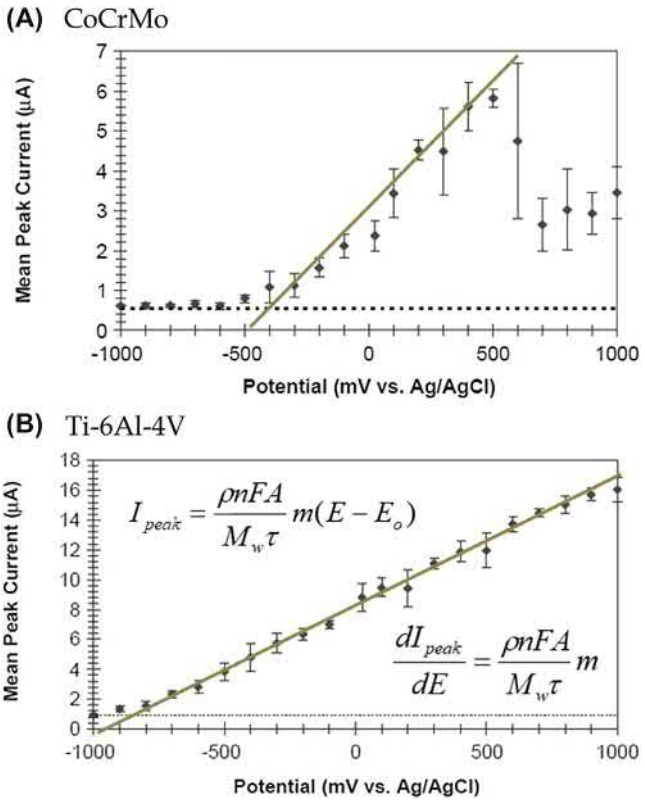
where:

$$\frac{dV}{dt} = h\frac{dA}{dt} = 2h\sqrt{\frac{L}{\pi H}}\frac{d\delta}{dt} \qquad (2.4.3.9)$$

Here, δ is the sliding distance, L is the normal load, H is the hardness of the alloy, and h is the thickness of the oxide film. The film thickness, h, varies linearly with potential above the passivation potential by about 2 nm/V (known as m, the anodization rate, see Table 2.4.3.1) and with these, one can obtain the current that arises from oxide film abrasion. Table 2.4.3.1 summarizes the various physical properties of the oxides of Ti, CoCrMo, and 316L SS used in the estimation of currents arising from tribocorrosion processes.

For example, if 1 mm^2 of oxide (2 nm thick) is abraded and reformed on titanium in 1 s, the associated currents would be about 43 μA of current. This analysis ignores the currents arising from ionic dissolution reactions as these currents are typically much smaller than the film currents (Gilbert et al., 1996; Goldberg et al., 1997). As a comparison, the currents typically measured in fretting corrosion tests of modular tapers are on the order of 1–10 μA, or about 0.1 mm^2 abraded area per second. This shows that currents that result from MAC can be highly sensitive to the rate of the area abraded, that the true contact area undergoing oxide disruption is only a small fraction of the nominal area, and that monitoring of these currents is an excellent means for assessing the damage process in experimental setups.

The thickness of oxide film reformed depends on the potential. It must be above the passivating potential to form oxide and for CoCrMo and 316L SS must be below the breakdown potential for the alloy (about +500 mV vs. Ag/AgCl). If the potential exceeds this latter potential, then the passive film is no longer passive and this analysis does not hold. The variation of single asperity scratch current with potential can be seen in Fig. 2.4.3.11A,B, which are the results of single diamond asperity high-speed scratch tests (Gilbert et al., 1996; Goldberg et al., 1997; Goldberg and Gilbert, 2004) on both CoCrMo and Ti–6Al–4V alloy surfaces. Using controlled loads and scratch distances, the current response as a function of applied potential shows that

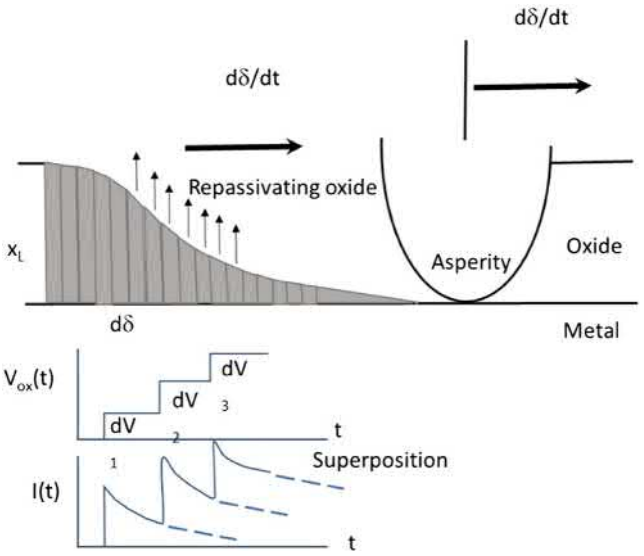


• **Figure 2.4.3.11** Single asperity high-speed scratch test peak currents plotted against applied potential. These plots show the passivation potential for the two alloys and how the peak scratch current varies linearly with potential over the passive range of the alloy. (Adapted with permission from Goldberg, J.R., Gilbert, J.L., 2004. The electrochemical and mechanical behavior of passivated and TiN/AlN-coated CoCrMo and Ti6Al4V alloys Biomaterials 25 (5), 851–864.)

there is a lower scratch current with more negative potentials that approach zero at unique potentials (–1 V for Ti–6Al–4V and –0.5 V for CoCrMo), which are the onset potentials or passivating potentials for the respective oxides (primarily TiO_2, Cr_2O_3). The linear increase of current above the passivation potential relates to the linear dependence of the oxide film thickness with potential.

Because MAC processes include tribological factors and electrochemical factors, the details of these interactions are important to study. Test methods, including electrochemical fretting pin-on-disk tests, have been developed to explore the range of interactions present (Swaminathan and Gilbert, 2012, 2013). These studies have shown, for example, that there are effects of potential on the fretting coefficient of friction (Swaminathan and Gilbert, 2012, 2013; Liu and Gilbert, 2017) and that the currents generated during fretting corrosion scale directly with the work of fretting (i.e., the energy dissipated per cycle of fretting motion).

Fretting corrosion currents generated by oxide film disruption and repassivation can be modeled using a heredity integral approach based on the idea (Fig. 2.4.3.12) that an asperity abrasion process can be thought of as consisting of infinitesimal increments of oxide disruption, dV, and repassivation, and that each increment in oxide disruption



• **Figure 2.4.3.12** Schematic of an asperity removing oxide film and the film regrowing where each infinitesimal volume of oxide removal and regrowth results in a current spike and decay transient. The overall current response is the sum (integral) of each of these infinitesimal processes over time and is related to the sliding speed. (Used with permission from Gilbert, J.L., Zhu, D., October, 2019. A tribocorrosion model linking fretting mechanics, currents and potentials: model development and experimental comparison. J. Biomed. Mat. Res. B Appl. Biomat. (In Review).)

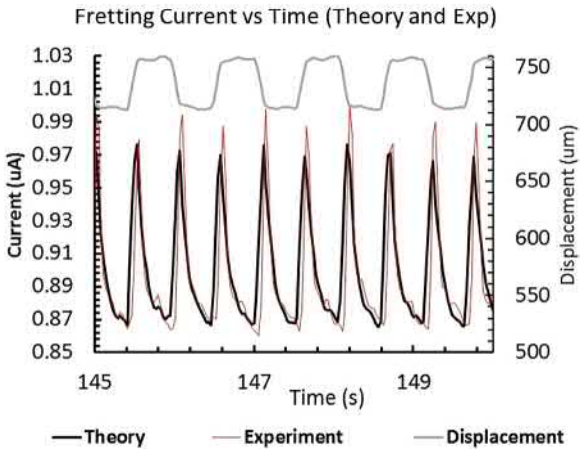
and repassivation results in current transient responses that can be superimposed and summed over time to obtain the full current response. This is similar to the approach of Boltzmann superposition used in viscoelastic theory to predict stresses in a viscoelastic material in response to an arbitrary strain path over time. Here, the currents can be determined from the integral over time of the current transient response of each infinitesimal oxide disruption event. The equation that describes this behavior, known as a Dumahel integral, is

$$I(t) = A^T(t)\,V(0) + \int_{\lambda=0}^{t} A^T(t-\lambda)\frac{dV}{d\lambda}d\lambda \qquad (2.4.3.10)$$

where V is the oxide volume abraded (and repassivated), λ is a dummy variable in time, and $A^T(t-\lambda)$ is the tribocorrosion admittance (or transfer function) relating currents to volume abraded. This function is

$$A^T(t-\lambda) = \frac{I_o}{V}e^{-\frac{t-\lambda}{\tau}} = \left(\frac{\rho nF}{M_w\tau} + \frac{i_o}{h}e^{\frac{\eta}{\beta_a}}\right) e^{-\frac{t-\lambda}{\tau}} \approx \frac{\rho nF}{M_w\tau}e^{-\frac{t-\lambda}{\tau}} \qquad (2.4.3.11)$$

where ρ is the oxide density, n is the valence of the cation, F is Faraday's constant (96,485 C/mol), M_w is the molecular weight of the oxide, h is the oxide thickness, i_o is the exchange current density for ionic release through bare metal, β_a is the anodic Tafel slope for ionic release, τ is the time constant for the current transient, and η is the overpotential for ionic release. This equation shows that the current transient that results from an instantaneous removal and repassivation of oxide film will result in an exponential decay of the current and has been developed previously from single asperity high-speed scratch tests of titanium and CoCrMo alloy surfaces in physiologically representative solutions (Gilbert et al., 1996; Goldberg et al., 1997; Goldberg and Gilbert, 2004).



• **Figure 2.4.3.13** Comparison of predicted currents and experimental currents resulting from a pin-on-disk fretting corrosion experiment of CoCrMo alloy in phosphate-buffered saline. Tribocorrosion currents can be modeled theoretically with this approach when the potential remains fixed.

Eq. (2.4.3A.10) describes how the current will vary over time, depending on the rate of volume abraded over time.

This equation predicts the tribocorrosion currents for any arbitrary sliding distance time response and has been verified experimentally (Fig. 2.4.3.13) where step-like displacements of pin-on-disk coupled to CoCrMo/CoCrMo were tested and comparison of the experimental currents with the theoretical currents shows high similarity.

These studies demonstrated that when mechanical disruption of the passive oxide film on titanium and CoCrMo alloys occurs, the resulting corrosion reactions are generated by the repassivation reaction and ionic release and these can be measured and calculated such that the degradation response can be modeled and assessed systematically.

Tribocorrosion Layer and Surface Damage on Metallic Biomaterials Surfaces

Studies of the resultant damage to metal surfaces experiencing tribocorrosion processes have identified a mixed tribocorrosion layer that may form within the top few nanometers of the surface wherein the oxide debris mixes with the alloy to result in a layer of mixed metal, metal oxide, and adsorbed protein (Wimmer et al., 2003, 2010). This tribocorrosion layer may alter the properties of the surface (hardness, corrosion response) and affect subsequent tribocorrosion processes. Other studies have investigated the plastic deformation damage observed in the near-surface alloy grains resulting from fretting contacts. Here, highly deformed surface grains may be induced to undergo strain-induced transformation and/or develop

highly deformed dislocation substructures that appear to be similar to nanocrystalline regions. Such fine crystalline zones may well egress from the surface and be a source of metal particulates released into the surrounding tissues (Oladokun et al., 2019).

Biology and Corrosion: Additional Insights

Starting in the 1970s and 1980s, Hans Willert et al. 1990, 2005) and Jasty and Harris (Jasty et al., 1994) recognized that particulates from a range of biomaterials can induce significant adverse biological reactions. These reactions may be chronic inflammatory reactions, dominated by macrophages, lymphocytes, and foreign body giant cells within granulomatous tissues (Davies et al., 2005), or may result in osteolysis (bone destruction) or soft tissue inflammation. For metallic biomaterials, the effects of tribocorrosion on local tissue responses have only more recently been identified as a result of the introduction of metal-on-metal hip implants. Here, metallic or metal oxide debris generated from tribocorrosion processes may be released into the joint fluid and surrounding joint tissues and be associated with significant adverse local tissue reactions. While the specific causal relationships and mechanisms of interaction are still not well understood, there appears to be an effect of CoCrMo degradation products on the local tissue reaction that is the result of an immunological response to the alloy degradation products (Davies et al., 2005). These effects are described in more detail in other sections of this text (Chapter 2.4.3) and will not be focused on here. However, there are certain interactions between the biological system and metallic biomaterials that merit further attention.

In particular, the biological system can affect the corrosion behavior of these alloys and the electrochemical behavior of the alloys can affect the local biology in ways that have not been fully appreciated. This feedback interaction may be a significant factor in why some people are more reactive to metallic degradation debris than others and why some implants show much more severe corrosion damage than others.

Reduction Reactions Affect Cells

The first new insight has to do with how cells respond to metal surfaces that are held to different electrochemical potentials. Work by Ehrensberger and Gilbert (Ehrensberger et al., 2010), Kalbacova et al. (2007), and Haeri et al. (2012) have shown that preosteoblast-like cells (e.g., MC3T3-E1 preosteoblasts) cultured on titanium and CoCrMo surfaces are highly sensitive to the electrode potential of the metal and, in particular, that cathodic potentials (wherein reduction reactions are taking place) can induce cell death (by an apoptotic process) within a few hours. That is, reduction reactions involving the reduction of oxygen and water induce the killing of cells on or near to the metal surface. It is thought that this killing effect may be the result of consumption of oxygen, shifting of the near-surface solution to higher pH, and/or the generation of reactive oxygen intermediates (ROS) from the reduction process.

As shown in Fig. 2.4.3.2, reduction of oxygen and water can create small fractions of ROS and these chemistries can have significant effects on cells cultured on the surface (Wiegand et al., 2019). This is true regardless of the alloy. The killing effect occurs for both mammalian cells and bacteria (Ehrensberger et al., 2015). This approach is now being adopted for the possible control of cancer cells (Kim and Gilbert, 2018) or bacterial biofilms on metallic implant surfaces (Ehrensberger et al., 2015). Reduction reactions can be induced on metallic medical devices, and such reactions can kill bacteria on the surface. These observations represent a new and potentially significant means for treating infection. In addition, tribocorrosion processes can induce large drops in potential and the increased associated reduction reactions have also been shown to induce cell killing on the surface (Kubacki et al., 2017). Thus redox reactions not specifically associated with metal ion release or oxide film formation can result in significant cellular effects that are as yet unrecognized and/or understudied.

Recent work (Wiegand et al., 2018) has sought to identify an "electrochemical zone of viability," which is defined as the electrode potential range wherein cells can remain viable and outside of which cells die. For titanium, cells can remain viable on the surface up to at least +1 V versus Ag/AgCl, but that by −0.4 V and lower, cells will rapidly die. For CoCrMo, the zone of viability is limited to +0.3 V where cells on CoCrMo above this potential rapidly die by necrosis and metal ion toxicity, while below −0.4 V cells die by reduction-induced apoptosis. These zones of viability may also be dependent of cell type (Wiegand et al., 2018) where it has been shown that macrophage-like cells can survive for longer periods to more negative potentials than preosteoblast-like cells. This is likely due to their increased ability to control their redox homeostasis in the presence of ROS generated by the electrode surface. Such electrochemical effects on cells may induce a wider range of responses than have been previously understood, and possible sensing and control of systems by electrochemical means remain a potentially important area of study.

Reactive Oxygen Species May Enhance Corrosion Reactions

In addition to the fact that reduction reactions affect biological systems, the effect of immune cell responses on the corrosion of metallic biomaterials is also a new area of focus. In these circumstances, it is hypothesized that the respiratory burst processes associated with a range of phagocytic cells can release a range of ROS and reactive nitrogen species molecules into the near implant space. These oxidizing species, if they come into contact with the alloy surface, have been shown to have significantly deleterious effects on the corrosion resistance, particularly

in CoCrMo alloys (Liu and Gilbert, 2018; Kubacki and Gilbert, 2018). That is, chemistry that includes hydrogen peroxide or hypochlorous acid, or other oxidizing species, lowers the impedance of the oxide films on CoCrMo and titanium alloys and can shift the electrode potential of the metal such that this combined effect can raise the rate of corrosion significantly and alter tribocorrosion processes (Liu and Gilbert, 2017). Such effects may play a significant role in the corrosion behavior of these alloys in vivo and additional work is needed to better understand this corrosion–biology interplay.

Summary

This chapter has outlined the principal means by which metallic biomaterial surfaces undergo degradation in the body. The central role of passive oxide films on these alloys and how mechanical disruption in conjunction with corrosion and biological environments can lead to severe degradation mechanisms. Degradation by corrosion can increase reduction reactions as well and has been shown to have killing effects on nearby cells. Inflammatory species (e.g., ROS) can increase the corrosion response of titanium, CoCrMo, and 316L SS alloys. In all, metal degradation in the biological environment is a complex interplay of conjoint mechanisms and can result in a wide range of damage modes and potential biological outcomes. Our understanding of the tribocorrosion processes present in many metallic implant systems and the physics, chemistry, and mechanics at play will assist in designing metal-based implants for the future.

Acknowledgments

There were many students and colleagues that participated in the development of this work and shared in the efforts to document and characterize the degradation of metals in the body. These include: Joshua J. Jacobs, Robert Urban, Jay Goldberg, Christine Buckley, Mark Ehrensberger, Viswanathan Swaminathan, Shiril Sivan, Jua Kim, Sachin Mali, Greg Kubacki, Yangping Liu, Morteza Haeri, and Michael Wiegand. Their efforts and contributions are greatly appreciated by the author.

2.4.4

Degradative Effects of the Biological Environment on Ceramic Biomaterials

MARIA VALLET REGI, PEDRO ESBRIT, ANTONIO J. SALINAS

Chemical Department of Pharmaceutical Sciences, Faculty of Pharmacy, Universidad Complutense of Madrid, Spain

Introduction

Ceramic materials are important sources of biomaterials for clinical applications. In this field, they are usually denoted as bioceramics and continue to be used to regenerate and repair ill or damaged tissues mainly in orthopedics and dentistry. Ceramics are inorganic materials exhibiting a combination of ionic and covalent bonding that show high melting temperatures, low conduction of electricity and heat, and high hardness. In addition, ceramics show high wetting degrees and surface tensions, which favor the adhesion of proteins and cells. Moreover, ceramics show great compression but low tensile strengths, stiffness and little plastic deformation. Bioceramics as implants are often manufactured with interconnected hierarchical porosity, which decreases the mechanical properties but allows ingrowth of cells and the necessary blood vessels.

The biological environment is both very aggressive and susceptible to material-provoked adverse reactions (Williams, 2008). Thus implanted bioceramics might suffer surface modifications and degradation during their required lifespan. Plasma is an aqueous medium containing anions (bicarbonate, chloride, phosphate, sulfate), cations (calcium, magnesium, potassium, sodium), as well as more than 20 different types of proteins: albumin, immunoglobulins, and fibrinogen being the most abundant. It also contains dissolved gases, mainly oxygen, carbon dioxide, and nitrogen. Finally, blood also includes red blood cells, white blood cells (neutrophils, eosinophils, basophils, lymphocytes, and monocytes), and platelets. This set of blood components is normally buffered at pH in the range 7.35–7.45, at a temperature of 37°C. Other biological fluids, such as cerebrospinal fluid, synovial fluid, saliva, tears, and lymph present some variations with respect to the components of blood but they are as complex and aggressive as blood itself on any material in contact with them.

Many of the blood components are extremely corrosive such as chlorine ions—present at a concentration that is one-third of that of sea water—or oxygen concentration in venous blood, a quarter of that in air. In addition, the presence of proteins is known to have a significant influence on the corrosive nature of the body fluids (Black and Hastings, 1998). Also of note, in inflammatory or infectious conditions, the biological medium pH can be acidified for short periods, reaching values of 4 or 5.

Reactivity of Bioceramics

When bioceramics are in contact with the biological fluids, three types of behavior can be expected. Whereas some ceramics, named *bioinert*, remain almost unchanged, others end up being reabsorbed after a certain period of time, and so are named *resorbable*; a third group of ceramics, called *bioactive*, undergo a set of reactions on their surface promoting binding to bone and, occasionally, soft tissues. Based on this different behavior, bioceramics are normally classified according to three subdivisions, which are described in depth in other chapters of this book:

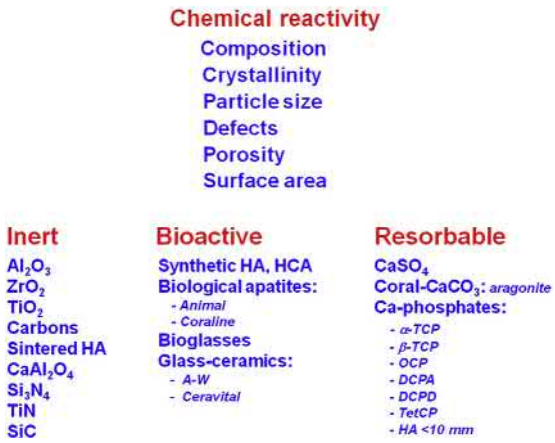
1. *Inert (or almost inert)* ceramics.
2. *Resorbable* ceramics
3. Ceramics with surface reactivity, i.e., *bioactive* ceramics.

Bioinert ceramics, namely Al_2O_3, ZrO_2, TiO_2, or TiN, which exclusively contain covalent bonds that require a high energy to break, are very stable in the biological environmental, as observed in clinical practice. However, these bioceramics are also denoted as "almost inert" (Hench, 1991), since in contact with biological fluids they are usually covered with water, proteins, and other biological components. The former concept of "aging" of inert ceramics, which decreases their mechanical properties, appears to be more associated with an incorrect way of their preparation (Chevalier, 2006). As an example, zirconia, ZrO_2, like

most of this type of ceramics, is brittle but when used to design implant components, it is prepared in a polymorphic phase with great toughness. The stability of this polymorph was achieved with addition of yttria (Y_2O_3) to reach partially stabilized zirconia (PSZ). However, incorrect thermal treatment of this material could cause the deterioration of mechanical properties of zirconia.

Resorbable bioceramics are ceramic materials containing ionic bonds that are stable in the air but dissolve in aqueous media. From their chemical structure, it is possible to identify their potential to produce bioceramics with a controlled degradation rate when implanted. Since any material that degrades in the body will release its constituents to the surrounding tissues, it is necessary to select as constituents of bioceramics cations and anions that are harmlessly incorporated in the metabolic processes. Ionic compounds containing sodium or calcium, including calcium phosphates and calcium carbonates, are widely used in this respect. The degradation rate of these bioceramics depends on their chemical composition and microstructure (Bohner, 2000). Hence, tricalcium phosphate [TCP, $Ca_3(PO_4)_2$] degrades quite rapidly, while hydroxyapatite [HA, $Ca_{10}(PO_4)_6(OH)_2$] is relatively stable. However, these compounds present variations in this regard: the α polymorphic form of [$Ca_3(PO_4)_2$] is more soluble than the β form. For this reason, α-TCP is frequently used as an ingredient of calcium phosphate cements, whereas β-TCP is used in bone grafts, pure, or as a component of biphasic calcium phosphates, containing HA and β-TCP. HA-based ceramics exhibit different solubility degrees depending on various factors. In general, HA can only be considered a resorbable material when obtained with a particle size smaller than 10 μm. Moreover, porosity highly affects ceramic solubility. Therefore dense ceramic materials will degrade slowly, while a porous material will be susceptible to a more rapid degradation. It is considered that dissolution rates in vivo can be predicted from their behavior in simple aqueous solutions mimicking the biological fluid, although there are some differences within the body in this regard, especially in the rate of degradation observed at the different implantation sites. It is possible that cell activity, related to phagocytosis or the release of free radicals, could be responsible for such variations.

Between the two extremes in terms of stability, represented by the (almost) inert and resorbable ceramics, there is a relatively small group of ceramics that exhibits a limited reactivity. This is particularly observed with a number of silica-based glasses and glass-ceramics mainly containing Si, Ca, Na, and P. In these ceramics, a selective dissolution of the surface takes place, involving the release of Ca and P, until a SiO_2 layer is formed. This is of considerable interest due to the ability of such surface layer to attract calcium and phosphate ions from the body fluids forming a calcium phosphate layer that makes possible the binding to bone, as discussed in other parts of this book. This bone-bonding ability was also reported for HA. In fact, in spite of some controversy regarding HA surface reactivity when soaked in simulated biological solutions, this ceramic is the best-known example



• **Figure 2.4.4.1** Factors governing the reactivity of ceramics and a classification of bioceramics according to their in vivo reactivity.

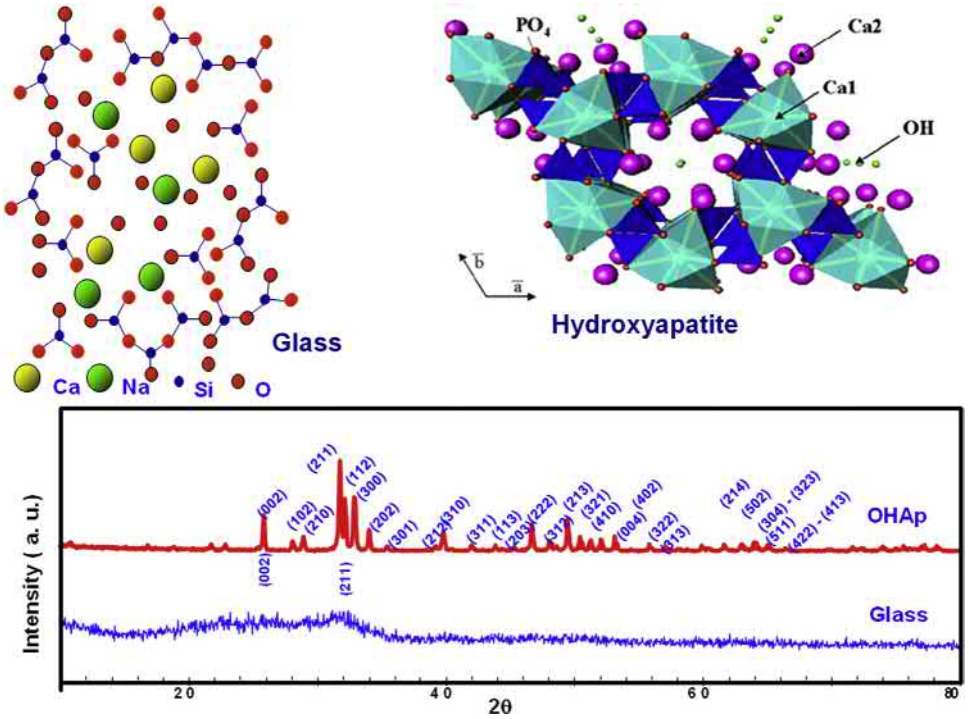
of *bioactive* ceramics. These implanted bioceramics are characterized by the absence of a fibrous tissue layer formation isolating them from the surrounding tissues, as occurs with inert ceramics as implants. A common method to evaluate the bioactivity of a ceramic under in vitro conditions is based on the use of a simulated body fluid (SBF), proposed by Kokubo (Kokubo et al., 1990). SBF is an aqueous acellular solution with a composition of inorganic ions almost equal to that of human plasma. In this assay, the formation of a layer of hydroxycarbonate apatite (HCA) nanocrystals on the material surface indicates an expected positive bioactive response in vivo (Vallet-Regí, 2001).

Fig. 2.4.4.1 shows representative examples of these three categories of bioceramics, including the family of carbon-based materials, which exhibit many ceramic-like properties.

Factors Influencing the Degradation of Bioceramics

The stability of ceramics in different environments displays a variable behavior depending on their chemical reactivity. In this regard, it is critical to bear in mind that selection of a particular bioceramic would be governed by a combination of its mechanical and physicochemical properties, depending on the intended application (e.g., as long-term or short-term implants). For a ceramic to be used as an implant for bone arthroplasty, inert ceramics are often used due to their very low friction coefficient that produces a minimum amount of wear particles. However, for those implant parts in contact with bone, a bioactive or biodegradable ceramic is mandatory to contribute to the process of bone regeneration, since inert ceramics cannot do that task.

Besides composition, other factors are known to affect bioceramic reactivity affecting their dissolution behavior in the biological medium (Fig. 2.4.4.1). Among them, the size of the crystalline domains (crystallinity), the particle size, or the presence of crystalline defects are critical. Thus decreasing the crystallinity and grain size augments the presence of

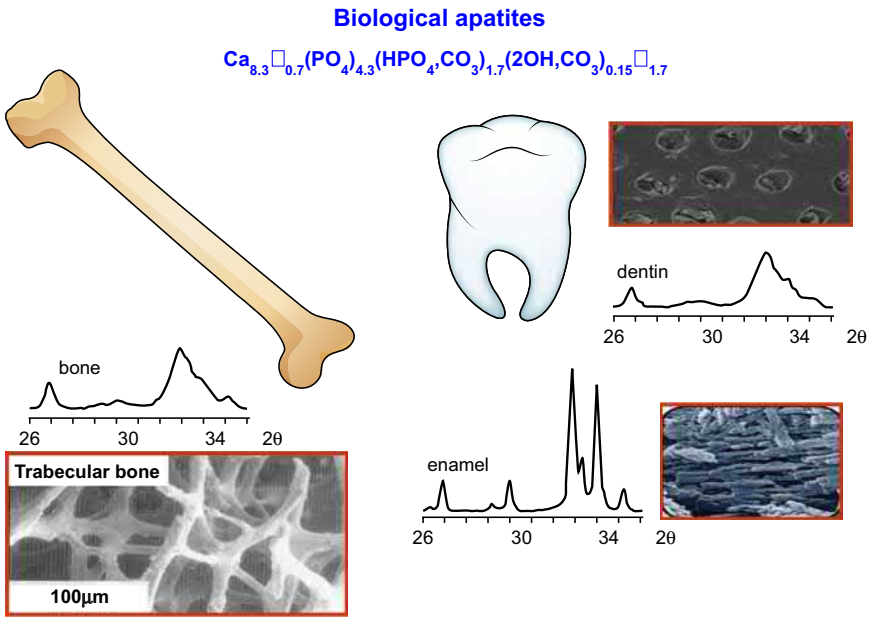


• **Figure 2.4.4.2** Comparison between the structure of a silica-based glass (disordered) and hydroxyapatite (ordered). The corresponding X-ray diffraction patterns are shown at the bottom.

network defects, which increase ceramic solubility. In addition, an increase in the surface area and porosity also promotes the latter. Fig. 2.4.4.2 shows in a comparative manner the different crystallinities exhibited by bioceramics, exemplified by the characteristic disordered structure of a silica-based glass containing a small proportion of phosphorus, calcium, and sodium as network modifiers, and the ordered crystalline structure of HA. These different structures produce very different X-ray diffraction patterns.

Increasing the crystallinity of a ceramic such as HA also tends to diminish its reactivity and, consequently, its bioactivity. However, since crystallinity is not the only factor responsible for ceramic reactivity, HA and other crystalline ceramics might exhibit a surface reactivity that makes them capable of binding to bone, i.e., to be bioactive. On the other hand, most of the available compositions of glasses behave as inert compounds when implanted. In fact, in traditional glasses obtained by quenching of a melt, the SiO_2 content should not exceed 60 mol%, and must contain over 10%–15% of monovalent oxides, such as Na_2O or K_2O, and divalent oxides, such as CaO or MgO, to be bioactive. The method of glass synthesis producing materials with radically different textural properties will also have a marked influence on their reactivity. Thus glasses obtained by wet methods, such as the sol–gel route, have high specific surface and porosity, which allow them to display bioactivity even with a SiO_2 content of 90 mol%. Likewise, glasses with compositions that make them totally degradable in the biological environment can also be obtained. Concerning the influence of particle size on ceramic bioactivity, glasses with a composition within the bioactivity window and a particle size of less than 90 μm can be completely degraded in vivo. Equally, by sintering at high temperatures, HA may reach a large particle size, which promotes formation of a thick fibrous nonadherent layer around the implanted material, thus preventing its bioactivity. In contrast, HA can be obtained by wet methods with very small particle size. This fact together with the presence of crystalline defects or ionic substitutions favors the release of reactive substances in the biological medium and its degradation. The complex behavior of a ceramic as determined by different structural variables justifies that HA was included in the three ceramic categories depicted in Fig. 2.4.4.1.

Considering the foregoing, reactivity has turned out to be a more suitable criterion than chemical composition or crystallinity for classifying bioceramics. Therefore slight differences in glass composition give rise to a bioinert, bioactive, or resorbable behavior (Hench and Anderson, 1993). In addition, it is possible to find glasses with identical composition behaving as bioinert or bioactive ceramics when synthesized by either melting or a sol–gel method (Vallet-Regi et al., 2003a; Salinas and Vallet-Regi, 2017). Moreover, some glass compositions considered bioactive can be completely resorbed when used as particles under a certain size limit, namely 90 μm for Bioglass 45S5 (Hench and Polak, 2002; Salinas et al., 2018). Similarly, in the case of crystalline ceramics the in vivo reactivity of HA can range from almost bioinert, when it is sintered at high temperatures as dense monoliths, to resorbable (Kumta, 2006), when having a particle size under 10 μm, and in between we have the bioactive character generally attributed to HA (Vallet-Regi and Gonzalez-Calbet, 2004).



• **Figure 2.4.4.3** Biological apatites present in bone and in tooth enamel and dentin.

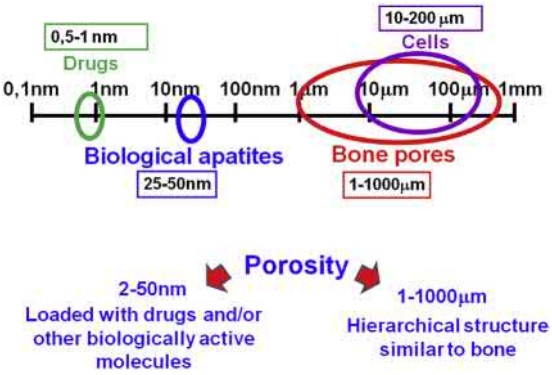
An implanted bioceramic may induce extracellular and/or intracellular responses in vivo. Implant biocompatibility ensures that these responses are not only harmless but indeed promote the function of target host tissues. In addition, degradability of bioceramics, which in part depends on their physicochemical structure, is also an important aspect to define their biocompatibility in vivo. In general, their predominant ionic bonds and chemical stability make bioceramics highly biocompatible materials for a range of clinical applications.

Reactivity and Degradation of Natural Apatites

A good example for understanding the complexity of factors that influence the reactivity and degradation of bioceramics can be provided by the three types of natural apatites present in tooth enamel, dentin, and bone (Fig. 2.4.4.3).

Bones of vertebrates are made of organic–inorganic composite materials whose structure includes an inorganic component made of carbonated and calcium-deficient nonstoichiometric HA. These biological apatite crystals, in the range of 25–50 nm (Vallet-Regi and Arcos-Navarrete, 2008; LeGeros, 1991), grow at the mineralization sites of the collagen molecules, which are grouped together forming collagen fibers. Furthermore, a certain hierarchical bone porosity is needed to accomplish bone physiological functions (Frieb and Warner, 2002). The order of magnitude of biological apatites and bone pores is shown in Fig. 2.4.4.4.

Bone remodeling, involving a coordinated process of bone degradation and new bone formation, is required for both bone repair and mineral homeostasis. For this reason,



• **Figure 2.4.4.4** Layout of different orders of magnitude in biological apatite and bone pores.

bone mineral contains nanometric pores and many crystallographic vacancies in the structure (i.e., empty positions in which there should be ions), which produces a calcium-deficient nonstoichiometric apatite. Likewise, this apatite structure can accommodate numerous types of extra ions in the three sublattices: Ca^{2+}, $(PO_4)^{3-}$, and OH^-; specifically, carbonate groups that are flat in shape and replace tetrahedral phosphate groups. Their presence in a proportion higher than 4% in bone apatite is very important since it produces structure stresses and increases apatite solubility. Therefore bone apatite is based on nanometric calcium-deficient carbonate HA. All these characteristics give them a high reactivity and ability to readily dissolve during bone remodeling.

However, in dentin and especially in enamel, mechanical behavior is most important; thus enamel contains much larger apatite crystals but lower defects, ion substitutions, and nonstoichiometry, compared to bone (Fig. 2.4.4.3).

Evolution in the Use of Bioceramics for Bone Repair

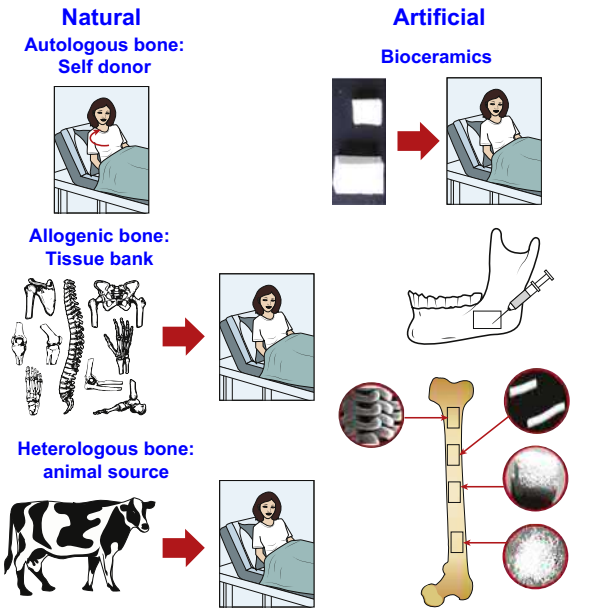
By the 1950s, inert ceramics like alumina, Al_2O_3, began to be used for structural applications in bone replacement due to their in vivo biocompatibility and excellent mechanical features. In the 1980s, ceramics based on calcium phosphates or calcium sulfates, bioactive glasses, and glass-ceramics started to be used as bone grafts or metallic implant coatings due to their degradation pattern and bioactive behavior. Current developments focus on new porous ceramics designed as scaffolds for hosting cells and bioactive molecules to help drive bone tissue regeneration. New advanced bioceramics, namely mesoporous silica-based materials, ordered glasses, and organic–inorganic hybrids, as well as mesoporous nanoparticles, are under investigation.

The field of bioceramics is an excellent example of translational biomedicine, since the synthesized material by chemists and engineers must be functionally validated as an implant into the host. The interaction of bioceramics with living tissues controls the biological behavior and degradation of the implanted materials, which requires the crossover of various clinical specialties and experimental sciences.

The development of a bioceramic implant for a specific clinical need in this field involves various stages, including in vitro and in vivo biocompatibility tests and other preclinical testing discussed elsewhere in this text. Regarding their mechanical behavior, ceramics exhibit great compression and low tensile strengths; they are stiff and brittle materials wherein failure takes place without plastic deformation. In addition, ceramics show high wetting degrees in a variety of forms: powder, porous pieces, dense pieces, injectable mixtures and cements, or as coatings. Ceramic surface tension favors the adhesion of proteins, cells, and other biological moieties, and the surface might exhibit antibacterial properties after appropriate treatment. However, recently developed ceramics with interconnected porosity show a significant decrease of their mechanical features.

Until recently, the most popular solutions in bone repair involved the use of natural materials, using autologous bone or bone allographs from a donor bank, or animal bone. This approach presents some drawbacks such as the need for two surgical interventions (autologous implant) and the risk of infection. Alternative inert, resorbable, or bioactive materials (ceramics) have found promising applications in this respect (Fig. 2.4.4.5).

The outcome of different ceramics as implants for bone repair and bone regeneration can be summarized as follows: *inert ceramics* induce the formation of an acellular collagen capsule, which isolates the material from the host tissue, and thus the artificial nature of the material prevails; *bioactive ceramics* react with the biological environment giving rise to bony apatite that, in concert with osteogenic cells, promotes new bone formation. These ceramics have excellent biocompatibility and bioactivity, but their mechanical properties are poor, rendering them unsuitable for the repair of large osseous defects. However, they are excellent for the filling of small defects. Glass-ceramics exhibiting improved mechanical properties with respect to the parent glass can be obtained by thermal treatments. Furthermore, organic–inorganic hybrid materials containing bioactive glasses as the inorganic component can also be manufactured. These hybrid materials have mechanical features like natural bone and are bioactive. The present technology allows design of bioactive ceramics with mechanical properties matching those of bone tissue in bone repair applications.

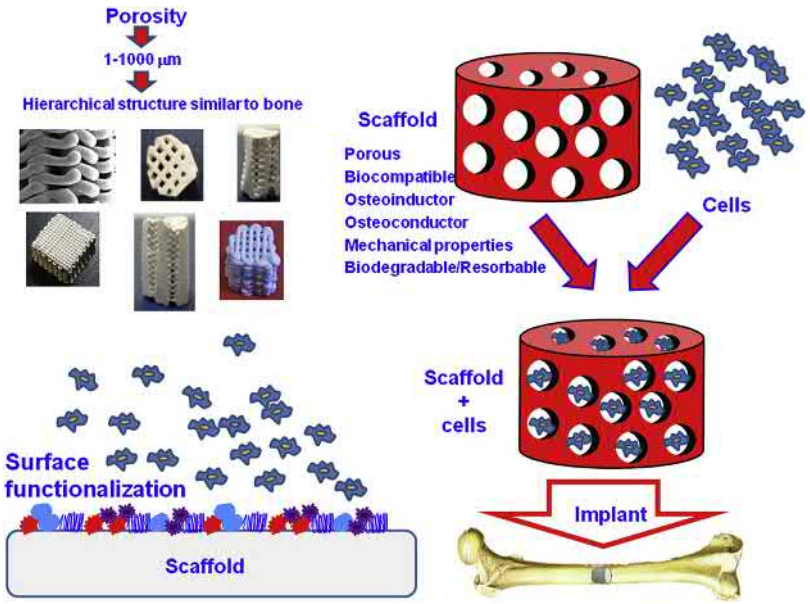


• **Figure 2.4.4.5** Natural bone and artificial bioceramics for human bone repair.

As mentioned earlier, ceramics with a hierarchical porous structure are now being investigated for putative use as scaffolds in bone tissue engineering. Pores, in the range of 2–50 nm (mesopores), enable the loading and release of biological molecules. Moreover, they must exhibit interconnected porosity with macropores and channels in the 2–1000 μm range, which allow cell interaction and vascularization when implanted (Fig. 2.4.4.4). This is an important point because the reactivity of ceramics begins at their surface in contact with a wet medium and in the presence of cells and proteins. This porosity though implies a certain sacrifice of their mechanical properties.

The pathway to reach third-generation bioceramics based on porous ceramic scaffolds as implants is depicted in Fig. 2.4.4.6. All of the ceramics mentioned earlier could be conformed into pieces with interconnected and hierarchical porosity within the micron range. Some sort of "smart" behavior is also required, so that these materials can modify their behavior in response to external or internal stimuli or to variations in the environment.

The possible ceramic degradation in vivo is an important issue to consider when designing a bioceramic as an implant. This applies to the so-called "traditional"



• **Figure 2.4.4.6** Requirements to be met by scaffolds for bone tissue engineering.

bioceramics of well-proven use in the clinic, and also to the *novel* bioceramics, whose development is at the forefront of knowledge and currently in progress. This aspect will be dealt with in more detail later on in this chapter.

As an example of these *new* bioceramics, silica-based mesoporous nanoparticles are currently at a preliminary research stage for putative cancer therapy. For this application their small size allows their incorporation into the bloodstream to carry antitumor drugs where necessary and deliver this cargo only where needed after receiving a stimulus that can be internal or external.

Bioceramic Interactions With the Biological Environment

When implanted, bioceramics trigger various cell and tissue responses, including acute and/or chronic inflammation, formation of granulation tissue, and fibrous encapsulation, which depend on the ceramic chemical composition and its structural features.

In Table 2.4.4.1, the most important bioceramics used clinically are shown.

Inert Ceramics: First-Generation Bioceramics

The most widely used near bioinert ceramics are alumina (Al_2O_3), zirconia (ZrO_2), TiO_2, and diverse forms of carbon, such as the low-temperature isotropic (LTI) form of pyrolytic carbon (PyC), glassy (vitreous) carbon, the ultralow temperature isotropic (ULTI) form of PyC and carbon fibers, carbon nanotubes, and graphene.

Applications of alumina and zirconia as load-bearing prosthetics in orthopedics and dentistry are similar, based on their excellent mechanical features such as wear resistance, high strength, and smooth surface; zirconia being superior to alumina for its higher toughness (Chevalier, 2006). Moreover, titanium and its alloys, first used as dental implants, have been subsequently and continuously used as long-lasting implants for their excellent biocompatibility and resistance to corrosion. Carbons are mainly used as coatings for improving the physicochemical and biological (e.g., antithrombogenic and antibacterial) properties of implants (Hu et al., 2010; Fan et al., 2010; Allen et al., 1994; Zhu et al., 2007; Bloomfield et al., 1991) or as fibers in reinforced composites.

Despite an almost bioinert character, first-generation ceramics can elicit a foreign body reaction, involving the recruitment of macrophages and the secretion of inflammatory cytokines (Rodrigo et al., 2006), and ultimately the formation of an acellular collagenous capsule isolating the implant from the host tissue (Ratner and Castner, 2002). This provokes interfacial micromovements that might eventually lead to implant failure. However, for most medical applications of these nearly bioinert ceramics, this foreign body reaction is rarely an issue.

The first applications of alumina as bone substitute (Smith, 1963) and dental implant were reported in the 1960s (Sandhaus, 1967). In addition, the first bioceramic couple (alumina–alumina), with enhanced wear resistance, was implanted in 1970 (Boutin, 1971). Alumina has been extensively used as an implant material for hip and knee arthoplastia (Oonishi et al., 1981) and as single crystal alumina bone screws and in dental applications since the 1980s (Kawahara, 1981). The mechanical properties (toughness and wear resistance) of alumina were improved by decreasing the grain size of alumina from 10 to 2 μm, increasing purity, lowering porosity, and using hot isostatic pressure as a processing method. Current research studies are focused

TABLE 2.4.4.1 First, Second, and Third-Generation Bioceramics

Type of Bioceramic	In Vivo Reactivity	Examples
First Generation:	Isolated by a nonadherent fibrous capsule	Alumina: Al_2O_3
		Zirconia: ZrO_2
Bioinert nonabsorbable		Carbons, mainly pyrolytic and as fibers in composites
Second Generation:	Dissolved after a specific time	Calcium phosphates
Biodegradable resorbable		Calcium sulfate
		Calcium phosphates and sulfates + ZnO, Al_2O_3, Fe_2O_3
		Coralline: $CaCO_3$
Bioactive surface reactive	Tightly bonded to the living tissues through a surface reaction	Hydroxyapatite, pure and substituted
		Hydroxycarbonate apatite
		Glasses: by melting and sol–gel
		Glass ceramics: apatite/wollastonite glass-ceramic and Ceravital
Third Generation:	Stimulating living tissue regeneration	Bioglass: in particulate form
Scaffolds of biologically active molecules		Porous bioactive and biodegradable ceramics
		Advanced bioceramics: Mesoporous materials, organic–inorganic hybrids

on reducing the alumina ball size to make it more appropriate for patients shorter in height; ZrO_2-based prostheses being more efficient in this respect. Postoperative failure of alumina, and other bioinert ceramic implants, is mainly a consequence of crack propagation (due to fabrication flaws or corrosion) under loading conditions (Morrell et al., 2012). Alumina has been used in dentistry for root analogs, endosteal screws, blades, and pin-type dental implants, and even ceramic crowns (Li and Hastings, 1998). However, mechanical tests showed functional limitations in some of these long-term devices. In this regard, single crystalline alumina showed mechanical strength superior to polycrystalline alumina as high-load devices. Alumina ceramics have also been used for total knee prosthesis, middle ear implants, and in ophthalmology (Schulte, 1990; Polack and Heimke, 1980).

Partially stabilized (with MgO or Y_2O_3) zirconia has been gaining market in orthopedics and dentistry as an option to alumina because of its enhanced mechanical properties, mainly toughness (Christel et al., 1988; Afzal, 2014; Akagawa et al., 1993). Moreover, in dentistry, compared to conventional titanium implants, the white color of zirconia makes it more similar to natural teeth. Large volume variations of around 5% take place when zirconia transforms from tetragonal to monoclinic polyform, which leads to an increase in the risk of cracking. Thus zirconia is usually stabilized by adding small amounts of oxides such as calcia (CaO), magnesia (MgO), or yttria (Y_2O_3), leading to PSZ or tetragonal zirconia polycrystals, which are partially or totally in tetragonal phase, respectively. PSZ zirconia represents the main form of modern medical-grade zirconia. This material also presents advantages over alumina in terms of lower friction and wear resistance. However, the use of zirconia as a bioceramic elicits adverse outcomes produced by surface degradation releasing particles and also radioactive impurities. Degradation is a major drawback in this respect, due to the phase transformation accelerated with material aging in the aqueous body environment, particularly under dynamic loads. Although surface degradation of zirconia balls due to phase transformation does not seem to be significant, and particulate debris is chemically stable and biocompatible, femoral head zirconia prostheses have a relatively short history and further investigation is required. Putative improvements of these bioinert ceramics might come from the preparation of alumina/zirconia composites (Kurtz et al., 2014).

Titanium and its alloys have been used as orthopedic and dental implants for more than 40 years (Elias et al., 2008). Upon air exposure, the formed outer TiO_2 layer prevents corrosion and greatly improves the biocompatibility of titanium by adsorbing proteins of the host environment (Liu et al., 2004). Attempts to further improve the biocompatibility of Ti-based biomaterials by HA coating and adsorption of osteogenic peptides have been carried out (Khorasani et al., 2015; Van der Stok et al., 2015).

Several carbon allotropes, including nanocrystalline glassy carbon, graphene, diamond-like carbon, and PyC, are widely used as implant coatings, since they show optimal adherence to both metallic and polymeric substrates and are not degraded in vivo. The most common form of carbon

TABLE 2.4.4.2 Clinical Applications of First- and Second-Generation Bioceramics

Ceramic	Clinical Application	Examples
Bioinert	Coatings for tissue ingrowth: orthopedic, dental, maxillofacial	Al_2O_3
	Orthopedic load-bearing applications	Al_2O_3, ZrO_2, PE–HA composite
	Artificial heart valves	Pyrolytic carbon coatings
	Artificial tendon and ligament	PLA–carbon fiber composites
Bioactive	Coatings for prosthesis fixation: orthopedic, dental, maxillofacial	HA, bioactive glasses, and glass-ceramics
	Percutaneous devices	Bioactive glasses, bioactive composites
	Periodontal pocket elimination	HA, HA–PLA composite, sodium phosphate, calcium phosphates, bioactive glasses
	Spinal surgery	Bioactive glass-ceramics, HA
Bioinert and bioactive	Dental implants	Al_2O_3, HA, bioactive glasses
	Alveolar ridge augmentations	Al_2O_3, HA, HA–autogenous bone, bioactive glasses
	Maxillofacial reconstruction	Al_2O_3, HA, HA–PLA composite, bioactive glasses
	Otolaryngological applications	Al_2O_3, HA, glasses, glass-ceramics
	Orthopedic fixation devices	PLA–carbon fibers, PLAca/p glass fibers
Resorbable	Temporary bone spacers, fillers	Calcium phosphates (α- and β-TCP, etc.), calcium sulfate

HA, Hydroxyapatite; *PE*, polyethylene; *PLA*, poly(lactic acid); *TCP*, tricalcium phosphate.

used in this regard is PyC, presented in two forms: LTI and ULTI (Dauskardt and Ritchie, 1993). The former material presents excellent biocompatibility with the cell and protein components of blood and soft tissues, and it has received special attention related to its nonthrombogenic behavior which has led to its wide use in prosthetic heart valves. Moreover, LTI carbon shows no degradation and excellent strength and resistance to wear and fatigue in vivo. At present, over 90% of mechanical heart valve prostheses use LTI–PyC as a coating on a polycrystalline substrate or as a monolithic material. PyC can also be used in small orthopedic joints such as fingers and as spinal inserts. However, current efforts are being addressed to eliminate the traces of silicon carbide in PyC, due to its thrombogenicity, and to improve PyC mechanical properties.

Future improvements of almost bioinert ceramics could be derived from manufacturing alumina/zirconia composites or, alternatively, from research on nonoxide bioinert ceramics, namely nitrides and carbides like Si_3N_4 or SiC.

Table 2.4.4.2 shows important clinical applications of bioinert ceramics and second-generation ceramics that will be described in the next section.

Resorbable and Bioactive Ceramics: Second-Generation Bioceramics

Bioactive ceramics denote those ceramics whose surface is able to form a strong bond with soft and hard tissues (Hench et al., 1971), making them suitable for many clinical applications. As mentioned in another section of this chapter, typical examples of bioactive ceramics are HA and some compositions of glasses and glass-ceramics (Vallet-Regi et al., 2006; Hench and Wilson, 1984; Yuan et al., 1999; Vallet-Regi et al., 1999; Livingston et al., 2002; Kokubo et al., 2003). In contact with biological fluids, dissolution products of these ceramics cause the formation of an HA-like layer on their surface, whereby they can promote cell attachment and cell differentiation (Kokubo, 1998; Sanders and Hench, 1973; Xynos et al., 2001). The apatite particles on the surface of bioactive ceramics are easily recognizable by scanning electron microscopy because they have a needle-like shape of around 500 nm in length, agglomerated in pseudospherical particles of 10 μm in diameter. These bioceramics are osteoinductive materials, so that they activate bone tissue regeneration (Hench and Polak, 2002). They have excellent features in terms of biocompatibility and bioactivity, which are strongly associated with ion release from their surface into the surrounding tissue (Hoppe et al., 2011). Furthermore, these implanted bioceramics induce no deleterious effects related to tissue inflammation. However, prepared as dense monoliths, they are brittle, which renders them unsuitable for repairing large osseous defects.

These bioceramics are available in different formats: powder, porous pieces, dense pieces, injectable mixtures, and coatings, dependent on the intended application. Thus a bioactive glass shaped as a porous piece exhibits a

fast bioactive response. In this form, the biological fluid can reach the inner structure of the glass more effectively, thus improving its reactivity. These bioceramics are excellent for the filling of small bone defects, where the rate of bone regeneration is the main concern, but the mechanical properties are a secondary aspect. In addition, glasses can also be used for the production of glass-ceramics (see later) by thermal treatment (Roman et al., 2003), which exhibit a somewhat lower bioactivity than glasses but mechanical properties closer to natural bone. In addition, both bioactive glasses and glass-ceramics can be used to design magnetic materials for promoting bone regeneration and, simultaneously, killing bone cancer cells by hyperthermia (Del Real et al., 2002).

Biodegradable ceramics are designed to fulfill a specific function for a certain period of time to help tissue regeneration, and they are resorbed thereafter. In this manner, possible deleterious effects associated with a prolonged permanence of a synthetic biomaterial in the host can be avoided. Calcium phosphates and calcium sulfates are typically considered major members of degradable ceramics (Elliott, 1994; De Groot, 1991; Dorozhkin and Epple, 2002; Pietrzak and Ronk, 2000). In vivo ceramic degradation usually occurs by passive dissolution of ions and/or by cell-mediated resorption in the biological environment (i.e., by enzymatic activities and pH changes). Host monocytes/macrophages and even osteoclasts from the bone marrow rapidly invade the bioceramic implant surface and play a key role in material degradation (Rae, 1986). Thus phagocytosis by monocytes/macrophages or acidification by osteoclasts causes the resorption of the bioceramic implant (Heymann et al., 1999). In addition, osteoblasts and other mesenchymal cells present at the implantation site have been shown to be able to phagocytose calcium phosphate (Heymann et al., 1999; Gregoire et al., 1990). As mentioned earlier in this chapter, decreasing the particle size or increasing the hydrophilic character can promote bioceramic degradation (Vallet-Regi et al., 2001; Colilla et al., 2006). Moreover, the loss of mechanical integrity of these ceramics during degradation might contribute to material disintegration (Tamimi et al., 2012; LeGeros, 1993). The latter generates particles that can adversely affect extracellular matrix production by osteoblasts and may result in periimplant osteolysis (Grover et al., 2003). Hence, a critical aspect in designing resorbable ceramics will be to adjust the ceramic degradation rate, which is usually faster than the process of tissue healing, to a specific biomedical application.

Present research is focused on the development of porous and new advanced bioceramics as scaffolds for hosting cells and bioactive molecules (growth factors, small peptides) to be released into the biological environment in a controlled manner for tissue-engineering applications (Langer and Vacanti, 1993; Salinas et al., 2013). This is discussed in detail in other sections of this chapter.

Calcium phosphates. Most of the second-generation ceramics used for bone regeneration are based on calcium phosphates Zhang et al. (2007); Dorozhkin (2010); Lew et al. (2012); Daculsi et al. (2014); Wang et al. (2014); Habraken et al. (2016). These include: synthetic apatites, pure and substituted biphasic mixtures of calcium phosphates, and calcium cements, containing calcium phosphates and calcium sulfate.

Synthetic apatites. HA and type B HCA are the most investigated calcium phosphate bioceramics due to similarities with the inorganic component of bone (Elliott, 1994). Submicrometric particles of HA can be obtained by aerosol pyrolysis (Vallet-Regi et al., 1994), precipitation (Naasaraju and Phebe, 1996; Vallet-Regi et al., 1997), or the liquid mix technique (Pechini, 1967; Peña and Vallet-Regi, 2003). The biological type B HCA, where CO_3^{2-} are located in the PO_4^{3-} positions, is synthesized using moderate temperatures (Doi et al., 1998). At higher temperatures a high CO_3^{2-} content is included in the structure but located in the OH^- sublattice; in this way a nonbiological type A HCA is obtained (LeGeros, 1991).

HA structure can accept many compositional variations in the Ca^{2+}, PO_4^{3-}, or OH^- sublattices. Thus apatite crystals usually included ions such as Na^+, K^+, Mg^{2+}, Sr^{2+}, Cl^-, F^-, or HPO_4^{2-} (Jha et al., 1997). The migration of these extra ions toward the surrounding tissues produces an increase in the crystal size, decreasing the solubility of the bioceramic. This effect has positive physiological consequences in the rapidly growing young—and less crystalline—bone. Ion substitutions in the HA structure turn bone into an important system to quench toxic heavy metals in the biological milieu. In addition, the ability to host ions allows the design of synthetic calcium phosphates with improved properties for specific biomedical applications. The ionic substitutions can modify the surface structure and electric charge of HA, with potential influence on the biological environments. In addition, while carbonate and strontium ions facilitate apatite dissolution, the release of certain chemical elements, namely strontium, zinc, or silicate, during resorption facilitates bone formation. Silicates in the network increase the mechanical strength of HA, and accelerate its bioactive response (Vallet-Regi and Arcos, 2005; Gibson et al., 1999). Thus the current trend is to obtain synthetic calcium phosphates partially substituted with different ions for use as implants.

Biphasic mixtures of calcium phosphates. The most popular materials of this type are based on HA and β-TCP, $\beta\text{-}Ca_3(PO_4)_2$, mixtures (Daculsi, 1998; Tancred et al., 1998; Kivrak and Tas, 1998; Sanchez-Salcedo et al., 2008a), which can evolve to HCA in the biological environment. This process involves the gradual dissolution of the mixture, releasing Ca^{2+} and PO_4^{3-} to the local environment, thus providing a source of newly formed bone minerals. This material can be injected and used as a coating or as bulk in bone replacement. Moreover, other biphasic mixtures have been investigated, including calcium phosphates together with other second-generation ceramics, namely bioactive glasses and calcium sulfates (Ramila et al., 2002; Cabañas et al., 2002).

Bone cements. Cements based on calcium phosphates, calcium carbonates, or calcium sulfates have attracted much attention due to their excellent biocompatibility. Most of the injectable calcium phosphate cements evolved to either a calcium apatite or octacalcium phosphate during the setting reaction. Physical–chemical properties of these materials, such as the setting time, porosity, and mechanical behavior, depend on the cement formulation and the presence of additives (Ginebra et al., 2004; Otsuka et al., 1995; Nilsson et al., 2002). These cements cured in field are biocompatible and they slowly resorb, while newly formed bone grows and replaces the cement in vivo. Research is under way on shortening the curing time in contact with blood and improving the mechanical toughness.

Calcium phosphate coatings. HA and other calcium phosphates are also used as coatings to protect the surface of metals (i.e., titanium alloys, Ti6Al4V, and commercially pure Ti) from the biological environment. Commercial implants with such coatings are produced by plasma spray at high temperature (Koch et al., 1990; García-Sanz et al., 1997; Sun et al., 2001), which is advantageous in terms of a rapid deposition rate and a relatively low cost. However, the formation of resorbable amorphous calcium phosphate (ACP) in the coating by this method compromises implant integrity. Other unresolved issues related to these coatings are the adherence to substrate and instability of HA at high temperatures or the phase transition of titanium at 1156 K. Alternative techniques to obtain the coatings at lower temperature, including physical vapor deposition (PVD) (Park et al., 2005), chemical vapor deposition (CVD) (Cabañas et al., 2003), magnetron sputtering (Wolke et al., 1998), electrophoretic deposition (Kannan et al., 2002), pulsed laser deposition (PLD) (Arias et al., 2003), and sol–gel-based dip coating (Hijon et al., 2006), allow a higher control of the coating thickness and crystallinity of phases.

Glasses. Specific compositions of glasses react with body fluids forming an HCA layer, which favors the generation of a bone matrix and bone growth. These glasses are used for filling osseous cavities, substitution of ear ossicles, maxillofacial reconstruction, and dental applications (Vallet-Regi et al., 2003a,b). Those glasses exhibiting a high bioactivity are eligible as bioactivity accelerators of mineral apatites or as bioactivity inductors of magnetic materials for hyperthermia treatment of osseous tumors.

Melt glasses. The first bioactive glasses, prepared by quenching of a melt, contained SiO_2 and P_2O_5 as network formers, and CaO and Na_2O as network modifiers (Hench et al., 1971). By using the SBF test, the silica-rich layer formed on the glass surface by the ionic exchange of calcium and sodium ions in the glass and protons in the solution were initially found to attract calcium, phosphate, and carbonate ions in the surrounding fluid to form ACP. This then crystallizes into a biologically active HCA layer that promotes new bone formation (Vallet-Regi, 2001). Those glasses with the highest bioactivity, as tested by this method, were able to bond to both hard and soft tissues. To explain these differences in reactivity, in 1994 Hench defined two classes of bioactivity: class A (osteoproductive) and class B (osteoconductive) (Hench, 1994, 2016).

The high bioactivity of sol–gel glasses (SGGs) makes them excellent candidates to be used in coatings, mixed materials, or as porous scaffolds in third-generation biomaterials, which will be described later on in this chapter.

Sol–gel glasses. The sol–gel synthesis of bioactive glasses produces materials (fibers and highly porous monoliths, or coatings) with high textural properties and excellent biocompatibility in both cell cultures (Olmo et al., 2003) and animal models (Gil-Albarova et al., 2005). The sol–gel route is more time consuming than the traditional quenching of a melt, but it requires noticeably lower temperatures. The $CaO–P_2O_5–SiO_2$ system has been the most studied type of SGGs (Li et al., 1991; Pereira et al., 1994; Peltola et al., 1999; Salinas et al., 2001), containing additions such as MgO, ZnO, or removing P_2O_5, to modify the mechanical properties, the resorption rate, or the interaction with osteoblasts (Perez-Pariente et al., 1999; Du and Chang, 2004; Oki et al., 2004). CaO plays an essential role in the texture and bioactive response of SGGs (Martinez et al., 2000); Ca^{2+} ions released to the medium increase exposure of the silanol (Si–OH) groups on the glass surface, which favors the formation of the HCA layer. Of note, formation of the latter depends on the presence of P_2O_5 in the glass (Salinas et al., 2002). $CaO–SiO_2$ glasses exhibit higher reactivity. In contrast, in $CaO–P_2O_5–SiO_2$ glasses, ACP formation is slower but evolves more rapidly to HCA nanocrystals than $CaO–SiO_2$ glasses.

Mesoporous bioactive glasses. (MBGs), first synthesized by Zhao et al. in 2004 (Yan et al., 2004), have more controlled and reproducible textural properties than SSGs. They also exhibit twofold higher surface areas and pore volumes than those of SGG analogs with identical composition (Izquierdo-Barba et al., 2013), consistent with the observed faster bioactivity kinetics than the latter glasses. Also, in contrast to SGGs, MBGs exhibit ordered mesopores with a pore diameter between 2 and 10 nm in a very narrow pore size distribution. MBGs also have abundant silanol groups on their surface that allow their functionalization as required and facilitate an excellent performance in SBF (Vallet-Regi and Salinas, 2017). The large surface area of MBGs is thought to be responsible for the high reactivity in SBF medium reaching a pH of 6.7 on the surface during the first stages of the assay, instead of a pH of 7.4 commonly observed in these assays for bioactive melt and SSGs in this assay (Vallet-Regi and Salinas, 2018). This lower pH made possible the formation of octacalcium phosphate as an intermediate phase between ACP and calcium-deficient HA (CDHA), as reported to occur during bone maturation in vivo. All these characteristics make MBGs excellent candidates for bone tissue-engineering applications.

As for the SGGs, most of the investigated MBGs belong to the $SiO_2–CaO–P_2O_5$ system synthesized by the evaporation-induced self-assembly method (Brinker et al., 1999). The CaO content and the temperature used for the aging of gel during the process of synthesis influence the

order of mesopores obtained (García et al., 2009). Analysis of the mesostructure of MBGs and SGGs by high-resolution transmission electron microscopy allowed a better understanding of the role of the P_2O_5 content in the behavior of these glasses in SBF medium (Vallet-Regi et al., 2005b; Vallet-Regi and Salinas, 2018). In both types of glasses, P_2O_5 binds to calcium to form calcium phosphate nuclei, removing calcium ions from the glass network and, as a consequence, retarding ACP formation in the in vitro assay. On the other hand, the formation of CDHA identical to that of biological apatite is accelerated. In vitro studies using SBF assay showed the different bioactive responses of two SGGs and two MBGs, with or without P in their composition, respectively. The presence of P was quite important for SGGs and minimal for MBGs.

There is now a growing tendency to include small amounts of other oxides with biological activity, such as CeO_2, Ga_2O_3, ZnO, CuO, SrO, CoO, or Ag_2O, for improving the biological performance of MBGs (Salinas et al., 2011; Kargozar et al., 2018; Sanchez-Salcedo et al., 2018). Surfactants are a necessary addition during MBG syntheses for self-assembly in aqueous solution to produce mesophases acting as structure-directing agents of the glass network. The most common mesoporous arrangements obtained for MBGs are 2D hexagonal, spatial group (SG) P6mm, and 3D cubic bicontinuous SG Ia-3d.

Bioactive glass coatings. As previously mentioned for calcium phosphate, many techniques can be used to obtain ceramic coatings on metallic substrates, including PLD, PVD, CVD, plasma spray, and dip coating. The latter method controls the porosity, roughness, and composition of the bioactive film formed on the metal surface. As an example of the stability of such coatings, a bioactive glass composed of 20%CaO–80%SiO_2 (mol%) coating the Ti6Al4V surface completely dissolved in 14 days in the SBF assay (Izquierdo-Barba et al., 2003). However, in the presence of osteoblasts, this coating not only remained stable in the culture medium, but it promoted cell adhesion, proliferation, and differentiation (Izquierdo-Barba et al., 2006). The influence of the substrate on the behavior of SGG coatings is well illustrated by using 316L stainless steel as substrate. In this case, silicon in the glass bonds to chromium in the substrate during the dip-coating synthesis, subsequently increasing the corrosion of this metallic alloy (Vallet-Regi et al., 2003b).

Mixed materials containing bioactive SGGs. Mixed materials, including bioactive SGGs, have been investigated, including: SGG–polymer–drug, SGG–magnetic component, and SGG–HA. *SGG–polymer–drug materials* were designed to obtain systems with controlled release of bioactive drugs. In this case, bone integration is improved, and the drug release is favored by the ionic exchange between the glass and the biological medium. *SGG–magnetic glass–ceramics* have been designed for treating bone tumors, based on the higher sensitivity of cancer cells to hyperthermia (Arcos et al., 2003). The in vitro biocompatibility of these mixed ceramics has been established (Serrano et al., 2008). SGG–HA materials have also been designed to ameliorate the bioactivity of HA. Thus a 30%CaO–70%SiO_2 glass/HA mixture was found to be covered with an HCA layer after 12 h in SBF, whereas HA alone was not modified in this regard after 45 days. The highest reactivity in this in vitro setting was achieved with biphasic HA and dried-gel glass mixtures with an average particle size of 30 μm.

Glass-ceramics. This family of compounds is obtained by the thermal treatment of glasses that produced the formation of crystalline phases inside the glass matrix. The synthesis of a glass-ceramic requires the stages of nucleation and growth. The former is favored by the addition of nucleating agents. Further annealing causes uniform crystal growth. Thus glass-ceramics behave as composites with the crystalline phases strengthening the glassy matrix. Consequently, they exhibit superior mechanical properties compared to the parent glass, and also to sintered crystalline ceramics, but without matching those of cortical bone (Vallet-Regi et al., 2005a,b). Glass-ceramics with rapid bioactive response were synthesized by thermal treatment of SGGs (Padilla et al., 2005; Boccardi et al., 2017). However, glass-ceramics present a poorer bioactive response than glasses due to a lower abundance of Si–OH groups on their surface and a decreased release of calcium ions from the crystalline phases. The bioactive response, expressed as the bioactivity index $I_B = 100/t_{0,5bb}$ (day^{-1}) ($t_{0,5bb}$ days required for 50% bioceramic surface bonding to bone) varied for different ceramics between 0 for alumina and other bioinert ceramics; 2.3 for HA; 3.2 for apatite/wollastonite glass-ceramic; and 12.5 for Bioglass 45S5 (Hench, 1998).

Table 2.4.4.3 shows important bioactive and resorbable bioceramics and their clinical applications.

Third-Generation Ceramics

Third-generation bioceramics are based on resorbable or bioactive materials obtained in a porous form that allows them to act as scaffolds for cells and inducting molecules to drive tissue regeneration. This category includes bioceramics based on porous second-generation bioceramics, like nanometric apatites, shaped as pieces with interconnected porosity, and new advanced bioceramics like silica mesoporous materials, mesoporous ordered glasses, or organic–inorganic hybrids. Manufacturing of these ceramic scaffolds for tissue engineering requires the use of conformation methods that yield pieces with interconnected porosity and pores in the 2–400 μm range (Sanchez-Salcedo et al., 2008b). Several of these methods proceed at room temperature (Roman et al., 2008), which makes it possible to include molecules with biological activity.

Silica-based mesoporous materials. These materials were initially proposed for use as drug delivery systems in biomedical applications (Vallet-Regi et al., 2001), and thereafter as bioactive ceramics (Vallet-Regi et al., 2006).

TABLE 2.4.4.3 Bioactive and Resorbable Bioceramics and Their Uses as Implants

Ceramic	Form	Application	Function
Calcium phosphates	Bulk	Bone graft substitutes, cell scaffolds	Replace the bone loss
	Coatings	Surface coatings on total joint prosthesis	Provide bioactive bonding to bone
Glasses	Bulk	Endosseous alveolar ridge maintenance	Space filling and tissue bonding
		Middle ear prosthesis	Replacement of part of the ossicular chain
		Orbital floor prosthesis	Repair damaged bone supporting eye
	Powder	Fixation or revision arthoplasty	Restore bone after prostheses loss
		Filler in periodontal defects	Periodontal disease treatment
		Bone graft substitutes and cranial repair	Augmentation after diverse illness or traumas
Glass-ceramics	Bulk	Vertebral prostheses	Replace vertebrae removed by surgery
		Iliac crest prostheses	Substitute bone removed for autogenous graft
	Coatings	Fixation of hip prosthesis	Provide bioactive bonding
Calcium sulfate	Bulk and powder	Bone graft substitutes	Repairing osseous tissues

They are synthesized with surfactants acting as templates to obtain materials with ordered porosity—in the nanometer range—and amorphous silica pore walls. Previously described MBGs obtained in this manner as powder can be processed to form scaffolds enabling decoration with osteogenic substances (Perez et al., 2018). Moreover, bioactive glass microspheres with accelerated deposition of HCA have shown to exhibit hemostatic efficacy (Ostomel et al., 2006) and magnetic silica microspheres for drug targeting have been reported (Ruiz-Hernandez et al., 2008).

Organic–inorganic hybrid materials. These materials are synthesized at room temperature to preserve the organic component as bulk, coatings, and fibers. Organic–inorganic hybrids containing SiO_2–CaO glasses as the inorganic component and several biocompatible polymers as the organic component have been investigated with regard to their mechanical features comparable to bone (Vallet-Regi and Arcos, 2006). In some hybrid systems, only weak physical interactions exist between inorganic and organic domains with several containing poly(vinyl alcohol) (PVA) (Pereira et al., 2000; Martin et al., 2005) or poly(hydroxyethyl methacrylate) (Schiraldi et al., 2004). In other cases, chemical links between both components are formed, as occurs with hybrids containing poly(methyl methacrylate) (Rhee and Choi, 2002), poly(ε-caprolactone) (Rhee, 2004), or gelatin (Ren et al., 2002; Coradin et al., 2004). To improve the bioactive response of these hybrids, inorganic components such as TiO_2 were added to hybrids with poly(dimethylsiloxane) (PDMS) (Chen et al., 2000; Manzano et al., 2006a) or poly(tetramethylene oxide) (Miyata et al., 2004). Examples of hybrid systems investigated for bone repair include: (1) CaO–SiO_2–PDMS, obtained as bioactive coatings (Hijon et al., 2005) or as bioactive monoliths with or without P additions to improve bioactivity (Salinas et al., 2007; Manzano et al., 2006b); (2) CaO–SiO_2–P_2O_5–PVA, synthesized as transparent films (Pereira et al., 2000) or as bioactive and degradable monoliths (Martin et al., 2005); and (3) CaO–SiO_2-based hybrids with organic polymers containing methacriloxy and amino groups (Colilla et al., 2006), designed with tailored bioactivity and degradability proposed for time release of bioencapsulates (Gonzalez et al., 2008). Components of bioactive organic–inorganic hybrids are based on the so-called star gels, a family of materials that exhibit remarkable mechanical properties (Michalczyk and Sharp, 1995). These materials have a unique structure made of an organic core surrounded by flexible arms that yield materials with a mechanical behavior between that of glasses and rubbers (Sharp, 1998). Addition of Ca^{2+} ions conferred bioactivity in SBF to the star gels (Manzano et al., 2006a,b). Notably, these hybrids exhibit fracture toughness comparable to that of the human tibia.

Organic–inorganic hybrid materials were also synthesized as porous scaffolds (Tsuru et al., 2008) with interconnected pore structure. Thus SiO_2–PDMS with 90% porosity and pore size between 200 and 500 μm, obtained using sieved sucrose particles as a template (Yabuta et al., 2003), were evaluated in a bioreactor and implanted in vivo into brain defects. Gelatin-siloxane (3-glicidopropyltrimethoxisilane, GPTMS) hybrid scaffolds with different orders of porosity (5–10, 30–50, and 300–500 μm), obtained by freeze drying wet hybrid gels (Ren et al., 2002), were also assessed after

CASE STUDY: BIPHASIC CALCIUM PHOSPHATES

What Problem Was Addressed?

The treatment of bone defects resulting from surgery, trauma, or disease requires the use of biomaterials to achieve faster and better healing outcomes. Indeed, the use of biomaterials is an essential requirement to treat critical bone defects where their size is too large to heal on their own. Autografts and allografts are the gold standard to be used in this respect. However, these approaches have important drawbacks, including the limited supply of donor bone grafts, secondary trauma in harvesting autografts, and the immune response and/or the possibility of disease transmission for allografts. These facts stimulated interest in the development of new synthetic materials with similar properties to native bone for bone replacement and regeneration.

What Properties Were Required of the Material?

In the context of bone regeneration, the design of new biocompatible, osteoconductive, and osteoinductive materials is an important challenge. With this aim, calcium phosphate bioceramics are processed as porous materials, which makes tissue ingrowth possible. Moreover, they exhibit a bioactive surface that facilitates cell attachment, proliferation, and differentiation. With this application, a family of compounds designated biphasic calcium phosphates (BCPs) is a promising alternative for bone reconstruction. BCPs are formed by two phases: one is more stable, which contributes to its bioactive and osteoconductive surface; the other degrades with time and releases phosphate and calcium ions to the medium enabling new bone formation and causing an increase in material porosity, which facilitates tissue ingrowth. The partial degradation of BCP allows the maintenance of sufficient mechanical properties of the implanted biomaterial until new bone is formed.

What Partially Degradable Bioceramic Was Used?

BCPs are a combination between the more stable bioactive phase of hydroxyapatite ($Ca_{10}(PO_4)_6(OH)_2$, HA) and the more soluble β-tricalcium phosphate ($Ca_3(PO_4)_2$, β-TCP), thus allowing control of the material dissolution rate and the tailoring of mechanical properties. BCPs were first elaborated in 1986 by LeGeros, although some of the materials previously implanted as HA were actually a mixture of HA and β-TCP. The most common way to prepare BCPs is the thermal treatment of calcium-deficient apatites obtained by precipitation. When the calcium deficiency is small, that is, the Ca/P molar ratio is close to 1.67, the amount of β-TCP formed after calcination is very small. However, when the deficiency in calcium increases to Ca/P values close to 1.50, the amount of β-TCP in the BCP becomes increasingly high. Therefore by varying the calcium deficiency of the precursor hydroxyapatite, BCPs with the desired proportion of HA and β-TCP can be obtained. Currently, there are over 30 commercially available BCPs as bone substitutes for various orthopedic and maxillofacial applications. At present, there is no general agreement on the optimum proportions of HA and β-TCP in BCP. The majority of these commercial products contain a 60:40 ratio of HA:β-TCP, but there are also several products with other ratio values: 20:80, 65:35, or even 96:4. Variations of pH, temperature, and duration of the sintering process produce unique materials with different chemical and physical properties that lead to different tissue responses. Furthermore, BCP has been used as either a carrier or delivery system for therapeutic drugs (antibiotics, hormones, and growth factors) in bone tissue engineering. Despite the many BCPs in use, much research must be done concerning the optimum features for specific applications, including composition and grain size, to improve the desirable osteoinductive behavior of these materials.

implantation in brain defects where no inflammation was observed (Deguchi et al., 2006). Moreover, in vitro biocompatibility of chitosan–GPTMS hybrids, with or without calcium addition, with 90% porosity and 100 μm pores, prepared by freeze-drying methods, were proven in cell cultures (Shirosaki et al., 2008). Taken together, these data point to organic–inorganic hybrids as promising candidates to be used as scaffolds in tissue engineering.

Summary and Future Perspectives

Ceramics are widely used for bone repair and bone regeneration in orthopedics and dentistry. This chapter described the key role played by the interactions of these materials with the biological environment in bioceramic efficiency when implanted. Specifically, ceramic degradation behavior allows classification of bioceramics into three categories. Inert (or almost inert) ceramics have no tendency to degrade in vivo. Resorbable ceramics, on the contrary, are degradable to various degrees. The degradation products of these ceramics are directly phagocytosed by inflammatory cells, osteoclasts, or even mesenchymal cells of the host, or chemically disintegrated (i.e., by local cell-mediated pH changes) after implantation. A third category of bioceramics, usually referred to as bioactive ceramics, shows a surface affinity for bone binding. Inert and second-generation (bioactive and resorbable) ceramics are currently used as implants and other medical devices for bone repair. The degradation rate of these implanted bioceramics should match or at least approximate the osteogenic rate. In addition, resorbable and bioactive bioceramics, obtained as porous forms, are used for manufacturing scaffolds susceptible to hosting osteogenic cells and molecules for bone tissue-engineering applications. Incorporation of small peptides (osteostatin) or inorganic compounds (i.e., Sr, Cu, Zn) influencing bone growth and function into these ceramics appears to be an attractive approach in this context. It is obvious that despite extensive research carried out in the field, the perfect bioceramic implant is still not available. In this regard, third-generation bioceramics, which refer to those actively driving tissue regeneration and displaying optimal controlled degradability, are currently under investigation. Likewise, bioceramic nanoparticles might be envisioned as easily functionalized materials for intravenous injection or integrated into polymeric scaffolds to specifically target damaged tissues.

Pathological Calcification of Biomaterials

FREDERICK J. SCHOEN[1], ROBERT J. LEVY[2], HOBEY TAM[3], NAREN VYAVAHARE[3]

[1]Department of Pathology, Brigham and Women's Hospital, and Harvard Medical School, Boston, MA, United States

[3]Department of Bioengineering, Rhodes Engineering Research Center, Clemson University, Clemson, SC, United States

Calcification of biomaterial implants is an important pathologic process affecting a variety of tissue-derived biomaterials, as well as synthetic polymers in various functional configurations. The pathophysiology has been partially characterized by some useful animal models; common features are the involvement of devitalized cells and cellular debris and often extracellular matrix proteins, and oxidative damage to the extracellular matrix and/or other reactive sites within the implant. Calcification of biomaterials often contributes to deleterious outcomes. Clinically useful preventive approaches based on modifying biomaterials appear to be promising in some contexts.

The formation of nodular deposits of calcium phosphate or other calcium-containing compounds may occur on biomaterials and prosthetic devices used in the circulatory system and at other sites. This process, known as *calcification* or *mineralization*, has been encountered in association with both synthetic and biologically derived biomaterials in diverse experimental and clinical settings, including chemically treated tissue (*bioprosthetic*), homografts, and polymeric cardiac valve substitutes (Mitchell et al., 1998; Schoen and Levy, 1999, 2005; Claiborne et al., 2012), blood pumps used as cardiac assist devices (Schoen and Edwards, 2001), breast implants (Peters et al., 1998; Legrand et al., 2005), intrauterine contraceptive devices (Patai et al., 1998), urological stents (Vanderbrink et al., 2008), intraocular lenses (Neuhann et al., 2008; Nakanome et al., 2008; Rimmer et al., 2010; Rahimi et al., 2018), and scleral buckling materials (Brockhurst et al., 1993; Yu et al., 2005). Vascular access grafts for hemodialysis and synthetic vascular replacements composed of Dacron or expanded polytetrafluoroethylene (e-PTFE) also calcify in some patients (Tomizawa et al., 1998; Schlieper et al., 2008). Importantly, calcification can lead to important clinical complications of implanted biomaterials and medical devices, examples of which are stiffening and/or tearing of tissue heart valve substitutes, encrustation with blockage of a urinary stent or clouding of intraocular lenses (Table 2.4.5.1).

Deposition of mineral salts of calcium (as calcium phosphates, especially calcium hydroxyapatite) occurs normally in bones and teeth and is a critical determinant of their mechanical and biological properties (called *physiologic* mineralization). Mineralization of skeletal tissues is both controlled and restricted to specific anatomic sites. The mature mineral phase of bone is a poorly crystalline calcium phosphate known as calcium hydroxyapatite, which has the chemical formula $Ca_{10}(PO_4)_6(HO)_2$. Mineralization of some implant biomaterials is desirable for proper function, e.g., osteoinductive materials used for orthopedic or dental applications (Habibovic and de Groot, 2007), and materials used to engineer skeletal and dental tissues (Kretlow and Mikos, 2007; Bueno and Glowacki, 2009). However, severe consequences can occur if mineralization occurs in regions that do not normally calcify (*pathologic* or *ectopic* mineralization) (Kirsch, 2008).

Because the biomaterials used in medical devices outside of the musculoskeletal and dental systems are not intended to calcify, calcification of these biomaterials is *pathologic*. The mature mineral phase of biomaterial-related and other forms of pathologic calcification is a poorly crystalline calcium phosphate that closely resembles the calcium hydroxyapatite present in bones and teeth. Indeed, as we

TABLE 2.4.5.1 Representative Prostheses and Devices With Clinical Consequences due to Biomaterials Calcification

Configuration	Biomaterial	Clinical Consequence
Cardiac valve prostheses	Glutaraldehyde-pretreated porcine aortic valve or bovine pericardium, and allograft aortic/pulmonary valves	Valve obstruction or incompetency
Cardiac ventricular assist bladders	Polyurethane	Dysfunction by stiffening or cracking
Vascular grafts	Dacron® grafts and aortic allografts	Graft obstruction or stiffening
Soft contact lens	Hydrogels	Opacification
Intrauterine contraceptive devices	Silicone rubber, polyurethane or copper	Birth control failure by dysfunction or expulsion
Urinary prostheses	Silicone rubber or polyurethane	Incontinence and/or infection
Breast implants	Silicone	Implant contracture

will see later, biomaterials-related calcification shares many features with other conditions of pathologic calcification and physiologic mineralization. Pathologic calcification of natural structures is also a common feature of important disease processes; for example, in native arteries and heart valves, calcification occurs as an important feature of disease processes such as atherosclerosis and calcific aortic stenosis (Mitchell and Schoen, 2010; Schoen and Mitchell, 2010; Andrews et al., 2018; Pawade et al., 2015).

Pathologic calcification is further classified as either *dystrophic* or *metastatic*, depending on its setting (Kumar et al., 2015). In dystrophic calcification the deposition of calcium salts (usually calcium phosphates) occurs in damaged or diseased tissues or in or related to biomaterials; moreover, dystrophic calcification usually occurs in the setting of normal systemic calcium metabolism (generally defined by a product of the serum levels of calcium and phosphorus within the physiologic range). In contrast, metastatic calcification comprises the deposition of calcium salts in otherwise normal tissues in individuals who have deranged mineral metabolism, usually with markedly elevated blood calcium or phosphorus levels. Conditions favoring dystrophic and metastatic calcification can act synergistically. Thus, the rate and extent of dystrophic mineralization within abnormal tissues are accelerated when calcium and/or phosphorus serum levels are high, for example, in kidney failure or calcium supplementation (Umana et al., 2003; Peacock, 2010), and in osteoporosis (Hofbauer et al., 2007; Hjortnaes et al., 2010). Moreover, the ability to form physiologic mineral (e.g., in bone) is regulated through adjustment of enhancing and inhibiting substances, many of which circulate in the blood (Weissen-Planz et al., 2008). In young individuals (especially into early adulthood) the balance appropriately favors bone formation; moreover, the biochemical environment that favors physiologic bone formation in children also promotes calcification of biomaterials (Bass and Chan, 2006; Peacock, 2010).

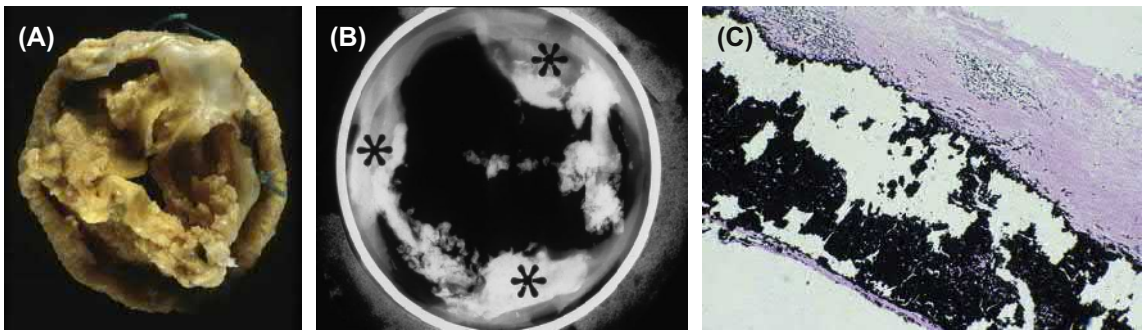
Additionally, calcification of an implanted biomaterial can occur either within the material (*intrinsic* calcification) or at the surface, usually associated with attached cells and proteins or in the implant fibrous capsule (*extrinsic* calcification). A notable instance of extrinsic calcification is that associated with prosthetic valve infection (also called prosthetic valve endocarditis) or thrombi.

The Spectrum of Pathologic Biomaterial and Medical Device Calcification

Bioprosthetic Heart Valves

Calcific degeneration of bioprosthetic heart valves composed of glutaraldehyde-pretreated heterograft materials, typically either porcine aortic valves or bovine pericardium (Fig. 2.4.5.1) is the most prevalent clinically significant and well-characterized dysfunction of a medical device due to biomaterials calcification (Schoen and Levy, 1999, 2005). The predominant pathologic process is intrinsic calcification of the valve cusps, largely initiated in the deep interstitial cells of the tissue from which the valve was fabricated and often involves collagen and elastin. Calcification leads to valve failure most commonly by causing tissue tears or tissue stiffening, and rarely by inducing distant emboli. Overall, approximately half of contemporary bioprostheses fail within 15–20 years.

Calcification is more rapid and aggressive in younger recipients; to exemplify, the rate of failure of bioprostheses is approximately 10% in 10 years in elderly recipients but is nearly uniform in less than 4 years in most adolescent and preadolescent children (Chan et al., 2006). In some young individuals with congenital cardiac defects or acquired aortic valve disease, human *allograft*/*homograft* aortic or pulmonary valves surrounded by a sleeve of the aorta or pulmonary artery, respectively, are used. Allograft valves are valves removed from a person who has died and transplanted to another individual; the tissue is usually cryopreserved (and thawed immediately prior to implantation), but not chemically cross-linked. Allograft vascular segments (without a valve) can be used to replace a large blood vessel.



• **Figure 2.4.5.1** Calcification of a pericardial bioprosthetic heart valve, implanted in a person for many years: (A) gross photograph, demonstrating marked thickening of cusps by nodular calcific deposits; (B) radiograph of another long-term valve, demonstrating predominant deposits at commissures; (C) photomicrograph demonstrating calcific nodule deeply embedded within cuspal tissue; von Kossa stain (calcium phosphates black) 100×.

Allograft vascular tissue, whether containing an aortic valve or not, can undergo severe calcification in the wall; calcification can lead to allograft valve dysfunction or deterioration (Mitchell et al., 1998).

Transcatheter (or Percutaneous) Cardiac Valve Replacements

Transcatheter aortic valve replacement (TAVR, also known as transcatheter aortic valve implantation [TAVI]) has emerged over the past decade as a widely used minimally invasive therapeutic option for patients with symptomatic severe aortic stenosis who are ineligible for or at excessive risk for conventional surgical aortic valve replacement (Baumgartner et al., 2017). In this procedure, the diseased valve is not removed; instead, it is simply pushed out of the flow stream by the expanded replacement valve. Transcatheter valves are usually fabricated from bovine pericardium and mounted on a self-expanding or balloon-expandable stent crimped into and deployed via a catheter inserted through the femoral artery and threaded retrograde through the aorta to the heart, or across the apex of the ventricle into the heart.

Although this procedure was initially preferred for people who have severe valve disease but are not suitable for open-heart surgery, recent demonstration of favorable outcomes (relatively to open surgery) in intermediate- and low-risk patients suggests that the use of transcatheter valve replacement may be expanding. These valve replacements are also deployed after a failure of a bioprosthetic heart valve implant in a *valve-in-valve* procedure. The old replacement valve is *left inside the patient,* and the TAVR is deployed inside of the old valve, thereby pushing open the old valve and opening up a smaller but unblocked/functional valve with effective orifice area. The overall long-term durability of transcatheter replacement valves is yet uncertain; nevertheless, calcification has been observed in some cases (Zareian et al., 2019; Kataruka and Otto, 2018). Furthermore, studies have shown that crimping is associated with higher level of passive tissue calcification (Ramin et al., 2019; Munnelly et al., 2012). Most of the TAVRs currently used are treated with proprietary anticalcification treatments.

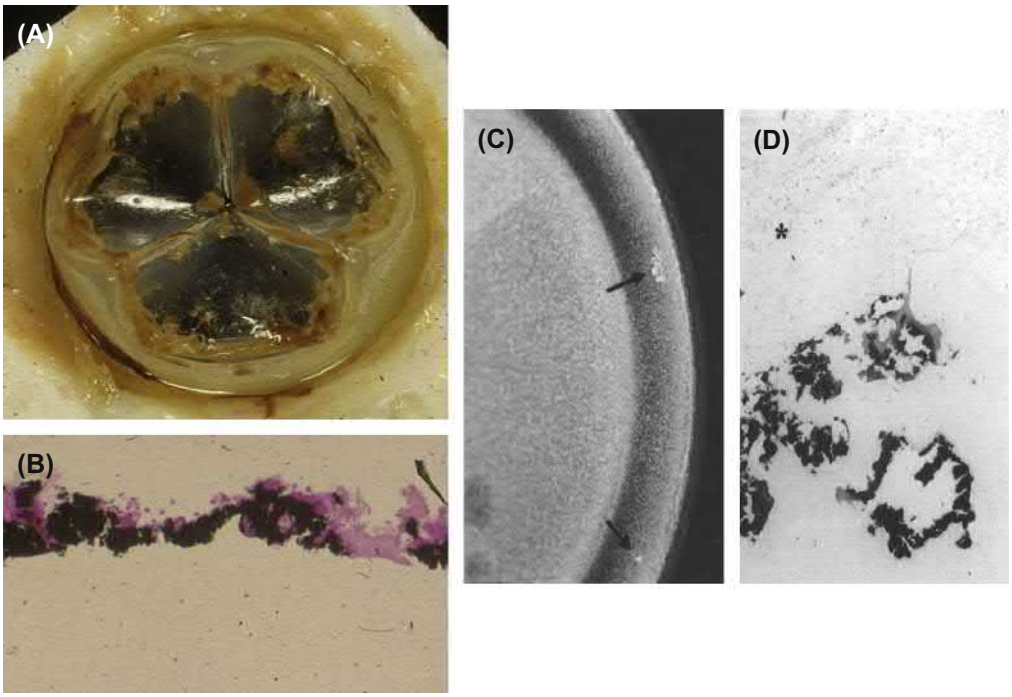
Polymeric Heart Valves and Blood Pump Bladders

Calcification has also complicated the use of heart valves and artificial mitral valve *chordae tendineae* composed of polymers (e.g., polyurethane) (Fukunaga et al., 2010; Hilbert et al., 1987; Schoen et al., 1992a; Schoen and Levy, 1999; Wang et al., 2010) and the flexing bladder surfaces of blood pumps used as ventricular assist devices or total artificial hearts (Schoen and Edwards, 2001) (Fig. 2.4.5.2). Massive deposition of mineral leading to failure of cardiac assist devices has been noted in experimental animals, but only a lesser degree of calcification has been encountered following extended human implantation. Mineral deposits can result in deterioration of pump or valve performance through loss of bladder pliability or the initiation of tears. Blood pump calcification, regardless of the type of polyurethane used, generally predominates along the flexing margins of the diaphragm, emphasizing the important potentiating role of mechanical factors in this system (Coleman et al., 1981; Harasaki et al., 1987; Kantrowitz et al., 1995).

Calcific deposits associated with a polymeric heart valve or blood pump components can occur either within the adherent layer of deposited thrombus, proteins, and cells on the blood-contacting surface (a form of extrinsic mineralization) or below the surface (a form of intrinsic calcification) (Joshi et al., 1996). In some cases, calcific deposits are associated with microscopic surface defects, originating either during bladder fabrication or resulting from cracking during the function.

Breast Implants

Calcification of silicone-gel breast implant capsules occurs as discrete calcified plaques at the interface of the inner fibrous capsule with the implant surface (Peters et al.,1998; Gumus, 2009). Capsular calcification has also been encountered with breast implants in patients with silicone envelopes filled with saline. Calcification could interfere with effective



• **Figure 2.4.5.2** Calcification of an experimental polymeric (polyurethane) heart valve: (A) gross photograph of valve; (B) photomicrograph of calcified material at surface of polymer (polymer at bottom of photo); and calcification of the flexing bladder of a ventricular assist pump removed from a person after 257 days. (C) Gross photograph. Calcific masses are noted by arrows; (D) photomicrograph. (B) and (D) von Kossa stain (calcium phosphates black) 100×.

tumor detection and diagnosis, which could potentially delay treatment, particularly during monitoring for recurrence in patients who have breast implants following reconstructive surgery for breast cancer. In a study of breast implants removed predominantly for capsular contraction, 16% overall demonstrated calcific deposits, including 26% of implants inserted for 11–20 years, and all those inserted for more than 23 years (Peters and Smith, 1995). Another study demonstrated calcification associated with virtually all implants examined after more than 20 years (Legrand et al., 2005).

Ivalon (polyvinyl alcohol) sponge prostheses, used quite extensively during the 1950s, were also frequently associated with calcification. In Japan, where augmentation mammoplasty was frequently performed using an injection of foreign material (liquid paraffin from approximately 1950 until 1964, and primarily liquid silicone injections thereafter), the incidence of calcification has been much higher. One study showed calcification in 45% of breast augmentations which were done by injection (Koide and Katayama, 1979).

Intrauterine Contraceptive Devices

Intrauterine contraceptive devices (IUDs) are composed of plastic or metal and placed in a woman's uterus chronically to prevent implantation of a fertilized egg. Device dysfunction due to calcific deposits can be manifested as a contraceptive failure or device expulsion. For example, accumulation of calcific plaque could prevent the release of the active contraception-preventing agent—either ionic copper from copper-containing IUDs or an active agent from hormone-releasing polymer IUD systems. Studies of explanted IUDs using transmission and electron microscopy coupled with X-ray microprobe analysis have shown that surface calcium deposition is virtually ubiquitous, but highly variable among patients (Khan and Wilkinson, 1985; Patai et al., 1998).

Urinary Stents and Prostheses

Mineral crusts form on the surfaces of urinary stents and nephrostomy tubes, which are used extensively in urology to alleviate a urinary obstruction or incontinence (Goldfarb et al., 1989; Vanderbrink et al., 2008). Observed in both male and female urethral implants and artificial ureters, this calcification can lead to obstruction and device failure. The mineral crust typically consists of either calcium oxalate or calcium phosphate mineral such as hydroxyapatite or struvite, ammonium- and magnesium-containing phosphate mineral derived from urine. There is some evidence that encrustation may both result from and predispose to bacterial infection.

Intraocular and Soft Contact Lenses and Scleral Buckles

Calcium phosphate deposits can opacify intraocular and soft contact lenses, typically composed of poly-2-hydroxyethyl-methacrylate polymers (pHEMA) (Bucher et al., 1995; Nakanome et al., 2008; Neuhann et al., 2008; Rimmer et al., 2010; MacLean et al., 2015; Phogat et al., 2017).

TABLE 2.4.5.2 Methods for Assessing Calcification

Technique	Sample Preparation	Analytical Results
Morphologic Procedures		
Gross examination	Gross specimen	Overall morphology
Radiographs	Gross specimen	Calcific deposit distribution
Microcomputed tomography	Gross specimen	Three-dimensional reconstruction of calcific deposit morphology, localization, and quantification
Light microscopy—von kossa or alizarin red stains	Formalin or glutaraldehyde fixed	Microscopic phosphate or calcium distribution, respectively
Transmission electron microscopy	Glutaraldehyde fixed	Mineral ultrastructure
Scanning electron microscopy with electron microprobe	Glutaraldehyde fixed	Elemental localization and quantitation
Electron energy loss spectroscopy	Glutaraldehyde fixed or rapidly frozen	Elemental localization and quantitation (high sensitivity)
Chemical Procedures		
Atomic absorption	Ash or acid hydrolysate	Bulk calcium
Colorimetric phosphate analysis	Ash or acid hydrolysate	Bulk phosphorus
X-ray diffraction	Powder	Nature of crystal phase
Infrared spectroscopy	Powder	Carbonate mineral phase

Tear fluid provides the source of the calcium in the deposits found on HEMA contact lens, and calcification may be potentiated in patients with systemic and ocular conditions associated with elevated tear calcium levels (Klintworth et al., 1977). Encircling scleral bands, used in surgery for retinal detachment, and composed of silicone or hydrogel materials, also can calcify (Lane et al., 2001).

Assessment of Biomaterial Calcification

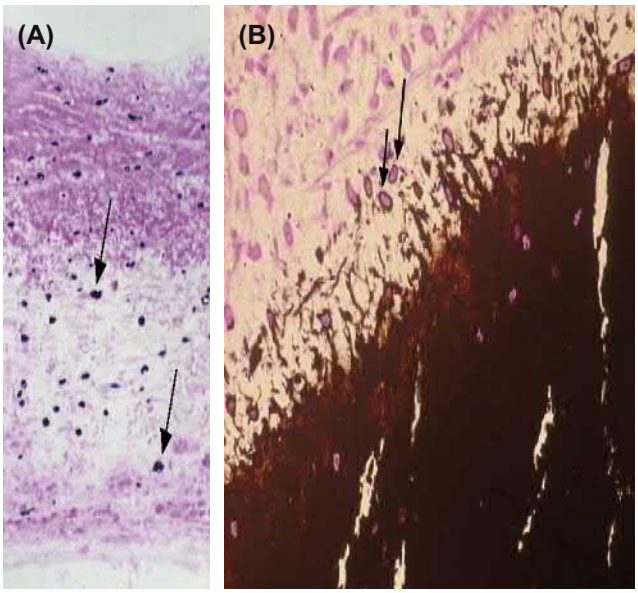
Calcific deposits are investigated using morphologic and chemical techniques (Table 2.4.5.2). Morphologic techniques facilitate detection and characterization of the microscopic and ultrastructural sites and distribution of calcific deposits, and their relationship to tissue or biomaterials structural details. Such analyses directly yield important qualitative (but not quantitative) information. In contrast, chemical techniques, which require destruction of the tissue specimen, permit identification and quantitation of both bulk elemental composition and determination of crystalline mineral phases. However, such techniques generally cannot relate the location of the mineral to the details of the underlying tissue structure. The most comprehensive studies use several analytical modalities to simultaneously characterize both morphologic and chemical aspects of calcification.

Moreover, newer techniques are available for nondestructive and potentially noninvasive characterizing of calcification, both in specimens (microcomputed tomography [micro-CT]) (Ford-Hutchinson et al., 2003; Rousselle et al, 2019; Neues and Epple, 2008), and in vivo using molecular imaging (Aikawa et al., 2007). Micro-CT has been used extensively in studies of bone-regenerative biomaterials (Jiang et al., 2009). Molecular imaging, which probes *biomarkers* of particular targets or pathways of the cellular and molecular mechanisms of calcification, is particularly exciting in this context to enable the visualization of the ongoing and dynamic process of calcification, potentially quantitatively and repetitively in living organisms (New and Aikawa, 2011).

Morphologic Evaluation

Morphologic assessment of calcification is done using several readily available and well-established techniques that range from macroscopic (gross) examination and radiographs (X-rays) of explanted prostheses to more sophisticated analytical techniques such as electron energy loss spectroscopy. Each method has advantages and limitations; several techniques are often used in combination to obtain an understanding of the structure, composition, and mechanism of each type of calcification.

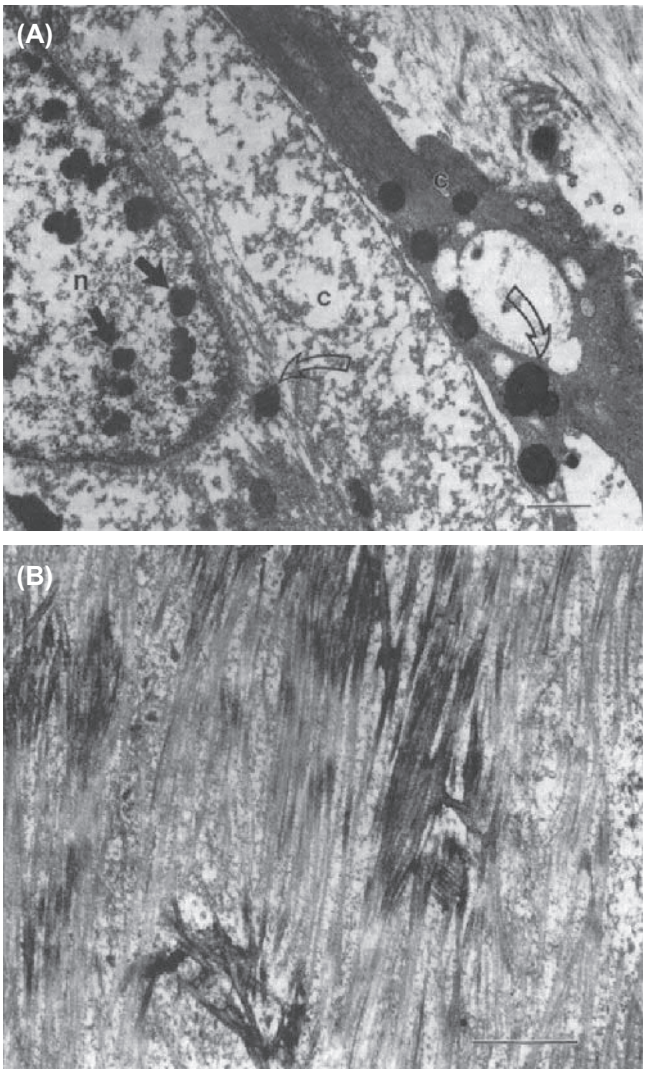
Careful visual examination of the specimen, often under a dissecting (low-power) microscope and radiography assess the distribution of mineral. Specimen radiography typically involves placing the explanted prosthesis on an X-ray film plate and exposing to an X-ray beam in a special device used for small samples (e.g., Faxitron, Hewlett–Packard, McMinnville, CA, with an energy level of 35 keV for 1 min for valves). Deposits of mineral appear as bright densities which have locally blocked the beam from exposing the film (see Fig. 2.4.5.1B).



• **Figure 2.4.5.3** Light microscopic appearance of calcification of experimental porcine aortic heart valve tissue. Note cell-based orientation of initial deposits (arrows). (A) Implanted subcutaneously in 3-week-old rats for 72 h; (B) implanted in growing sheep for 5 months, demonstrating predominant site of growing edge of calcification in cells of the residual porcine valve matrix (arrows). ((B) Reproduced by permission from Schoen, F. J. (2001). Pathology of heart valve substitution with mechanical and tissue prostheses, In: Cardiovascular Pathology, third ed., Silver, M. D., Gotlieb, A. I. and Schoen, F. J. (Eds.). W. B. Saunders: Philadelphia, PA, pp. 629–677.)

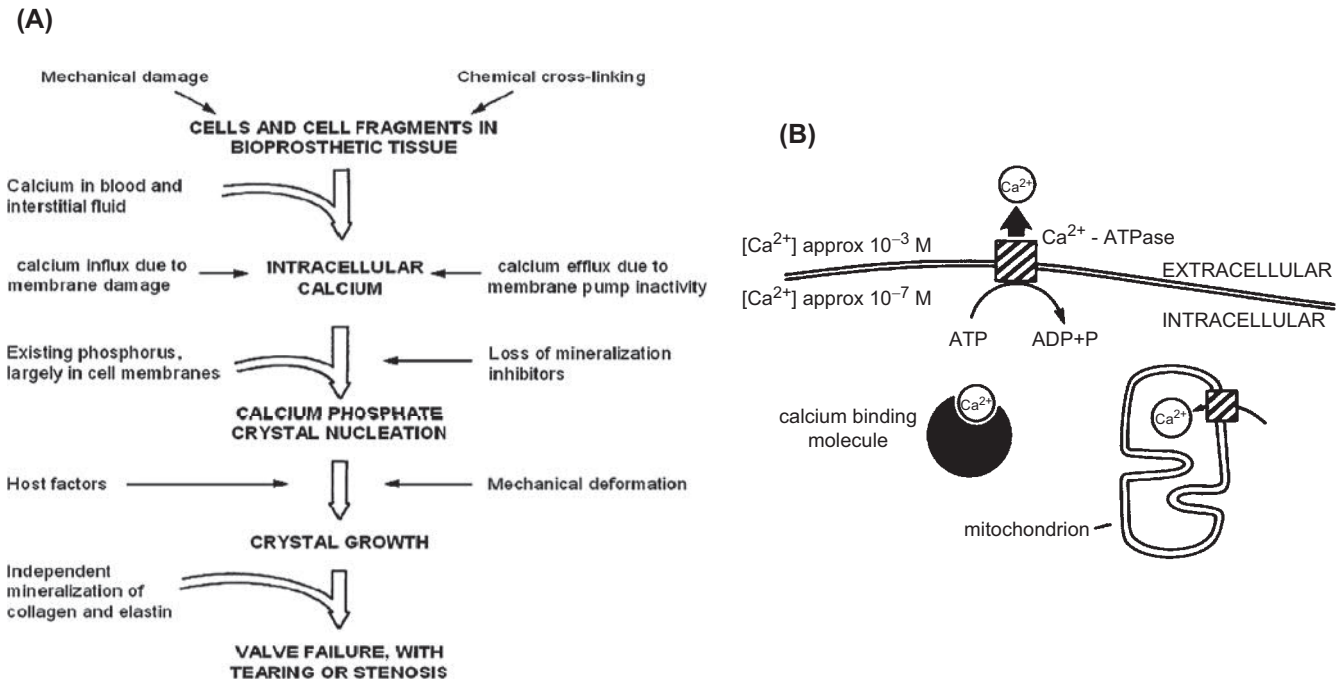
Light microscopy of calcified tissues is widely used. Identification of calcium-phosphate mineral is facilitated through the use of either calcium- or phosphorus-specific stains, such as alizarin red (which stains calcium red) or von Kossa (which stains phosphates brown-black) (Figs. 2.4.5.2B and 2.4.5.3). The von Kossa stain generally permits the most discrete localization of the mineral deposits. Staining for alkaline phosphatase, an enzyme involved in the pathogenesis of some forms of calcification, can also be useful in some contexts (Maranto and Schoen, 1988; Levy et al., 1991). These histologic stains are readily available, can be easily applied to tissue sections embedded in either paraffin or plastic, and are most useful for confirming and characterizing suspected calcified areas which have been noted by routine hematoxylin and eosin staining techniques. Sectioning of calcified tissue which has been embedded in paraffin often leads to considerable artifacts due to fragmentation; embedding of tissue with calcific deposits in a harder medium such as glycolmethacrylate polymer can yield superior section quality. On light microscopic sections, the extent of calcification can be semiquantitatively graded, and its locations described relative to key landmarks of the implant (Bennink et al., 2018).

Transmission electron microscopy may facilitate determination of early sites of calcific deposits. In TEM, an electron beam traverses an ultra-thin (0.05 μm) section of tissue (Fig. 2.4.5.4); observation of the ultrastructure (i.e., submicron tissue features) of calcification by TEM may contribute to an understanding of the mechanisms by which calcific



• **Figure 2.4.5.4** Transmission electron microscopy of calcification of experimental porcine aortic heart valve implanted subcutaneously in 3-week-old rats. Lab. Investig., 52, 523–532.)

crystals form. Scanning electron microscopy (SEM) images the specimen surface and can be coupled with elemental localization by energy-dispersive X-ray analysis (EDXA), allowing a semiquantitative evaluation of the local progression of calcium and phosphate deposition in a site-specific manner. Electron energy loss spectroscopy (EELS) couples transmission electron microscopy with highly sensitive elemental analyses to provide a most powerful localization of incipient nucleation sites and early mineralization (Webb et al., 1991). In general, the more highly sensitive and sophisticated morphologic techniques require more demanding and expensive preparation of specimens to avoid unwanted artifacts, which may complicate interpretation of high-resolution morphologic information. Since choice



• **Figure 2.4.5.5** Extended hypothetical model for the calcification of bioprosthetic tissue. (A) Overall model, which considers host factors, implant factors, and mechanical damage, and relates initial sites of mineral nucleation to increased intracellular calcium in residual cells and cell fragments in bioprosthetic tissue. The ultimate result of calcification is valve failure, with tearing or stenosis. The key contributory role of existing phosphorus in membrane phospholipids and nucleic acids in determining the initial sites of crystal nucleation is emphasized, and a possible role for the independent mineralization of collagen is acknowledged. Mechanical deformation probably contributes to both nucleation and growth of calcific crystals. (B) Events at the cell membrane and other calcium-binding structures. There is a substantial physiologic (normal) gradient of free calcium across the cell membrane (10^{-3} M outside, 10^{-7} M inside) which is maintained as an energy-dependent process. With cell death or membrane dysfunction, calcium phosphate formation can be initiated at the membranous cellular structures. ((A) Reproduced by permission from Schoen, F. J. and Levy, R. J. (2005). Calcification of tissue heart valve substitutes: Progress toward understanding and prevention. Ann. Thorac. Surg., 79, 1072–1080. (B) Reproduced by permission from Schoen, F. J. et al. (1988). Biomaterials-associated calcification: Pathology, mechanisms, and strategies for prevention. J. Appl. Biomater., 22, 11–36.)

of analytical methodology involves trade-offs, forethought about, and careful planning, specimen handling optimizes the yield provided by the array of available techniques and allows multiple approaches to be used on specimens from a particular experiment.

Chemical Assessment

Quantitation of calcium and phosphorus in biomaterial calcifications permits characterization of the progression of deposition, comparison of severity of deposition among specimens, and determination of the effectiveness of preventive measures (Levy et al., 1983a, 1985a; Schoen et al., 1985, 1986, 1987; Schoen and Levy, 1999). However, such techniques destroy the specimen (and hence obliterate any spatial information) during preparation. A widely used technique for quantitation of calcium is atomic absorption spectroscopy of acid-hydrolyzed or ashed samples. Phosphorus is usually quantitated as phosphate, using a molybdate complexation technique with spectrophotometric detection. The degree of calcification associated with a gross explant specimen can also be semiquantitatively graded by specimen radiographs (Schoen et al., 1987). The specific crystalline form of the mineral phase can be determined by X-ray diffraction. Carbonate-containing mineral phases may also be analyzed by infrared spectroscopy.

Mechanisms of Biomaterial Calcification

Regulation of Pathologic Calcification

Three factors regulate biomaterial mineralization: (1) biological factors (local environment of function and recipients systemic metabolic state and circulating regulatory factors); (2) biomaterial factors (the structure and chemistry of the substrate biomaterial); and (3) biomechanical factors (degree and locations of stress and strain). (see Fig. 2.4.5.5).

Role of Biological Factors

The most important host metabolic factors relate to young age, with more rapid calcification taking place in younger patients or experimental animals (Levy et al., 1983a), and pathologic alterations of mineral concentrations in the

circulating blood. Although the relationship with age is well-established and incontrovertible, the mechanisms accounting for this "physiologic" effect of age are uncertain but may be related to a more active mineral metabolism that exists at a young age to create and strengthen the skeleton. Other factors that can change blood chemistry such as comorbidities (e.g., chronic kidney impairment or diabetes) may aggravate the mineral deposition process. Local tissue factors such as oxidative potential and pH alteration due to inflammation can also stimulate material degradation and calcification.

Dystrophic pathologic calcification has typically been considered a passive, unregulated, and degenerative process. However, the observations of matrix vesicles, hydroxyapatite mineral, and bone-related morphogenetic and noncollagenous proteins in situations of pathological calcification have suggested that the mechanisms responsible for pathologic calcification may be at least partially regulated, similarly to physiologic mineralization of bone and other hard tissues. Moreover, some of the mechanisms regulating biomaterial-associated calcification may be shared with other pathological process that have calcification as a prominent feature, such as atherosclerosis and calcific aortic valve disease (Johnson et al., 2006; Demer and Tintut, 2008; Persy and D'Haese, 2009). In healthy blood vessels and valves, inhibitory mechanisms outweigh procalcification-inductive mechanisms; in contrast, in bone and pathologic tissues, inductive mechanisms dominate. Naturally occurring inhibitors to crystal nucleation and growth (of which many have been identified) may also play a role in biomaterial and other cardiovascular calcification (Weissen-Plenz et al., 2008). Specific inhibitors in this context include osteopontin (Steitz et al., 2002) and phosphocitrate (Tew et al., 1980). Naturally occurring mineralization cofactors, such as inorganic phosphate (Jono et al., 2000), bone morphogenic protein (a member of the transforming growth factor [TGF] beta family) (Bostrom et al., 1993), proinflammatory lipids (Demer, 2002), and other substances (e.g., cytokines) may also play a role in pathologic calcification. The noncollagenous proteins osteopontin, TGF-beta1, and tenascin-C involved in bone matrix formation and tissue remodeling have been demonstrated in clinical calcified bioprosthetic heart valves, natural valves, and atherosclerosis, suggesting that they play a regulatory role in these forms of pathologic calcification in humans (Srivasta et al., 1997; Bini et al., 1999; Jian et al., 2001, 2003), but a direct mechanistic relationship has not yet been demonstrated.

Role of Biomaterial Factors

Biomaterial structural and chemical properties play a significant role in the propensity of calcification. An important implant factor for calcification of bioprosthetic tissue is pretreatment with glutaraldehyde, done to preserve the tissue (Golomb et al., 1987; Grabenwoger et al., 1996). It has been hypothesized that the cross-linking agent glutaraldehyde stabilizes and perhaps modifies phosphorous-rich calcifiable structures in the bioprosthetic tissue. These sites seem to be capable of mineralization upon implantation when exposed to the comparatively high calcium levels of extracellular fluid. Calcification of the two principal types of tissue used in bioprostheses—glutaraldehyde-pretreated porcine aortic valve or glutaraldehyde-pretreated bovine pericardium—is similar in extent, morphology, and mechanisms (Schoen and Levy, 2005). Glutaraldehyde also has been shown to be an inefficient cross-linker for other tissue-based materials.

Nevertheless, the elastin and glycosaminoglycans present in the tissue are not stabilized, and degradation and leaching of those components can create voids and a site for additional calcification (Lovekamp et al., 2006). Thus stabilizing those components in the biological tissue has been shown to improve calcification resistance (Tripi and Vyavahare, 2014). Degraded elastin fibers can also be calcification-prone sites (Bailey et al., 2003).

Calcification mechanisms of synthetic polymers are different from those of tissue-based materials and mostly occur on the surface of the materials, a feature generally considered to be related to protein and platelet attachment (Bernacca et al., 1997). Surface properties of the materials play a significant role in material calcification. Segmented polyether urethanes are prone to oxidation, and that can cause surface cracking that would provide sites for mineralization (Stachelek et al., 2006). Increasing hydrophilicity of degradable polyurethanes has been shown to increase the extent of calcification (Gorna and Gogolewski, 2002). Surface modification of synthetic polymers has been extensively investigated to prevent calcification (Bernacca and Wheatley, 1998).

Role of Biomechanical Factors

Mechanical factors also regulate calcification. Both intrinsic and extrinsic mineralization of a biomaterial are generally enhanced at the sites of intense mechanical deformations generated by motion, such as the points of flexion in heart valves (Thubrikar et al., 1983; Schoen and Levy, 1999). The mechanisms underlying mechanical potentiation of calcification associated with biomaterials are incompletely understood, but the effect mimics the well-known Wolf's law in bone, in which formation and adaptation occurs in response to the mechanical forces that it experiences (Chen et al., 2009). Moreover, enhancement of mineral deposition is seen in systems where static but not dynamic mechanical strain is applied (Levy, 1983a), and in systems where live stem cells are subjected to a spectrum of mechanical environments (Yip et al., 2009). Furthermore, long-term cyclic wear on materials has been demonstrated to cause permanent geometric deformations that are due to ECM degradation in tissue-based valves, specifically the collagen triple helix unraveling (Sun et al., 2004). Recently, it has been suggested that preimplantation crimping of the pericardium in transcatheter aortic valves can lead to material damage that promotes calcification (Zareian et al., 2019).

Experimental Models for Biomaterial Calcification

Animal models have been developed for the investigation of the calcification of bioprosthetic heart valves, aortic homografts, cardiac assist devices, and trileaflet polymeric valves

TABLE 2.4.5.3 Experimental Models of Calcification and Typical Durations

Type	System	Typical Duration
Calcification of bioprosthetic or other tissue heart valve	In vitro incubation of tissue fragment or flexing valves	Days to weeks
	Rat subdermal implant of tissue fragment	3 weeks
	Calf or sheep orthotopic valve replacement	3–5 months
	Rat or sheep descending aorta	1–5 months
Calcification of polyurethane	Rat subdermal implant of material sample after induction of calciphylaxis	1–3 months
	Calf or sheep artificial heart implant	5 months
	Trileaflet polymeric valve implant in calf or sheep	5 months
Calcification of hydrogel	Rat subdermal implant of material sample	3 weeks
Calcification of collagen or elastin	Rat subdermal implant of material sample	3 weeks
Urinary encrustation	In vitro incubation	Hours to days
	In vivo bladder implants (rats and rabbits)	10 weeks

(Table 2.4.5.3). The most widely used experimental models are used as a preclinical screen in the development of new or modified materials and design configurations, and to investigate the pathophysiology of bioprosthetic tissue calcification. They include orthotopic valve replacements (in the tricuspid, pulmonary, mitral, or aortic positions) or conduit-mounted valves in sheep or calves, and isolated tissue (i.e., not in a valve) samples implanted subcutaneously in mice, rabbits, or rats (Levy et al., 1983a; Schoen et al., 1985, 1986). In both circulatory and noncirculatory models, bioprosthetic tissue calcifies progressively with a morphology similar to that observed in clinical specimens, but with markedly accelerated kinetics. In vitro models of biomaterial calcification have been investigated, but have not yielded useful information in studying mechanisms or preventive strategies (Schoen et al., 1992a; Mako and Vesely, 1997).

Compared with the several years normally required for calcification of clinical bioprostheses, valve replacements in sheep or calves calcify extensively in 3–6 months (Schoen et al., 1985, 1986, 1994). However, these models are expensive, limiting the number of subjects, and they are technically complex, demanding a high level of surgical expertise, postoperative care, and stringent housing and management procedures. Also, the available large animal models grow rapidly, have differences in anatomy from that of humans, and are without the pathologic substrate into which human implants are placed, and often yield results that vary among subjects treated similarly. These limitations stimulated the development of subdermal (synonym, *subcutaneous*—under the skin) implant models. Subdermal bioprosthetic implants in rats, rabbits, and mice provide the following useful features: (1) a markedly accelerated rate of calcification in a morphology comparable to that seen in circulatory explants; (2) sufficient economies that permit many specimens to be studied with a given set of experimental conditions, thereby allowing quantitative characterization and statistical comparisons; and (3) quick retrieval of specimens from the experimental animals, which facilitates the careful manipulation and rapid processing required for detailed analyses (Levy et al., 1983a,b; Schoen et al., 1985, 1986). Moreover, controls are easily generated so that specific factors that may place a role in calcification can be isolated, and hypothetical mechanisms studied in detail. Moreover, these models provide a data set to which inhibitory approaches can be screened.

Polymer calcification has also been studied with subdermal implants in rats (Joshi et al., 1996). Calcification of a synthetic polymer such as polyurethane mostly occurs on the surface due to the hydrophobic nature of the materials, and it is therefore much more difficult to assess. Changes in surface or bulk properties or topology of the polymer due to these degradation processes or adherent biological material may promote extrinsic calcification. Oxidation of polymer chains may promote polymer degradation. For example, polyether urethanes calcify more than polycarbonate urethanes due to susceptibility of ether bonds to oxidation (Bernacca et al., 1997; Joshi et al., 1996). These degradation and subsequent calcification processes often mechanically weaken the polymer (surface cracking and tearing) and enhance vulnerability to failure in a dynamic setting of cardiovascular applications. Aggravated calcification animal models such as calciphylaxis are often needed to accelerate and augment calcification of polymers (Joshi et al., 1996).

Thus, the subcutaneous model provides a technically convenient and economically advantageous vehicle for investigating host and implant determinants and mechanisms of mineralization, as well as for an initial screening of potential strategies for its inhibition (*anticalcification*). Promising approaches may be investigated further in a large animal valve implant model. Large animal implants

as valve replacements are also used: (1) to elucidate further the processes accounting for clinical failures; (2) to evaluate the performance of design and biomaterial modifications in valve development studies; (3) to assess the importance of blood–surface interactions; and (4) to provide data required for approval by regulatory agencies (Schoen et al., 1992b, 1994). Indeed, regulatory guidelines require such large animal implants and prescribe many of the parameters of these animal studies and postexplant analysis (Gallegos et al., 2005; Zhang et al., 2019).

Data from valve explants from patients and subdermal and circulatory experiments in animal models using bioprosthetic heart valve tissue have elucidated the pathophysiology of this significant clinical problem and enhanced our understanding of pathologic biomaterial calcification more generally (Fig. 2.4.5.4). The similarities of calcification in the different experimental models and clinical bioprostheses suggest common mechanisms, independent of the implant site (across vascular and extravascular locations). Indeed, calcification of bioprosthetic tissue appears to depend on exposure of a susceptible substrate to calcium-containing extracellular fluid; other local implant-related or circulating substances may play a regulatory role. Residual phosphorus in cell-related membranes localizes the Ca–P mineral nucleation sites. Consistent with a dystrophic mechanism, and encountered in other situations (Cardoso and Weinbaum, 2018), the initial calcification sites in bioprosthetic tissue are predominantly dead cells and cell membrane fragments (Levy et al., 1983a; Schoen et al., 1985, 1986; Schoen and Levy, 1999) (see Fig. 2.4.5.4).

Role of Cells

Normally, extracellular calcium concentration in tissues is approximately 1 mg/mL (10^{-3} M). In contrast, the intracellular concentration of calcium (in the cytoplasm) is 1000–10,000 times lower (approximately 10^{-7} M). This steep calcium gradient is maintained in healthy cells because mechanisms in their intact membranes pump calcium to the exterior using calcium ATP-ases and other vehicles for extrusion. In cells which have been rendered nonviable by glutaraldehyde fixation, the physiologic cellular handling of calcium ions is disabled. The cell membranes and other intercellular structures are high in phosphorus (as phospholipids, especially phosphatidyl serine, which can bind calcium); such sites can serve as nucleators. Glutaraldehyde pretreatment also stabilizes these phosphorous stores. Other susceptible sites can include collagen and elastic fibers of the extracellular matrix, denatured proteins, phosphoproteins, fatty acids, blood platelets and, in the case of infection, bacteria.

Moreover, since the morphology and extent of calcification in subcutaneous implants is analogous to that observed in clinical and experimental circulatory implants, despite the lack of dynamic mechanical activity characteristic of the circulatory environment, it is clear that dynamic stress promotes, but is not prerequisite for, calcification of bioprosthetic tissue. In the subcutaneous model, calcification is enhanced in areas of tissue folds, bends, and areas of shear, suggesting that static mechanical deformation also potentiates mineralization (Levy et al., 1983a). Also, long-term bioprosthetic valve function is accompanied by collagen degradation in the most highly stressed regions (Sun et al., 2004; Vyavahare et al., 1997; Sacks and Schoen, 2002); highly stressed regions typically manifest the earliest and most substantial calcification. Nevertheless, although these data suggest that local tissue disruption mediates the mechanical effect, the precise mechanisms by which mechanical factors influence calcification are uncertain.

Role of Collagen and Elastin

Calcification of the extracellular matrix structural proteins collagen and elastin has been observed in clinical and experimental implants of bioprosthetic and homograft valvular and vascular tissue and has been studied using a rat subdermal model. Collagen-containing implants are widely used in various surgical applications, such as tendon prostheses and surgical absorptive sponges, but their usefulness is compromised owing to calcium phosphate deposits and the resultant stiffening. Cross-linking by either glutaraldehyde or formaldehyde promotes the calcification of collagen sponge implants made of purified collagen, but the extent of calcification does not correlate with the degree of cross-linking (Levy et al., 1986). Elastin calcification has also been studied (Vyavahare et al., 1999; Lee et al., 2006). As mentioned previously, elastin is not stabilized by glutaraldehyde cross-linking in bioprosthetic valves and its degradation, in particular in an aortic portion of the valve, can lead to elastin-specific calcification (Isenburg et al., 2005).

Role of Glutaraldehyde

The role of glutaraldehyde (GA) in promoting calcification is well established and strong (Golomb et al., 1987). Two key processes, not yet fully understood, yet both directly related to the chemical effects of GA, are believed to dominate: (1) the reaction between the residual phosphorus and associated phospholipids with calcium in the surrounding fluid to yield calcium-phosphate mineral associated with the cells of the tissue devitalized by GA (as described above), and (2) chemical reactions related to the presence of active residual-free aldehyde functional groups induced by GA fixation (Simionescu, 2004). Collagen and elastic fibers can also serve as calcium-phosphate nucleation sites, independent of cellular components, perhaps through reactive aldehyde-related mechanisms. It is unknown whether these several mechanisms are independent or interrelated.

In addition to cellular devitalization and stabilizing phosphorus in the tissue, glutaraldehyde treatment produces functional group residuals (i.e., aldehydes, various carbonyls, Schiff bases, etc.) by which not only cells, but potentially

matrix glycosaminoglycans and structural proteins, such as collagen and elastin, may also bind calcium. Tissue levels of reactive functional group residuals can be directly correlated to bioprosthetic tissue calcification (Manji et al., 2006; Zilla et al., 1997a,b; Cunanan et al., 2001; Tod and Dove, 2016). Indeed, tissue levels of calcification correlate with aldehyde content. The close association between aldehyde content and the calcification of bovine pericardial tissue suggests that processing of bioprosthetic valves to reduce the content or reactivity of reactive residual aldehydes may offer a significant advantage in terms of reducing the potential for long-term bioprosthetic valve calcification (Webb et al., 1988; Shang et al., 2017; Christian et al., 2015; Everaerts et al., 2006). Oxidative mechanisms may also play a role (Christian et al., 2014; Lee et al., 2017).

Role of Immunologic Factors

A potential role for inflammatory and immune processes has been postulated by some investigators (Love, 1993; Human and Zilla, 2001a,b), since (1) experimental animals can be sensitized to both fresh and cross-linked bioprosthetic valve tissues; (2) antibodies to valve components can be detected in some patients following valve dysfunction; and (3) some failed tissue valves have brisk mononuclear inflammation. However, no definite evidence for a role of immunologic mechanisms in calcification has been demonstrated, and many lines of evidence suggest that neither nonspecific inflammation nor specific immunologic responses appear to favor bioprosthetic tissue calcification. Specific evidence against a contributory role of immunologic process is as follows: (1) calcification in either circulatory or subcutaneous locations is not usually associated with inflammation, and (2) in experiments in which valve cusps were enclosed in filter chambers that prevent host cell contact with tissue, but allow free diffusion of extracellular fluid and implantation of valve tissue in congenitally athymic ("nude") mice who have essentially no T-cell function, calcification morphology, and extent were unchanged (Levy et al., 1983a,b). Clinical and experimental data detecting antibodies to valve tissue after failure might reflect a secondary response to valve damage, rather than a cause of failure.

Calcification of the adjacent aortic wall portion of glutaraldehyde-pretreated porcine aortic valves, and valvular allografts and vascular segments, is also observed clinically and experimentally. Mineral deposition occurs throughout the vascular cross-section but is accentuated in the dense bands at the inner and outer media, and cells and elastin (itself not a prominent site of mineralization in cusps) are the major sites. In nonstented porcine aortic valves which have higher portions of the aortic wall exposed to blood than in currently used stented valves, calcification of the aortic wall could stiffen the root, altering hemodynamic efficiency, causing nodular calcific obstruction, potentiating wall rupture or providing a nidus for emboli. Some anticalcification agents, including 2-amino-oleic acid (AOA) and ethanol, prevent experimental cuspal but not aortic wall calcification (Chen et al., 1994a,b).

Prevention of Calcification

The major strategy for preventing calcification of biomaterial implants has been biomaterial modifications, whether by removal of a calcifiable component, the addition of an exogenous agent, or chemical alteration. The principles are well-illustrated by the work done with bioprosthetic heart valves, in which the subcutaneous model has been used to screen potential strategies for calcification inhibition (*anticalcification* or *antimineralization*). Promising approaches have been investigated further in a large animal valve implant model. However, some strategies that appeared efficacious in subcutaneous implants have not proven favorable when used on valves implanted into the circulation.

Analogous to any new or modified drug or device, a potential antimineralization treatment must be effective and safe. The treatment should not impede valve performance such as hemodynamics or durability. Investigations of an anticalcification strategy must demonstrate not only the effectiveness of the therapy but also the absence of adverse effects (Schoen et al., 1992b). Adverse effects in this setting could include systemic or local toxicity, a tendency toward thrombosis or infection, induction of immunological effects, or accelerated structural degradation, with either immediate loss of mechanical properties or premature deterioration and failure. Indeed, there are several examples whereby an antimineralization treatment contributed to an unacceptable degradation of the tissue (Jones et al., 1989; Gott et al., 1992; Schoen, 1998). As summarized in more detail in Table 2.4.5.4, a rational approach for preventing bioprosthetic calcification must integrate safety and efficacy considerations with the scientific basis for inhibition of calcium-phosphate crystal formation. This will of necessity involve the steps summarized in Table 2.4.5.5, before appropriate clinical trials can be undertaken (Schoen et al., 1992b; Vyavahare et al., 1997a).

Experimental studies have demonstrated that adequate doses of systemic agents used to treat clinical metabolic bone

TABLE 2.4.5.4 Criteria for Efficacy and Safety of Antimineralization Treatments

Efficacy

- Effective and sustained calcification inhibition

Safety

- Adequate valve performance (i.e., unimpaired hemodynamics and durability)
- Does not cause adverse blood–surface interactions (e.g., hemolysis, platelet adhesion, coagulation protein activation, complement activation, inflammatory cell activation, binding of vital serum factors)
- Does not enhance local or systemic inflammation (e.g., foreign body reaction, immunologic reactivity, hypersensitivity)
- Does not cause local or systemic toxicity
- Does not potentiate infection

Modified from Schoen F.J. et al. (1992). Antimineralization treatments for bioprosthetic heart valves. Assessment of efficacy and safety. J. Thorac. Cardiovasc. Surg., 104, 1285–1288.

TABLE 2.4.5.5 Preclinical Efficacy and Safety Testing of Antimineralization Treatments

Type of Study	Information Derived
Subcutaneous implantation in rats	• Initial efficacy screen • Mechanisms • Dose–response • Toxicity
Biomechanical evaluation	• Hemodynamics • Accelerated wear
Morphologic studies of unimplanted valves	• Structural degradation assessed by light and transmission electron microscopy • Scanning electron microscopy
Circulatory implants in large animals	• Device configuration, surgical technique, in vivo hemodynamics, explant valve pathology • Durability, thrombi, thromboembolism, hemolysis, cardiac and systemic pathology

Modified from Schoen F.J. et al. (1992). Antimineralization treatments for bioprosthetic heart valves. Assessment of efficacy and safety. J. Thorac. Cardiovasc. Surg., 104, 1285–1288.

disease, including calcium chelators (e.g., diphosphonates such as ethane hydroxybisphosphonate [EHBP]), can dramatically lower the calcification potential of bioprosthetic tissue implanted subcutaneously in rats (Levy et al., 1987). However, systemic therapy is unlikely to be safe, because such chemicals generally also interfere with physiologic calcification (i.e., bone growth), causing growth retardation. To avoid this difficulty, coimplants of a drug-delivery system adjacent to the prosthesis, in which the effective drug concentration would be confined to the site where it is needed (i.e., the implant), were investigated, in the hope that systemic side-effects would be prevented (Levy et al., 1985b). A localized anticalcification effect would be particularly attractive in young people. Although studies incorporating EHBP in non-degradable polymers, such as ethylene-vinyl acetate (EVA), polydimethylsiloxane (silicone), silastic, and polyurethanes showed effectiveness of this strategy in animal models, this approach has been challenging to implement clinically.

Thus, modification of the substrate, either by removing or altering a calcifiable component or binding an inhibitor has been an area of focus. Forefront strategies should also consider: (1) a possible synergism provided by multiple anticalcification agents and approaches used simultaneously; (2) new materials; and (3) the possibility of tissue-engineered heart valve replacements. The agents most widely studied, for efficacy, mechanisms, lack of adverse effects, and potential clinical utility are summarized below and in Table 2.4.5.6. Combination therapies using multiple agents may provide a synergy of beneficial effects (Levy et al., 2003). The paragraphs below describe some of the approaches that have been investigated in preclinical studies; several have achieved regulatory approval and proven successful in clinical bioprosthetic valves.

TABLE 2.4.5.6 Prototypical Agents for Mechanism-Based Prevention of Calcification in Bioprosthetic Heart Valves

Mechanisms	Strategy/Agent
Inhibition of hydroxyapatite formation	Ethane hydroxybisphosphonate (EHBP)
Inhibition of calcium uptake	2-Alpha-amino-oleic acid (AOA™)
Inhibition of Ca–P crystal growth; inhibition of alkaline phosphate; chemical modification of elastin	Ferric/aluminum chloride exposure
Phospholipid extraction	Sodium dodecyl sulfate (SDS)
Phospholipid extraction and collagen conformation modification	Ethanol exposure
Binding of agents that prevent calcification	Osteopontin, EDTA, heparin
Eliminate glutaraldehyde potentiation of calcification: • Amino acid neutralization of glutaraldehyde residues • Polyepoxide (polyglycidal ether), acyl azide, carbodiimide, cyanimide and glycerol cross-linking • Dye-mediated photooxidation • Natural cross-linkergenipin, tannic acid • Polymerization of aldehydes by thermal treatment	Modification of (alternatives to) glutaraldehyde fixation

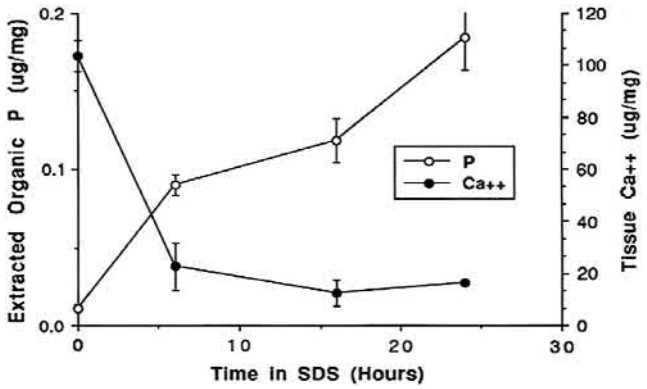
Inhibitors of Hydroxyapatite Formation

Bisphosphonates

Ethane hydroxybisphosphonate (EHBP) has been approved by the FDA for human use to inhibit pathologic calcification, and to treat hypercalcemia of malignancy. Compounds of this type probably inhibit calcification by poisoning the growth of calcific crystal by chelation. As discussed above, either cuspal pretreatment or systemic or local therapy of the host with diphosphonate compounds inhibits experimental bioprosthetic valve calcification (Levy et al., 1985a,b, 1987; Johnston et al., 1993). Recently, controlled clinical trials which have orally administered bisphosphonates have demonstrated the ability to stabilize osteoporosis.

Trivalent Metal Ions

Pretreatment of bioprosthetic tissue with iron and aluminum (e.g., $FeCl_3$ and $AlCl_3$) inhibited calcification of subdermal implants with glutaraldehyde-pretreated porcine cusps or



• **Figure 2.4.5.6** Reduction of calcification of bioprosthetic tissue by preincubation in 1% SDS demonstrated in a rat subcutaneous model of glutaraldehyde cross-linked porcine aortic valve. These results support the concept that phospholipid extraction is an important but perhaps not the only mechanism of SDS efficacy. (Reproduced by permission from Schoen, F. J., Levy, R. J. and Piehler, H. R. (1992). Pathological considerations in replacement cardiac valves. Cardiovasc. Pathol., 1, 29–52.)

pericardium (Webb et al., 1991; Carpentier et al., 1997). Such compounds are hypothesized to act through complexation of the cation (Fe or Al) with phosphate, thereby preventing calcium phosphate formation. Both ferric ion and the trivalent aluminum ion inhibit alkaline phosphatase, an important enzyme in bone formation. This may be related to their mechanism for preventing the initiation of calcification. Furthermore, research from our laboratories has demonstrated that aluminum chloride prevents elastin calcification through a permanent structural alteration of the elastin molecule (Vyavahare et al., 1999). These compounds are also active when released from polymeric controlled-release implants.

Calcium Diffusion Inhibitor

2-Alpha-amino-oleic acid (AOA, Biomedical Designs, Inc., Atlanta, GA) bonds covalently to bioprosthetic tissue through an amino linkage to residual aldehyde functions, and inhibits calcium flux through bioprosthetic cusps (Chen et al., 1994a,b). AOA is effective in mitigating cusp, but not aortic wall, calcification in rat subdermal and cardiovascular implants. This compound is used in FDA-approved porcine aortic valves (Fyfe and Schoen, 1999; Celiento et al., 2012; El-Hamamsy et al., 2010).

Removal/Modification of Calcifiable Material

Surfactants

Incubation of bioprosthetic tissue with sodium dodecyl sulfate (SDS) and other detergents extracts the majority of acidic phospholipids (Hirsch et al., 1993); this is associated with reduced mineralization, probably resulting from suppression of the initial cell-membrane-oriented calcification (Fig. 2.4.5.6). This compound is used in an FDA-approved porcine aortic valve bioprosthesis (David et al., 1998; Bottio et al., 2003).

Alcohol Treatments

Ethanol preincubation of glutaraldehyde cross-linked porcine aortic valve bioprostheses prevents calcification of the valve cusps in both rat subdermal implants, and sheep mitral valve replacements (Vyavahare et al., 1997b, 1998). Eighty percent ethanol pretreatment: (1) extracts almost all phospholipids and cholesterol from glutaraldehyde cross-linked cusps; (2) causes a permanent alteration in collagen conformation as assessed by attenuated total reflectance-Fourier transform infrared spectroscopy (ATR-FTIR); (3) affects cuspal interactions with water and lipids; and (4) enhances cuspal resistance to collagenase. Ethanol is in clinical use as a porcine valve cuspal pretreatment in both Europe and the United States, and use in combination with aluminum treatment of the aortic wall of a stentless valve is under consideration. Other alcohols that have shown promise to remove phospholipids include methanol, isopropanol, and 1,2 octanediol (Vyavahare et al., 2000; Pettenazzo et al., 2008).

Glutaraldehyde Neutralization

As glutaraldehyde cross-linking itself has been shown to aggravate tissue calcification (Levy, 1994; Gong et al., 1991), several approaches have been suggested to neutralize remnant aldehyde residues in the tissue after glutaraldehyde cross-linking. Several amino acids, amines, and natural compounds such as taurine have been used to bind to unreacted glutaraldehyde residues (Jorge-Herrero et al., 1996; Meuris et al., 2018). These treatments have shown promise in preventing tissue calcification in rodent subcutaneous models and sheep heart valve replacement models. Storage of tissues in glutaraldehyde after the anticalcification treatment has shown a partial return of calcification for the tissues. Thus, other storage conditions without glutaraldehyde have been investigated. One product where the bioprosthetic valve is stored in dry conditions after glycerol treatment is now clinically available (Inspiris Resilia by Edwards Lifesciences, Irvine, California). New methods where the combination of multiple treatments such as removing phospholipids and glutaraldehyde neutralization followed by storage in glutaraldehyde free solutions have shown promise in animal studies to prevent calcification (Meuris et al., 2018).

Decellularization

Since the initial mineralization sites are devitalized connective cells of bioprosthetic tissue, these cells may be removed from the tissue, with the intent of making the bioprosthetic matrix less prone to calcification (Courtman et al., 1994; Wilson et al., 1995). Decellularized tissues have been used as scaffolds for tissue-engineered heart valves that would be populated with host cells and would grow with patients and hopefully not calcify. In vivo animal studies have seen some success for patency of a functional valve (Dohmen et al., 2006; Baraki et al., 2009). However, clinical experiments have shown valve failure due to inflammation and calcification (Simon et al., 2003). It is clear from these studies that extracellular matrix in the tissue (collagen and elastin) can degrade and create sites for calcification. Physical stabilization of collagen and elastin by pentagalloyl glucose

TABLE 2.4.5.7 Currently Used Anticalcification Treatments for Bioprosthetic Heart Valves

Heart Valve Producer	Anticalcification Trade Name	Anticalcification Method
Edwards Lifesciences	Thermafix™	Proprietary annealing process developed internally to increase the durability of the material and rid excess aldehyde residues
Edwards Lifesciences	Inspiris Resilia	Dehydration of the tissue and reduction in lipid content, dry storage
Medtronic	AOA™	Alpha-oleic-acid treatment to decrease high-affinity sites of calcification, neutralizes residual glutaraldehyde
Abbott (formerly St. Jude Medical)	Linx™	Ethanol treatment to decrease high-affinity sites of calcification combined with a proprietary method to rid excess aldehyde residues

has been shown to reduce valvular calcification (Deborde et al., 2016). CorMatrix, a decellularized porcine intestinal submucosa, is also being investigated for cardiovascular implants (Zaidi et al., 2014).

Modification of Glutaraldehyde Fixation and Other Tissue Fixatives

Since previous studies have demonstrated that conventional glutaraldehyde fixation is conducive to calcification of bioprosthetic tissue, several studies have investigated modifications of, and alternatives to, conventional glutaraldehyde pretreatment. For example, and paradoxically, fixation of bioprosthetic tissue by extraordinarily high concentrations of glutaraldehyde (5–10× those normally used) appear to inhibit calcification (Zilla et al., 1997a,b, 2000). Moreover, residual glutaraldehyde residues in bioprosthetic tissue can be neutralized ("detoxified") by treatment with lysine or diamine, which inhibits calcification of subdermal implants (Grabenwoger et al., 1992; Zilla et al., 2000, 2005; Trantina-Yates et al., 2003). Removing phospholipids or neutralizing aldehyde residues by end capping with amines, reduction with borohydride, or using high-temperature fixation strategies have been now clinically used for preventing tissue calcification (Table 2.4.5.7) Nonglutaraldehyde cross-linking of bioprosthetic tissue with epoxides, carbodiimides, acyl azides, and other compounds reduces their calcification in rat subdermal implant studies (Xi et al., 1992; Myers et al., 1995), and with triglycidylamine (TGA), an epoxy cross-linker (Connolly et al., 2005).

Additionally, alternative cross-linking chemistries (i.e., carbodiimide, triglycidylamine, or epoxies; Connolly et al., 2011), and photooxidative preservatives in sheep implants (Moore and Phillips, 1997) with tissue still embedded with devitalized cells results in a marked reduction of calcification (Tam et al., 2017). This further supports the notion that glutaraldehyde products themselves, in conjunction with devitalized cells, may serve as high-affinity sites for calcification. It is also known that glutaraldehyde does not stabilize many components in the tissue such as glycosaminoglycans and elastin. The degradation and depletion of those components can create voids and high-affinity calcium-binding sites that can aggravate calcification (Isenburg et al., 2005; Raghavan et al., 2010).

Novel methods of material fabrication can also include combining methods in more irreversible cross-linking chemistries to produce a more chemically resilient material to biological and chemical insult. Moreover, the discussion above emphasizes that mechanisms of calcification can be complex. Indeed, several material factors can work in concert to cause calcification, and inhibition of one factor alone is not likely to prevent long-term calcification. For instance, carbodiimide can be used with a network extender to provide a more stable, irreversible cross-linking mesh in a tissue-based material than carbodiimide or glutaraldehyde can do alone (Leong et al., 2013). Other current approaches include combination of decellularization/delipidation, end-capping aldehydes, storage in nonglutaraldehyde-based conditions so that calcification of the valve materials could be completely prevented (Meuris et al., 2018). Additives like pentagalloyl glucose that have been shown to physically stabilize elastin and collagen as well as prevent calcification can be imparted into the implants and stacked together in these fixation techniques (Tedder et al., 2009; Chuang et al., 2009). These different additives that modularly protect different parts of the base tissue material ECM are being combined to produce superior biomaterials that resist calcification and cyclic wear while maintaining native-like biomechanics (Tam et al., 2017).

Alternative Materials

Synthetic polymers have been investigated as possible candidates for heart valve leaflets. Polyurethane trileaflet valves have been fabricated and studied as a reasonable alternative to bioprostheses or mechanical valve prostheses (Ghanbari et al., 2009). Despite versatile properties, such as superior abrasion resistance, hydrolytic stability, high flexural endurance, excellent physical strength, and acceptable blood compatibility, the use of polymers has been hampered by calcification, thrombosis, tearing, and biodegradation. Although the exact mechanism of polyurethane calcification is as yet unclear, it is

TABLE 2.4.5.8 Design Considerations for Preventing Calcification of Biomaterials

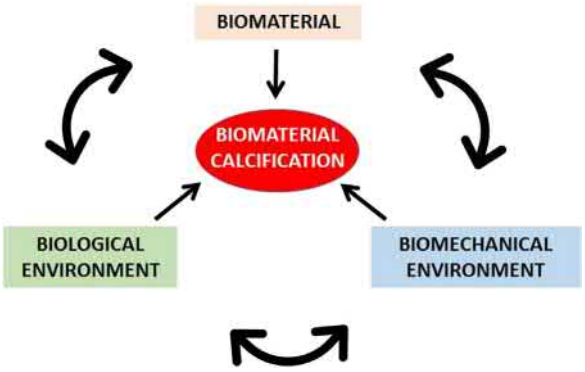
Material Considerations	Biomechanical Environment Considerations	Biological Environment Considerations
• Principal chemical bond stability • Chemical bond oxidation potential • High-affinity binding sites for calcium phosphates • Toxicity of residuals and leachables • Surface texture and topography	Structural degradation leading to creation of voids, new nucleation sites, or fragmentation of material during cyclic wear and shear flow	Patient factors • Age • Metabolism • Comorbidities Local factors • pH • Oxidative potential
Material Characterization Techniques	**Biomechanical Testing Conditions**	**Biological Testing Conditions**
• In vitro aqueous hydrolytic degradation • Water and lipid swelling study • In vitro oxidative stress testing • Incubation in supersaturated Ca:P solution • SEM for surface characterization • Uniaxial/biaxial testing • SFDI imaging analysis	• Prolonged static or dynamic strain/stress to study creep/stress relaxation; determines material's ability to resist permanent geometric deformations[a] • Cyclic fatigue for >500M cycles to determine long-term material durability[b]	• In vitro enzymatic challenges that can degrade the material • Cytotoxicity testing with leachables • In vitro/in vivo hemocompatibility testing • Implantation in rodents and small animals as a subcutaneous implant in either healthy animals or under harsher conditions like calciphylaxis or diabetes • Large animal model device implantation

[a]These tests can be done in biological testing conditions for more robust model.
[b]In vitro/in vivo calcification studies can be performed on fatigued material.

believed that several physical, chemical, and biologic factors (directly or indirectly) play an important role in initiating this pathologic disease process (Schoen et al., 1992c; Joshi et al., 1996; Hyde et al., 1999). A new generation of polyurethanes and other materials are showing promise as an alternative for fabrication of calcification-resistant bioprosthetic heart valves (Bezuidenhout et al., 2015).

Design Considerations and Selection of Materials to Avoid Calcification

Preclinical studies comprise in vitro (i.e., engineering and materials characterization) and in vivo components (i.e., animal models). For example, in the United States, animal model testing of heart valve substitutes is guided by document ISO-5840 from the International Standards Organization, supplemented by appropriate FDA guidance documents, which identifies the goals of preclinical in vivo assessment in evaluation of performance characteristics not amenable to be assessed by in vitro testing (Zhang et al., 2019). Selecting a material candidate appropriate for heart valve replacements remains to this day a difficult task because of the inherent mechanical requirements (hundreds of millions of cycles with high flexural pressure) as well as the short- and long-term failure modes it must resist—namely calcification and/or noncalcific structural deterioration, manifest in vivo as leaflet stiffening and/or tearing. These two failure modes are not mutually exclusive and have covariate factors that are illustrated in Table 2.4.5.8. This table illustrates the design considerations from material



• **Figure 2.4.5.7** Biomaterials calcification triad. The pathophysiology of calcification involves three interrelated factors:

(column 1), biomechanical (column 2), and biological (column 3) perspectives as well as the associated tests used to assess material characteristics. Finding the ideal material candidate for heart valve replacements involves designing around a multitude of criteria that could very quickly narrow down the list of suitable materials that merit further development. The animal model for in vivo studies must be carefully considered, for example, it is well known that juvenile animals of some species (e.g., sheep) have accelerated calcification of tissue heart valve and other biomaterials in device configurations. The design considerations discussed above must be applied to any candidate material that, using appropriate tests, shows it is not likely to calcify. This should be done before investing substantial amounts of resources for further verification or validation testing of new materials in novel configurations (Fig. 2.4.5.7).

Conclusions

Calcification of biomaterial implants is an important pathologic process affecting a variety of tissue-derived biomaterials, as well as synthetic polymers in various functional configurations. The pathophysiology has been partially characterized through the judicious use of animal models. Common features of biomaterial calcification in several clinical applications includes the involvement of devitalized cells and cellular debris, extracellular matrix degradation, and oxidative degradation of materials. Preventive approaches based on modifying biomaterials to make them resistant to degradation due either to biological insult or biomechanical factors appear to be promising. Several anticalcification strategies are already used clinically, particularly for extending the functional lifetime of bioprosthetic heart valves. The long-term data suggest that these new technologies may be efficacious and safe. Further materials development based on the principles described in this chapter may be beneficial and translatable to the clinic.

2.5.1 Introduction to Applications of Biomaterials

MICHAEL J. YASZEMSKI[1], FREDERICK J. SCHOEN[2], JACK E. LEMONS[3]

[1]Orthopaedic Surgery and Biomedical Engineering, Mayo Clinic College of Medicine, Rochester, MN, United States

[2]Department of Pathology, Brigham and Women's Hospital and Harvard Medical School, Boston, MA, United States

[3]Schools of Dentistry, Medicine and Engineering, University of Alabama at Birmingham, Birmingham, AL, United States

Most students of biomaterials have a strong interest in medical, surgical, or dental applications. Biomaterials are used for the construction of components in an extensive array of devices across a wide range of biomedical disciplines. When considering the applications of biomaterials as a section in *Biomaterials Science, Fourth Edition: An Introduction to Materials in Medicine*, the primary consideration is on outcomes of treatments. Outcomes are evaluated in terms of the medical discipline involved and the specific biomaterial properties needed for a targeted application to improve the outcomes of patients with specific clinical problems. For example, a total joint replacement has very different considerations than a tooth root replacement, although both anchor in bone for function. Similarly, requirements for a heart valve are very different compared to a vessel replacement or an endovascular stent, although all have extensive blood contact and some biomaterial properties are in common. A central theme is the generation and use of design criteria based on desired functionality, potentially deleterious biomaterials–tissue interaction mechanisms, pathologies of the underlying conditions for which the implant is needed, and the basic properties of the various biomaterials available or needing to be developed. It should not be surprising that considerable research and development has led to clinically used devices with active mechanical, electrical, biologic, or mass exchange functions.

Most implants serve their recipients well for extended periods by alleviating the conditions for which they were implanted. Considerable effort is expended in understanding biomaterials–tissue interactions and eliminating patient–device complications (the clinically important manifestations of biomaterials–tissue interactions). Moreover, many patients receive substantial and extended benefit, despite complications. For example, heart valve disease is a serious medical problem affecting over 100,000 people per year in the United States. Patients with aortic stenosis (the most common form of heart valve disease) have a 50% chance of dying within approximately 3 years without surgery. Surgical replacement of a diseased valve leads to an expected survival of 70% at 10 years, a substantial improvement over the natural course. However, of these patients whose longevity and quality of life have clearly been enhanced, approximately 60% will suffer a serious valve-related complication within 10 years after the operation. Thus long-term failure of biomaterials leading to a clinically significant event does not preclude clinical success for a significant duration. The estimated annual expenditure for implanted medical devices in the United States is 100 billion dollars, and the worldwide expenditure is 300 billion dollars.

The following chapters that constitute Section 2.5 present a broad spectrum of biomaterials applications and the key properties needed for specific physiological environments.

Section 2.5 begins with Chapter 2.5.2A, "Cardiovascular Medical Devices: Heart Valves, Pacemakers and Defibrillators, Mechanical Circulatory Support and Other Intracardiac devices," by Robert F. Padera and Frederick J. Schoen and Chapter 2.5.2B "Cardiovascular medical devices: stents, grafts, stent-grafts" by Michael A. Seidman, Robert F. Padera and Frederick J. Schoen. Multifunction endovascular implants, for example, an aortic stent that includes an aortic valve, can significantly lessen the procedural risk in treating aortic valvular disease when compared to open valve replacement in patients who often have multiple comorbidities.

Chapter 2.5.3, "Extracorporeal Artificial Organs and Therapeutic Devices," by Rei Ukita, Alastair Campbell Richie, Angela Lai and Keith E. Cook, discusses the role of functional biomaterials that provide bodily functions that no longer exist because of disease or trauma.

Chapter 2.5.4, "Orthopedic Applications," by Joshua J. Jacobs and Nadim James Hallab, presents the spectrum of biomaterials that replace musculoskeletal functions, which include joints, cartilaginous surfaces, tendons, ligaments, and bones.

Chapter 2.5.5, "Dental Applications," by David H. Kohn and Jack E. Lemons, discusses the hard and soft tissues whose function is replaced by biomaterials when those tissues' functions are absent because of normal wear, disease, or trauma.

Chapter 2.5.6, "Ophthalmologic Applications," by Heather Sheardown, Emily Anne Hicks, Ben Muirhead, and Aftab Taiyab, gives an introductory overview on biomaterials used to treat diseases of the eye.

Chapter 2.5.7, "Bioelectronic and Neural Implants," by Jeffrey R. Capadona and Andrew J. Shoffstall, presents the fundamentals of these devices, including the materials used, their selection criteria, the neuroinflammatory response to them, and the brain–computer interface.

Chapter 2.5.8, "Burn Dressings and Skin Substitutes," by Steven T. Boyce, Petra M. Warner, and Philip Hyungjin Chang, discusses the sequence of treatment for burn patients, beginning with debridement/escharotomy, selection of wound dressings, including subatmospheric ("negative") pressure dressings, management of microbial contamination, fluid balance, and temporary and/or permanent skin substitutes (some of which are polymeric biomaterials), all leading to wound closure. As an example of the advances made in this area by Dr. Boyce's team, Dr. Yannas' team and other colleagues working in this field, my medical/surgical colleagues and I treated a wounded soldier with an 81% body surface area burn in a middle east theater hospital. After escharotomy and temporary wound coverage with a degradable polymeric dressing, he was flown directly, nonstop, from the combat zone to the US Army Institute of Surgical Research Burn Center at the San Antonio Military Medical Center for his definitive treatment. He survived; an engineered skin substitute with which he was treated at the Burn Center, and the temporary biodegradable wound dressings applied at the field hospital, played significant roles in his survival.

Chapter 2.5.9, "Description and Definition of Adhesives, and Related Terminology," by Bryan K. Lawson and Darshan Shah, discusses three distinct and yet related biomaterial categories. Adhesives effect a bond between tissues or between a tissue and a biomaterial that is the same or different from the adhesive biomaterial. In addition, the adhesive biomaterials may link hard tissues together, soft tissues together, or a hard tissue to a soft tissue. Hard tissue adhesives find many applications in both dental and bone applications. Sealants find uses in minimizing blood loss during surgery, after trauma, and/or after surgery. Sutures keep wound edges apposed as the wound, whether it be surgical or traumatic, heals to a point that it can resist failure without the presence of the sutures. Lawson and Shah discuss natural and synthetic sutures, degradable and nondegradable sutures, polymeric and metallic sutures, and the appropriate uses for these myriad biomaterials.

Chapter 2.5.10, "Biomaterials for Immunoengineering," by Susan Thomas, Margaret P. Manspeaker, and Paul A. Archer, describes interactions between the immune system and biomaterials with the goal of inducing the immune system to behave in a desired manner to treat disease. The sections of this chapter include biomaterial use in vaccine development, vaccine efficacy, and increased vaccine performance via biomaterial adjuvants. The chapter also covers biomaterial use for B cell activation and to effect an increased humoral response. Finally, the authors discuss biomaterials use in the targeting and modulation of T cell therapies.

Chapter 2.5.11, "Biomaterials-based model systems to study tumor-microenvironment interactions," by Claudia Fischbach-Teschl, Brittany Elizabeth Schutrum, and Matthew A. Whitman, presents the tumor microenvironment and its importance in understanding cancer behavior. The authors then discuss the development of biomaterial systems to model the function of the tumor microenvironment to learn how best to alter the cancer's natural behavior in a way that is optimal for the patient.

Chapter 2.5.12, "Drug Delivery Systems," by Danielle Benoit, Marian Adriana Ackun-Farmmer, Kenneth R. Sims Jr., and Clyde Thomas Overby III, discusses the history of controlled drug delivery, and presents the design factors that are important for the development of drug delivery systems. These include pharmacokinetics, targeting, solubility behavior, delivery routes, biomaterial properties, and biomaterial stability.

Chapter 2.5.13, "Responsive Polymers in the Fabrication of Enzyme-Based Biosensors," by John R. Aggas and Anthony Guiseppi-Elie, presents the role of polymers in the design of enzyme-based biosensors: bioconjugation, bioimmobilization, biohosting, biocompatibility, and active transduction. Examples of polymers that fulfill these roles include inherently conductive polymers, responsive hydrogels, polymeric redox mediators, and ferroelectric, piezoelectric, and pyroelectric polymers.

The range of tolerable risks of adverse effects varies directly with the medical benefit obtained by the therapy. Benefit and risk go hand in hand, and clinical decisions are made to maximize the ratio of benefit to risk. The tolerable benefit–risk ratio may depend on the type of implant and the medical problem it addresses. Thus more risk can be tolerated with a heart assist device (a life-sustaining implant) than with a prosthetic hip joint (an implant that relieves pain and disability and enhances function), or with a breast implant (an implant with predominantly cosmetic benefit). As an example, total hip arthroplasties (THAs) with metal-on-metal (MoM), or more correctly cobalt alloy-on-cobalt alloy articulating surfaces (the metal stem trunion–metal femoral head junction, and the metal femoral head–metal acetabular component junction) have been used clinically since the 1950s. The history of implant innovation is replete with examples of implants that performed well during the in vitro and in vivo phases of their development, and performed well during the Food and Drug Administration (FDA) clinical studies to determine safety and effectiveness, only to have something unexpected occur after FDA marketing approval and subsequent widespread clinical use. MoM THAs were introduced to general clinical use in the 2000–02 timeframe. After being in use for about 5–7 years after FDA marketing approval, concerns arose regarding both foreign body reactions to metallic wear debris that produced benign "pseudotumors" and neurologic illnesses from cobalt toxicity. Both the United Kingdom and the United States performed product recalls, and warned patients about these previously unknown responses to the cobalt metal debris. Further information regarding this specific topic can be found on the following FDA Website: http://www.fda.gov/MedicalDevices/ProductsandMedicalProcedures/ImplantsandProsthetics/MetalonMetalHipImplants/default.htm. The message for us is that we must constantly be on the lookout for potential complications that may arise both before and after FDA approval to market a new biomaterial implant. We must expect that something unexpected may occur even after a thorough evaluation of an implant leading to marketing approval. MoM THAs, once thought to herald the arrival of the ultimate THA implant, have disappeared (correctly so) from the armamentarium of the total joint reconstructive surgeon.

In summary, Section 2.5 explores the most widely used applications of materials in medicine, biology, and artificial organs. The progress made in many of these areas has been substantial. In most cases, the individual chapters describe a device category from the perspective of the clinical need, the spectrum of devices available to the practitioner, the results and complications, and the challenges to the field that must be addressed and solved to optimize success.

2.5.2A

Cardiovascular Medical Devices: Heart Valves, Pacemakers and Defibrillators, Mechanical Circulatory Support, and Other Intracardiac Devices

ROBERT F. PADERA, FREDERICK J. SCHOEN

Department of Pathology, Brigham and Women's Hospital and Harvard Medical School, Boston, MA, United States

Introduction

Cardiovascular disease continues to be the leading cause of mortality and morbidity in the Western world, resulting in over 800,000 (nearly one-third of) deaths in the United States each year. Moreover, as the leading cause of death globally, cardiovascular disease kills more than 17 million individuals per year, a number that is expected to grow to more than 23 million by 2030. The most important subtype is coronary heart disease accounting for more than 1 in 7 deaths, killing over 360,000 people a year in the United States. Additionally, over 25,000 persons per year in the United States succumb to valvular heart disease, of which 17,000 have aortic valve disease, a number which is expected to double by 2040 and triple by 2060 (Benjamin et al., 2019).

The good news is that the past several decades have witnessed a virtual explosion in the number and scope of innovative surgical and interventional diagnostic and therapeutic procedures for patients with cardiovascular diseases. Data from the National Center for Health Statistics and the American Heart Association indicate that approximately 8 million major cardiac and vascular operations are performed annually in the United States. Concurrent with and integral to the broad application of these surgical and interventional procedures is the use of various prostheses and medical devices composed of highly advanced biomaterials. Data from 2014 show 475,000 percutaneous coronary interventions (almost all using endovascular bare-metal or drug-eluting stents), 371,000 coronary artery bypass graft procedures, 156,000 cardiac valve procedures, pacemakers, leads, and cardioverter-defibrillators (420,000), and use of many cardiac assist devices, vascular grafts, umbrellas, patches, and other devices (D'Agostino et al., 2018; Benjamin et al., 2019).

Thus cardiovascular prostheses and medical devices, and their constituent biomaterials, are of critical importance to the practices of interventional cardiologists and cardiac and vascular surgeons. The number and complexity of devices permit choices among surgical or catheter-based interventional options that optimize short- and long-term patient management. The recognition and understanding of complications of these devices, many of them related to the biomaterials that comprise them, has led to iterative efforts to improve their performance and safety through biomaterials and device research and development. The result has been highly significant improvements, which have been translated into better patient care. The nature, frequency, and pathologic anatomy of their complications, as well as the responsible blood–tissue–biomaterials interaction mechanisms, have been published for widely used devices used for many years, but are less well appreciated for recently introduced or modified devices and those currently in development (Schoen and Gotlieb, 2016; Buja and Schoen, 2016).

This chapter and the one following summarize key considerations in cardiovascular medical devices, including the

underlying pathology of the conditions they are designed for and used to treat, relevant biomaterials information, and the most important complications that need to be circumvented. The first chapter emphasizes biomaterials and engineering design issues relevant to cardiac valve prostheses, which have been used extensively for approximately six decades and are clinically important; the outcomes and pathological descriptions of complications encountered with many different types of valve prostheses are well known. The chapter also discusses pacemakers and implantable cardioverter-defibrillators (ICDs), implantable cardiac assist devices and artificial hearts, and miscellaneous intracardiac devices, including percutaneous catheter-based techniques to treat cardiovascular disease in a minimally invasive manner, such as septal defect closure devices, and left atrial occlusion devices. The second chapter discusses devices used for vascular repair and replacement (including vascular grafts and endovascular stents and stent grafts), filters to prevent pulmonary embolism, and other catheters and cardiovascular devices that reside outside the heart.

Heart Valve Function and Valvular Heart Disease

The four intracardiac valves play a critical role in assuring unidirectional forward blood flow through the heart. The tricuspid valve allows one-way flow from the right atrium to the right ventricle, and correspondingly the pulmonary valve from the right ventricle to the pulmonary artery, the mitral valve from the left atrium to the left ventricle, and the aortic valve from the left ventricle to the aorta. The heart valves open and close with each cardiac cycle, i.e., approximately once per second, which equates to approximately 40 million times per year and 3 billion times in a 75-year lifetime.

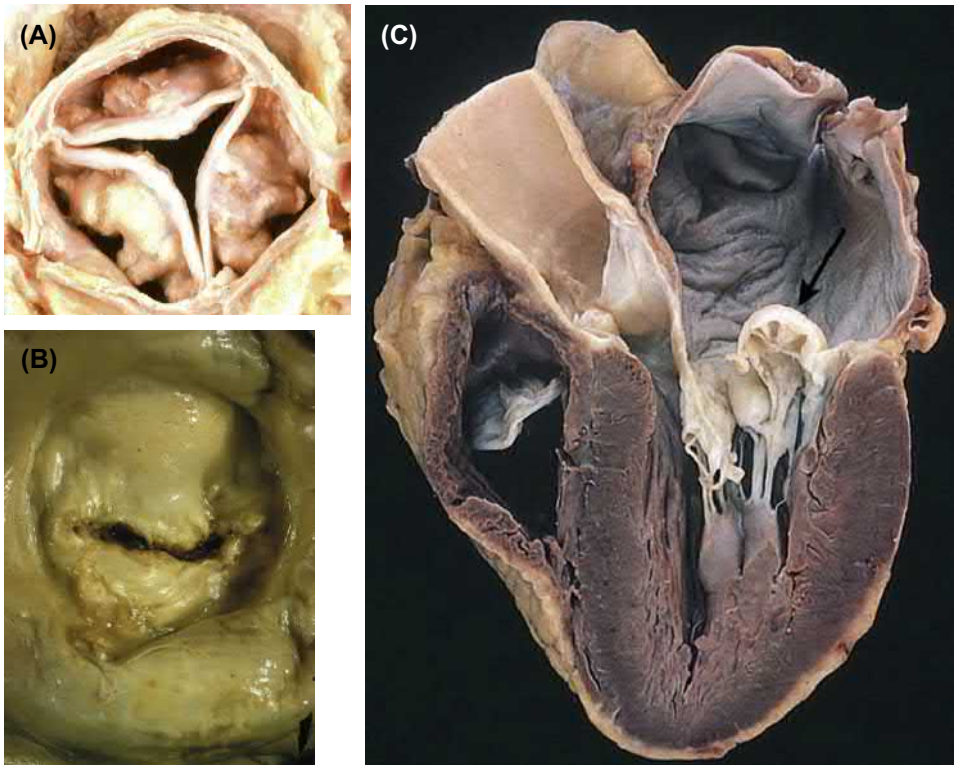
Disorders of heart valves can cause stenosis (i.e., obstruction to flow) or regurgitation (i.e., reverse flow across the valve) (Schoen and Mitchell, 2015; Schoen and Butany, 2016). Sometimes, both stenosis and regurgitation are present in the same valve. Some disease processes such as infective endocarditis (infection of a heart valve) can cause rapid (in days) destruction of the affected valve and lead to abrupt heart failure and death, while others such as calcific aortic stenosis can take many decades to develop clinical manifestations. Progress has been made in recent years toward elucidating a conceptual framework that integrates the dynamic functional structure of heart valves from macro- to micro- to ultrastructure, the biomechanical properties, and the pathobiological behavior of the cardiac valves (Ayoub et al., 2017).

There are several major forms of valvular heart disease; most involve the aortic and/or the mitral valve. The most common type of valve disease and most frequent indication for valve replacement overall is calcific aortic stenosis—obstruction at the aortic valve secondary to age-related calcification of the cusps of a valve that was previously anatomically normal (Fig. 2.5.2A.1A) (Carabello and Paulus, 2009). Elucidating the precise mechanisms of calcification of the aortic valve has been elusive, but recent insights have been gained through the study of the effects of continuous and cyclical mechanical forces on the behavior of the valvular interstitial cells and the associated inflammatory cytokine milieu within the valve tissue (Merryman and Schoen, 2013). Calcific nodules form in the valve cusps, which do not allow the valve to fully open, resulting in pressure overload of the left ventricle, which induces hypertrophy (enlargement of the mass) of the walls of this chamber. This condition takes decades to develop and typically produces symptoms in approximately the seventh and eighth decades of life.

Although the normal aortic valve has three cusps, 1%–2% of all individuals are born with a bicuspid aortic valve (i.e., with only two cusps), a condition called congenital bicuspid aortic valve (Mathieu et al., 2015). A congenitally bicuspid valve generally functions well initially and into adulthood, but persons who have this condition develop valve dysfunction and thereby symptoms at relatively younger ages—approximately 10 years earlier than in a patient having a valve with three cusps.

Aortic regurgitation (also known as insufficiency) is a less frequent but nevertheless important problem, most often caused by dilation of the aortic root. This prevents complete and effective closure of the cusps, allowing backflow across the valve and leading to volume overload of the left ventricle (Goldbarg and Halperin, 2008). Mitral stenosis (Fig. 2.5.2A.1B) has a single predominant cause—chronic rheumatic heart disease—which leads to scarring and stiffening of the mitral leaflets. This condition usually becomes clinically manifest many years or even decades following an episode of acute rheumatic fever secondary to streptococcal pharyngitis (a common form of childhood throat infection) (Chandrashekhar et al., 2009). Mitral regurgitation, on the other hand, results from many different conditions; the most frequent is myxomatous valve degeneration (also known as floppy mitral valve), in which the strength of the mitral valve tissue is deficient, thereby causing the valve leaflets to deform excessively (Carabello, 2008) (Fig. 2.5.2A.1C). Conditions in which the left ventricle is abnormally dilated and/or scarred and consequently the valve is not supported properly, and infective endocarditis (i.e., infection of the valve), are among the other major causes of mitral regurgitation.

Diseases of the right-sided valves (tricuspid and pulmonic) are much less common than those of the left-sided valves. However, in children with congenital heart disease, there is a need for valves in the pulmonary position (in addition to left-sided valves); replacement of valves for congenital anomalies account for approximately 5% of valve replacements (Barnett and Ad, 2009). The major clinical complication of valvular heart disease is cardiac failure secondary to changes in the myocardium induced by pressure or volume overload of the chambers either upstream or downstream of the diseased valve.



• **Figure 2.5.2A.1** Types of heart valve disease. (A) Severe degenerative calcification of a previously anatomically normal tricuspid aortic valve, the predominant cause of aortic stenosis, and the leading form of valvular heart disease. (B) Chronic rheumatic heart disease, manifest as mitral stenosis, viewed from the left atrium. (C) Myxomatous degeneration of the mitral valve, demonstrating hooding with prolapse of the posterior mitral leaflet into the left atrium (*arrow*). Heart valve disease is common and serious, and individuals with its various forms have significant mortality and morbidity. For example, the mortality of nonsurgically treated critical aortic stenosis, the most deleterious functional abnormality, is approximately 50% at 2–3 years following the onset of symptoms (Fig. 2.5.2A.2A); thus this natural history is more severe than that of many cancers. Valve replacement is a highly beneficial therapy for such patients; survival following valve replacement is 50%–70% and serious complication-free survival is approximately 30%–50% at 10–15 years (Rahimtoola, 2003). Operative mortality for aortic and mitral valve replacement is 3% and 6%, respectively. While valve replacement thus provides a substantial improvement over the natural history of disease, patients with artificial valves can suffer complications related to the device (Fig. 2.5.2A.2A).

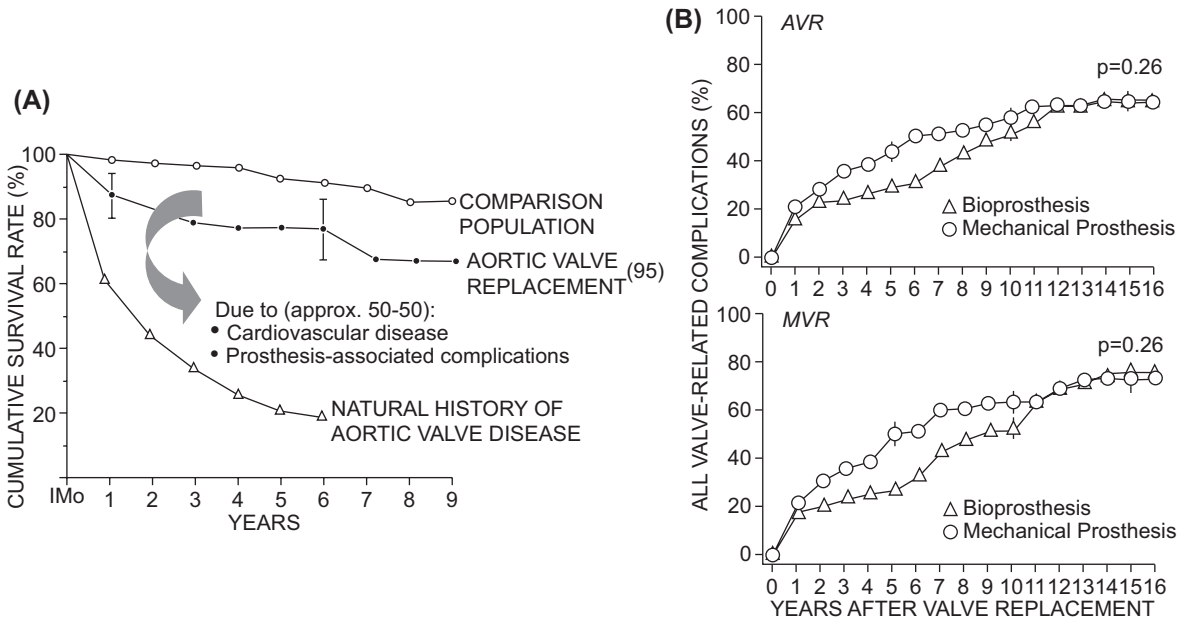
The surgical treatments available for valvular heart disease include replacement of the valve with a prosthesis and repair of the existing abnormal valve tissue to make it functional (Fedak et al., 2008). According to estimates derived from data collected by the Healthcare Cost and Utilization Project, Agency for Healthcare Research and Quality, in 2005, 36,678 individuals had aortic or mitral valve replacement in the United States and 8669 had valve repairs (Barnett and Ad, 2009). Reconstructive/repair procedures to eliminate mitral insufficiency and to minimize the severity of rheumatic mitral stenosis are now highly effective and commonplace. A recent survey of practice in the United States showed that 69% of mitral valve operations for mitral regurgitation currently use repair rather than replacement (Gammie et al., 2009). Whenever possible, repair of a valve is preferable over replacement; advantages of repair relate to the elimination of both the risk of prosthesis-related complications and the need for chronic anticoagulation that is required in many patients with substitute valves, and mandatory in patients with mechanical valves. Surgical valve repair is often accompanied by stabilization of the annulus with or without implantation of a prosthetic annuloplasty ring. Unfortunately, repair is usually not possible for most forms of aortic valve disease.

When repair is not possible, severe symptomatic valvular heart disease is treated by surgical valve replacement, which comprises excision of part or all of the diseased valve and replacement by a functional substitute. From a design standpoint, the ideal replacement valve would be nonthrombogenic, nonhemolytic, infection resistant, chemically inert, durable, and easily inserted. It would open fully and close quickly and completely, heal appropriately in place, and not be noticed by the patient (for example, it would be noise free) (Harken et al., 1962; Sapirstein and Smith, 2001).



• **Figure 2.5.2A.2** Outcome following cardiac valve replacement. (A) Survival curves for patients with untreated aortic valve stenosis (natural history of valve disease) and aortic valve stenosis corrected by valve replacement, as compared with an age-matched control population without a history of aortic valve stenosis. The numbers presented in this figure for survival following valve replacement nearly four decades ago remain accurate today. This reflects the fact that improvements in valve substitutes and patient management have been balanced by a progressive trend toward operations on older and sicker patients with associated medical illnesses. Outcomes 15 years after valve replacement with a mechanical versus a bioprosthetic valve: Final report of the Veterans Affairs Randomized Trial. J. Am. Coll. Cardiol. 36, 1152–1158.)

Surgical Bioprosthetic and Mechanical Heart Valves

The evolution of prosthetic heart valves and related cardiovascular surgical technology was enabled during the first half of the 20th century by multiple key developments, including cardiac catheterization, innovative surgical techniques, cardiopulmonary bypass machines, and the anticoagulant heparin (Chaikoff, 2007). In the late 1950s, stimulated by collaborations established between surgeons and biomedical engineers, innovative procedures and device technology matured in the surgical research laboratory were translated to clinical practice. These developments fostered new opportunities to replace dysfunctional cardiovascular components with biologic or synthetic prostheses. A key step in modern valve replacement technology was the Hufnagel ball valve, designed to be implanted rapidly into the descending thoracic aorta with the use of proximal and distal fixation rings in patients with aortic regurgitation (Butany et al., 2002). However, with this valve, regurgitant flow from the lower body was prevented, but cardiac work was only partially relieved and coronary flow was not improved. Subsequently, cardiac surgeon Dr. Albert Starr and his colleagues, along with a mechanical engineer, Lowell Edwards, fabricated a valve consisting of a stainless-steel cage, a heat-cured Silastic ball, and a base surrounded by a Teflon fabric sewing cuff, the latter component permitting the surgeon to suture the valve in place orthotopically (i.e., in the anatomically appropriate location within the heart). The three generic components just described, moving part (either synthetic or biologic), superstructure to guide the motion of the moving occluder, and sewing cuff (anchored at the anastomotic site), comprise the key parts of all previous and present surgical heart valve prostheses. Now used extensively for more than a half century, cardiac valve prostheses are a clinically important achievement of biomaterials science and biomedical engineering. Indeed, the prestigious 2007 Lasker Award for Clinical Medical Research was granted to Drs. Albert Starr and Alain Carpentier to recognize the importance of cardiac valve replacement as a major clinical success (Chaikoff, 2007; Lifton, 2007). Starr performed the first successful valve replacement in the heart in 1960 by implanting a caged-ball mechanical valve prosthesis in the mitral position (Starr, 2007). Carpentier fabricated a "bioprosthesis," combining chemically treated biologic tissue and a mechanical structure to create a tissue-based (though nonliving) heart valve replacement (Carpentier, 2007). Relevant outcome data and pathological descriptions of complications of many different types of valve prostheses are well known (Vongpatanasin et al., 1996; Bonow et al., 2006; Schoen and Butany, 2016).

The achievements of Starr and Carpentier provided the foundation on which the clinical success of heart valve replacement is built. Today, more than 80,000 valves are replaced each year in the United States and more than 275,000 worldwide. Moreover, devices and techniques for minimally invasive and percutaneous (catheter-based) valve replacement and repair and other interventional techniques are undergoing rapid innovation and development, and there has been exciting progress toward the creation of a living tissue-engineered heart valve replacement.

Hundreds of designs of substitute heart valve replacement devices have been explored experimentally and in patients; most have been abandoned because of design and materials deficiencies that manifest in complications that became apparent only in clinical use (Dewall et al., 2000; Edmunds, 2001; Schoen and Butany, 2016). The opening and closing of a prosthetic valve are purely passive, with the moving parts (occluder or disk[s]) responding to changes in pressure and blood flow within the chambers of the heart and great vessels. Today's cardiac valvular substitutes are of two generic types: mechanical valves and biological tissue valves. The choice of which valve to use in a particular patient is often difficult (Rahimtulla, 2003; Head et al., 2017; Hirji et al., 2018), even though the overall complication rates for mechanical versus bioprosthetic valves is similar over time in both the aortic and mitral positions (Fig. 2.5.2A.2B).

Mechanical prosthetic heart valves (Fig. 2.5.2A.3) are composed of nonphysiologic biomaterials that employ rigid, mobile occluders in a metallic cage (cobalt-chrome or titanium alloy) as in the Bjork-Shiley, Hall-Medtronic, and OmniScience valves, or two carbon hemidisks in a carbon housing as in the St. Jude Medical (the most widely used), CarboMedics CPHV, Medical Carbon Research Institute, or On-X prostheses. Visually, mechanical valves do not resemble the natural heart valves. Today, all mechanical valve occluders are fabricated from pyrolytic carbon. Pyrolytic carbon has high strength, fatigue and wear resistance, and exceptional biocompatibility, including relative thromboresistence. Patients receiving mechanical valves must be treated with lifelong anticoagulation to reduce the risk of thrombosis and thromboembolic events.

Having a trileaflet configuration with a central orifice, tissue valves (Fig. 2.5.2A.4) resemble natural valves. The term "bioprosthesis" describes a special type of tissue valve composed of three cusps of tissue derived from animals—most frequently either a porcine (pig) aortic valve or bovine (cow) pericardium—each treated with glutaraldehyde. Glutaraldehyde fixation preserves the tissue, decreases its (already relatively low) immunological reactivity, and kills the cells within the valve tissue. No immunosuppression is required for these xenografts as is required for whole organ transplants (e.g., kidney, liver, or heart). However, since

these valves no longer contain viable cells, the cusps themselves cannot remodel or respond to injury as does normal tissue. Fabricated tissue valve cusps are usually mounted on a metal or plastic stent with three posts (or struts) to simulate the geometry of a native semilunar valve. As with mechanical valves, the base ring is covered by a Dacron- or Teflon-covered sewing cuff to facilitate surgical implantation and healing. The most widely used valve type is the Carpentier-Edwards pericardial valve.

Also used occasionally are tissue valves derived from human cadaveric aortic or pulmonary valves with or without the associated vascular conduit (called allografts, or homografts). These valves have good hemodynamic profiles, a low incidence of thromboembolic complications without chronic anticoagulation, and a low reinfection rate following valve replacement for endocarditis (O'Brien et al., 2001). Several decades ago, when the use of valve allografts began, they were sterilized and/or preserved with chemicals or irradiation; such valves suffered a high rate of leaflet calcification and rupture. Subsequent technical developments have led to the current practice—allografts that are cryopreserved rather than chemically preserved. Freezing is performed with protection from ice crystal formation using dimethyl-sulfoxide. The valves are subsequently stored until use at −196°C in liquid nitrogen. Contemporary allograft valves yield freedom from degeneration and tissue failure equal to or better than those of conventional porcine bioprosthetic valves, but their use is limited by availability, difficulty in obtaining the proper size, and a more complex surgical procedure for implantation.

The reliability of a valve prosthesis and its interactions with the host and local tissues play a major role in patient outcome. Four categories of valve-related complications have been most important in limiting success (Fig. 2.5.2A.5): thrombosis and thromboembolism, infection, structural dysfunction (i.e., failure or degeneration of the biomaterials comprising a prosthesis), and nonstructural dysfunction (i.e., miscellaneous complications and modes of failure not encompassed in the previous groups). The major advantages of tissue valves compared to mechanical prostheses are their pseudoanatomic central flow and relative nonthrombogenicity (see later); consequently, patients with tissue valves usually do not require anticoagulant therapy unless they have atrial fibrillation (AF) or another specific propensity to thrombose the valve.

Thromboembolic complications are the major cause of mortality and morbidity after cardiac valve replacement with mechanical valves. No synthetic or modified biological surface is as resistant to thrombosis (*thromboresistant*) as normal unperturbed endothelium. As in the cardiovascular system in general, Virchow's triad (surface thrombogenicity, hypercoagulability, and locally static blood flow) largely predicts the relative propensity of a device to thrombus formation and location of thrombotic deposits with cardiovascular prostheses (Bennett et al., 2009). Exposure of blood to an artificial surface can induce thrombosis, embolization, and consumption of platelets and plasma coagulation factors, as well as the systemic effects of activated coagulation, complement products, and platelets. Thus patients who have received mechanical substitute heart valves require lifetime therapeutic anticoagulation with warfarin derivatives, which induces a risk of hemorrhage, is potentially serious, and in some cases is fatal (Vahanian, 2008). Thrombotic deposits forming on valve prostheses can immobilize the occluder or shed emboli to downstream arterial beds (Fig. 2.5.2A.5A–C).

Prosthetic valve infection (endocarditis) occurs in 3%–6% of recipients of substitute valves (Fig. 2.5.2A.5D). When endocarditis was the reason for the original valve replacement, the risk is markedly increased. Rates of infection of bioprostheses and mechanical valves are similar. However, since mechanical valve biomaterials cannot themselves become infected, endocarditis on mechanical valves is localized to the prosthesis/tissue junction at the sewing ring, with accompanying tissue destruction in this area (Piper et al., 2001). While bioprosthetic valve endocarditis can also be localized to the host tissue/prosthesis junction, biological tissue (despite being chemically fixed) can support growth of bacteria and other microorganisms, and thus the cusps are involved in some cases. The most frequent portals of entry include the mouth via dental procedures, urologic infections and interventions, and indwelling catheters; all comprise breaches of a natural mucosal or cutaneous barrier that may release organisms into the blood. Prosthetic valve endocarditis can occur either early (less than 60 days postoperatively) or late (can be years). The microbial etiology of early prosthetic valve endocarditis is dominated by the staphylococcal species *Staphylococcus epidermidis* and *Staphylococcus. aureus*, even though prophylactic antibiotic regimens used routinely at the time of implantation are targeted against these microorganisms. The clinical course of early prosthetic valve endocarditis tends to be fulminant. The most common organisms in late prosthetic valve endocarditis are *S. epidermidis*, *S. aureus*, *Streptococcus viridans*, and *Enterococci*. Prosthetic valve endocarditis is very difficult to eradicate by antibiotics alone, and thus usually necessitates surgical reintervention.

Prosthetic valve dysfunction because of materials degradation can necessitate reoperation or cause prosthesis-associated death. Many valve models have been withdrawn from clinical use because of poor durability. Durability considerations vary widely for mechanical valves and bioprostheses, for specific types of each, for different models of a particular prosthesis utilizing different materials or having different design features, and even for the same model prosthesis placed in the aortic rather than the mitral position. Fractures of metallic or carbon components of mechanical valve prostheses are usually catastrophic but are fortunately rare (Fig. 2.5.2A.5E). Contemporary single-leaflet or bileaflet tilting disk valves with pyrolytic carbon occluders and either metallic struts or carbon housing have generally favorable durability. Fractures related to past design defects are noteworthy in two valve cohorts. In one instance, the Bjork-Shiley single-leaflet tilting disk valve was redesigned with the intention of enhancing disk opening and

Pathological considerations in replacement cardiac valves. Cardiovasc. Pathol. 1 (29).)

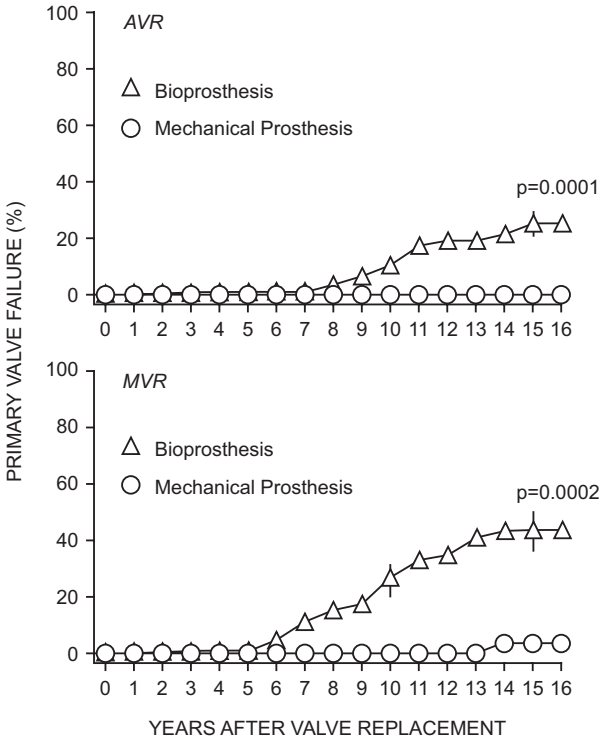
relieving obstruction and thromboembolic complications that occurred with the original and widely used model. The resultant Bjork-Shiley 60- and 70-degree convexo-concave tilting disk valves suffered fractures of the welded metallic outlet strut and separation from the valve, leading to frequently fatal disk escape (Blot et al., 2005; Harrison et al., 2013). Over 80,000 valves of this model were implanted and at least 600 fractured in this manner. The underlying problem was due to the unanticipated consequence of disk closure at a higher velocity and force, causing

the overrotation and an excessively hard contact with the metallic outlet strut. When the outlet strut stress exceeded its endurance limit, fatigue fracture occurred, most frequently in the region of the welds anchoring this strut to the housing. In another instance, fractures of carbon valve components (hemidisk or housing) occurred in implanted Edwards (previously Hemex)-Duromedics bileaflet tilting disk valves. At least 46 valves of this type failed in this manner (Mastroroberto et al., 2000). Studies of these explants suggest that valve fracture with leaflet escape resulted from variable combinations of five factors: (1) microporosity in the pyrolytic carbon coating in the leaflets, (2) cavitation bubbles impacting on the carbon surfaces during function, (3) unusual combinations of dimensional tolerances, (4) poor shock-absorbing qualities of the annular tissues in some patients (perhaps due to calcification-induced rigidity), and (5) structural defects in the valve prosthesis induced by fabrication or surgical mishandling. Fractures of carbon components have been encountered only rarely with other carbon bileaflet tilting disk valves, such as the St. Jude Medical valve.

In contrast, structural valve failure with dysfunction is frequent and is the major cause of failure of the most widely used bioprostheses (Fig. 2.5.2A.5F). Bioprosthetic valve structural tissue failure usually results in progressive symptomatic deterioration, which requires reoperation (Schoen and Levy, 2005). Within 15 years following implantation, 30%–50% of porcine aortic valves implanted as either mitral or aortic valve replacements require replacement because of primary tissue failure (Fig. 2.5.2A.6). Cuspal calcification (see Chapter 2.4.5) is the major responsible pathologic mechanism, with regurgitation through tears the most frequent failure mode in porcine valves. The more frequently used contemporary bovine pericardial valves also suffer design-related tearing and/or calcification. Calcification is markedly accelerated in younger patients, with children and adolescents having an especially accelerated course (Saleeb et al., 2014).

Within the group of complications causing nonstructural failure are those that relate to healing of the valve in the site of implantation, either too little or too much. Inadequate healing can cause paravalvular leaks, which permit reverse flow usually through a relatively small defect at the junction of prosthesis and host tissue when the valve is closed. Paravalvular leaks may be clinically inconsequential, may cause hemolysis (i.e., destruction of red blood cells through mechanical destruction of their membranes by the high shear stresses engendered by blood being forced at high velocity through small spaces), or may cause heart failure through regurgitation. In contrast, overexuberant healing, called tissue overgrowth (or pannus), can block occluder motion or lead to secondary thrombus.

Various incremental improvements to valve prostheses are being investigated in preclinical studies and clinical research and implementation. For example, methods are being actively studied and some are being used clinically to prevent calcification of bioprosthetic valves. The confidence engendered by early data that these methods may have extended the durable



• **Figure 2.5.2A.6** Frequency of primary valve failure (nonthrombotic valve obstruction or central valvular regurgitation) for mechanical and tissue valves following mitral valve replacement (MVR) and aortic valve replacement (AVR). Cuspal mineralization is the major responsible pathologic mechanism with regurgitation through tears the most frequent failure mode. (Reproduced by permission from Hammermeister, K., et al., 2000. Outcomes 15 years after valve replacement with a mechanical versus a bioprosthetic valve: Final report of the Veterans Affairs Randomized Trial. J. Am. Coll. Cardiol. 36, 1152–1158.)

lifetime of bioprosthetic valves has led to a dramatic resurgence of their use. Thus as reflected in overall heart valve replacement industry data, innovations in tissue valve technologies and design have stimulated this segment of the market to grow disproportionately in the last decade by expanding indications for tissue valve use and potentially enhanced durability. Thus there has been a trend toward an increasing fraction of tissue valves implanted relative to mechanical valves. Tissue valve use continues to expand, and studies estimate that tissue valves now represent as much as 80% of all substitute heart valves used in some countries (Mohr, 2014; Isaacs et al., 2015; Goldstone et al., 2017). The trend toward increasing use of bioprostheses (relative to mechanical valves) is especially high in older recipients, who generally have diminished rates of calcific failure and in whom anticoagulation carries increased risk of serious hemorrhage.

The advent of so-called sutureless valves for aortic valve disease has allowed for quicker implantations using a more minimally invasive surgical approach (Zannis et al., 2012). The surgery involves removing the diseased aortic cusps and deploying the sutureless valve device. While the valves are implanted surgically, they incorporate several design features discussed later for percutaneous transcatheter valves. The 3f Enable valve (Medtronic, Inc., Minneapolis, MN) consists of three equal pieces of equine pericardium mounted

on a self-expanding Nitinol frame, which contains a polyester flange on the inflow aspect to prevent migration and minimize paravalvular leak. The Perceval S valve (LivaNova, London, UK) contains bovine pericardial cusps mounted within a Nitinol frame. The frame consists of proximal and distal segments with connecting elements to support the valve cusps and allow anchoring to the aortic root. Both of these valves have shown promise clinically for selected patient populations (Chauvette et al., 2018; Fuzellier et al., 2016).

Other approaches to provide improved valves include modifications of bioprosthetic valve stent design and tissue-mounting techniques to reduce cuspal stresses, tissue treatment modifying or an alternative to conventional glutaraldehyde pretreatment to enhance durability and postimplantation biocompatibility, and minimally cross-linked autologous pericardial valves. Near-anatomic configuration, central flow trileaflet prostheses using three flexible synthetic polymeric leaflets in an anatomy that resemble the natural aortic valve, may be facilitated by major developments in the technology of polymeric materials, particularly in the thermoplastic polyurethanes (Bezuidenhout et al., 2015). Although a polymer valve has been used clinically in a cardiac assist device (Leat and Fisher, 1993), durability limitations have been the major concern in an orthotopic (in the natural site) flexible polymeric valve replacement, with preclinical valve failures being marked by thrombosis, tearing, and/or calcification of the cusps (Fishbein et al., 1975; Claiborne et al., 2012). Sutureless valves provide the opportunity in minimally invasive and conventional aortic valve surgery to minimize aortic cross-clamp time and maximize effective valve area. Performance and safety have been demonstrated for up to 5 years (Meuris et al., 2015; Di Eusanio and Phan, 2015).

Scientific and technological progress has stimulated the goal of generating a living valve replacement that would obviate the complications of conventional valve replacement, adapt to changing environmental conditions in the recipient, and potentially grow with a growing patient (Schoen, 2011; Rippel et al., 2012; Bouten et al., 2012; Emmert et al., 2014). The long-term success of a tissue-engineered (living) valve replacement will depend on the ability of its viable cellular components (particularly valvular interstitial cells) to assume normal function with the capacity to repair structural injury, remodel the extracellular matrix, and potentially grow in a growing patient. Translational challenges are substantial (Rabkin et al., 2002; Stassen et al., 2017; Zhang et al. 2019).

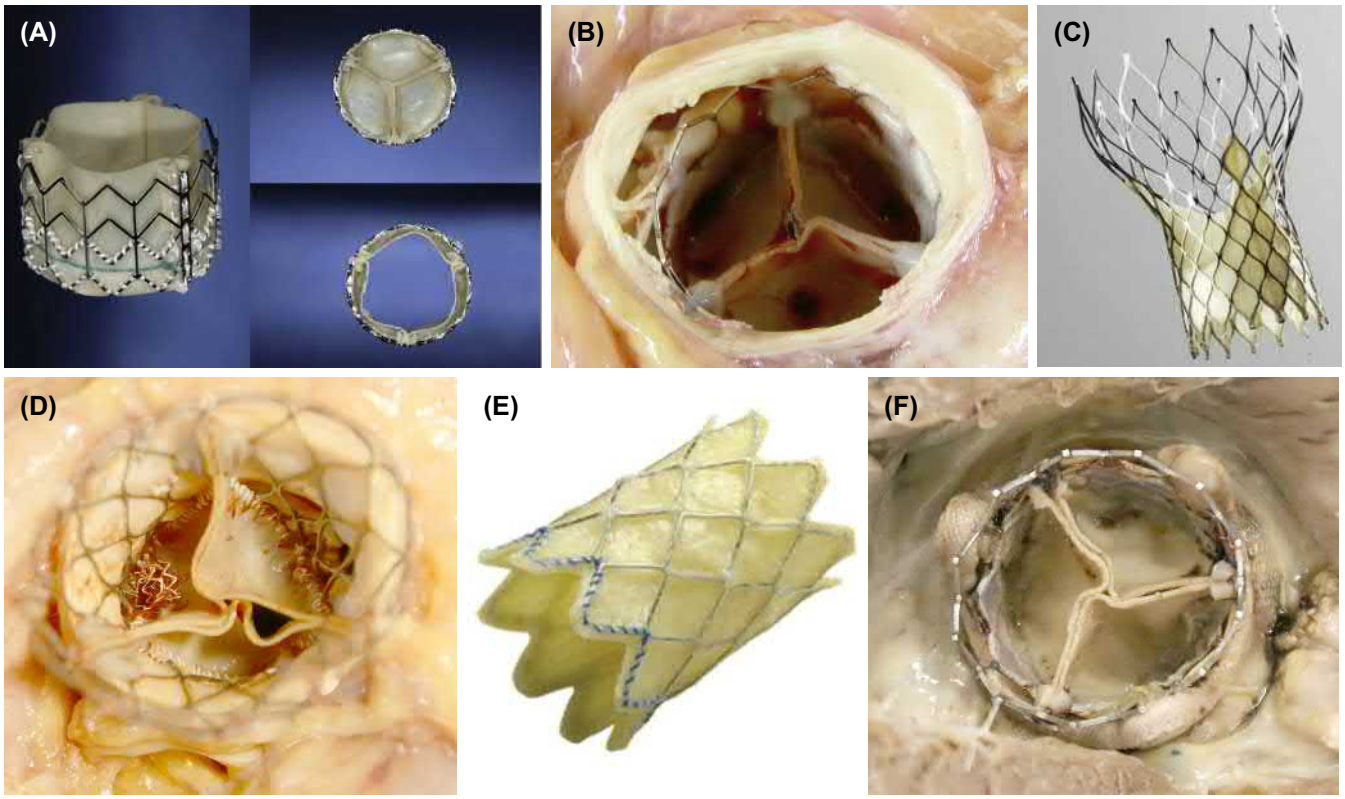
Tissue-engineered heart valves grown as valved conduits from autologous cells (either vascular wall cells or bone marrow-derived mesenchymal stem cells) seeded on biodegradable synthetic polymers (e.g., polyglycolic acid mesh coated in poly-4-hydroxybutarate) grown in vitro have functioned in the pulmonary circulation of growing lambs for up to 5 months (Hoerstrup et al., 2000; Rabkin et al., 2002). In some studies, these grafts evolved in vivo to a specialized layered structure that resembled that of a native semilunar valve. Pulmonary vascular walls fabricated from vascular wall cells and biodegradable polymer and implanted into very young lambs enlarged proportionally to overall animal growth over a 2-year period (Hoerstrup et al., 2006). Innovative heart valve tissue approaches may be enabled by emerging biomaterials technologies, including 3D bioprinting, multilayer biomaterials, metal mesh scaffolds, and decellularized valves (Cheung et al., 2015; Lueders et al., 2014; Zhang et al., 2015; Alavi and Kheradvar, 2015; Masoumi et al., 2014).

To eliminate the need for in vitro cell seeding and culture steps, an alternative tissue-engineering strategy has used a scaffold of either decellularized naturally derived biomaterial (such as animal xenograft or human allograft valve, decellularized sheep intestinal submucosa) or a porous polymer matrix implanted without prior seeding but with the intent of harnessing intrinsic circulating cells to populate and potentially remodel the scaffold (Matheny et al., 2000; Ghazanfari et al., 2015; Boroumand et al., 2018). Tissue-derived scaffolds must possess desirable three-dimensional architecture, mechanical properties, and potential adhesion/migration sites for cell attachment and ingrowth. Nevertheless, decellularized porcine valves implanted in humans had a strong inflammatory response and suffered structural failure (Simon et al., 2003). Work is also being done on cell-seeded, engineered tissue valves for transcatheter implantation (Driessen-Mol et al., 2014).

Percutaneous Transcatheter Valves and Other Devices

Surgical implantation of bioprosthetic and mechanical valves (discussed previously) has a long and proven track record of success, with symptom and quality of life improvements, and enhanced survival. However, a substantial fraction of patients with aortic stenosis, estimated to be 30%–40% overall, is deemed unsuitable for surgical aortic valve replacement because of advanced age, frailty, and often multiple comorbidities (Goldbarg et al., 2007). However, a highly significant development over the past several decades is a minimally invasive alternative to conventional aortic valve replacement, called *transcatheter aortic valve implantation* (TAVI), which was initially used clinically in 2002, and has extended the opportunity for effective mechanical correction of valve disease to a potentially large population of otherwise untreatable individuals (Rodes-Cabau, 2012; Genereux et al., 2012; Hamm et al., 2016). Thus TAVI, with its associated novel valve replacement devices, has rapidly become the new standard of care for many (especially elderly) patients who would otherwise be deemed inoperable.

In contrast to classical open surgical treatment of heart valve disease, catheter-based valve implantation uses peripheral arterial access into the femoral artery via a catheter passed retrograde up the aorta to the aortic valve where a novel type of valve device is deployed (i.e., expanded); thus this procedure avoids opening the chest. Alternatively, the device can be deployed in the heart via an antegrade and minimally invasive surgical approach that exposes the apex



• **Figure 2.5.2A.7** Percutaneous valve replacement technology. (A) The Edwards-Sapien balloon-expandable aortic valve replacement designed for percutaneous implantation, constructed from bovine pericardium attached to a stainless-steel stent. A fabric sealing cuff covers the ventricular aspect to prevent leaks between the prosthesis and surrounding tissues. The valve is mechanically crimped onto a valvuloplasty balloon catheter and expanded within the aortic annulus to displace and exclude the stenotic native valve from the circulation. (B) The Sapien valve in situ, which has been deployed within the aortic valve to treat aortic stenosis, viewed from the ascending aorta. (C) Corevalve aortic bioprosthesis, constructed of bovine pericardium attached to a self-expanding nickel-titanium alloy (Nitinol) stent. The ventricular portion has a high radial force to compress the native valve. The midportion is tapered to avoid interference with the coronary arteries. The aortic portion is flared to provide additional fixation against the wall of the ascending aorta. Nitinol can be made soft at cold temperatures allowing the stent to be tightly compressed within a delivery sheath. Once positioned within the native valve the sheath is withdrawn allowing the stent to assume its predetermined shape. There is adequate radial force to compress the native valve. (D) The Corevalve in situ, which has been deployed within the aortic valve to treat aortic stenosis viewed from the ascending aorta. A coronary artery stent that was placed in the left main coronary artery can be seen peeking through the Nitinol stent of the Corevalve at the left of the image. (E) The Melody pulmonary valve is constructed from a bovine jugular venous valve attached with sutures to a platinum-iridium alloy stent. The relatively delicate venous valve functions well in the pulmonary circulation but is too fragile for use in the systemic circulation. Although often referred to as a pulmonary valve, its maximum expanded diameter of 22 mm largely limits its use for surgically constructed right ventricular to pulmonary artery conduits in the pediatric population. (F) A Sapien valve has been deployed within a failing surgically placed bioprosthesis in the mitral position in a "valve-in-valve" application, viewed from the left ventricle. ((A) and (C) reproduced by permission from Schoen, F.J., Webb, J.G., 2008. Prosthetics and the Heart. In: McManus, B.M., Braunwald, E. (Eds.), Atlas of Cardiovascular Pathology for the Clinician, Current Medicine, Philadelphia, 241–256.)

of the left ventricle (called *transapical implantation*). This approach is favored in patients in whom manipulation of catheters through severely atherosclerotic sites in the femoral artery and aorta might dislodge debris leading to emboli. The delivery strategy involves collapsing the device and placing it within a catheter-based sheath; for balloon expandable devices, they must be collapsed over a balloon. In the case of aortic stenosis, the valve device is deployed between the cusps of the calcified aortic valve, pushing the diseased cusps out of the flow stream (i.e., in contrast to open surgery, the diseased valve tissue is not removed during TAVI—Fig. 2.5.2A.7B). During TAVI, delivery, positioning, and permanent fixation in the optimal location are critical to procedural success and usually guided by a combination of external imaging modalities.

Clinical experience with TAVI is growing rapidly; since the first clinical implantations in 2002, an estimated 300,000+ TAVI procedures have been performed worldwide. Randomized and observational clinical trials from different countries, including observational studies and

randomized trials, have compared TAVI to classical aortic valve replacement (Smith et al., 2011; Kodali et al., 2012; Kim et al., 2014). The consensus of these studies is that TAVI is at least as good as classical aortic valve replacement in terms of procedure "success" regarding morbidity and mortality in high-risk patients to at least 2 years (Tice et al., 2014; Reardon et al., 2015). TAVI and surgical valve replacement are comparable hemodynamically. Recent data suggest that TAVI may also be an excellent alternative to open surgery in patients with intermediate or lower surgical risk (Reardon et al., 2017; Mack et al., 2019; Popma et al., 2019).

The devices used in transcatheter valve implantation have an outer stent-like structure that contains leaflets. The stent holds open a valve annulus and resists the tendency of a valve annulus or diseased native leaflets to recoil following balloon dilation, supports the valve leaflets, and provides the means for seating the prosthesis in the annulus. Tissues used for the valve component include bovine, equine, or porcine pericardium and bovine jugular venous valves. The stents are made from self-expandable stainless steel, platinum-iridium, or other alloys, or shape-memory materials such as nickel-titanium alloys (e.g., Nitinol).

Several catheter-based devices are currently in various stages of development and clinical use in the aortic and pulmonary position. The two transcatheter aortic valves with the largest clinical experience are the Edwards-Sapien family of devices (Edwards LifeSciences) and the CoreValve ReValving system (Medtronic). The Sapien device is composed of a balloon-expandable stainless-steel stent that houses a bovine pericardial trileaflet valve (Fig. 2.5.2A.7A and B). There is a polymer skirt circumferentially attached to the stent to reduce paravalvular leaks. The CoreValve device is composed of a self-expandable Nitinol stent that houses a porcine pericardial trileaflet valve (Fig. 2.5.2A.7C and D). For children with failed right-ventricular to pulmonary artery devices used to correct certain types of congenital heart defects, the Medtronic Melody transcatheter pulmonary valve, composed of a balloon-expandable platinum-iridium alloy stent that houses a segment of bovine jugular vein with its native venous valve, is threaded from the femoral vein to the inferior vena cava through the right side of the heart (Fig. 2.5.2A.7E) (Lurz et al., 2009). Catheter-based valves may also play a role in the treatment of surgically implanted bioprosthetic valves that are failing due to stenosis or regurgitation in a so-called "valve-in-valve" application in which a new prosthesis is inserted directly into a prior one (Fig. 2.5.2A.7F).

Transcatheter valve implantation presents novel challenges (Fishbein et al., 2014). Valved stents are significantly larger than most existing percutaneous cardiac catheters and devices, and thus vascular access is difficult, potential damage along the course of the catheter passage is possible, and dislodging debris that can become emboli is a significant risk. In the aortic position, there is the potential to impede coronary flow, or interfere with anterior mitral leaflet mobility, the conduction system, or the native diseased leaflets. Stent architecture may also preclude future catheter access to the coronaries for possible interventions. Secure seating within the aortic annulus or a pulmonary conduit and long-term durability of both the stent and the valve tissue are also major challenges. Surgical complications include most frequently paravalvular leak, vascular injury with hemorrhage, and embolic stroke (Fassa et al., 2013; Van Mieghem et al., 2015). Transcatheter heart valves are also likely susceptible to prosthesis-associated failure modes typical of surgical bioprostheses and unique to their specific design; prosthetic valve endocarditis (Mylotte et al., 2015; Neraqi-Miandoab et al., 2015; Amat-Santos et al., 2015) and structural valve failure due to leaflet calcification and thrombosis are the most frequent complications. A critical unknown in the expanding use of transcatheter techniques is the durability of the prostheses.

Many patients with mitral valve disease also are in need of less invasive transcatheter therapies. The first transcatheter mitral valve replacement (TMVR) in a native valve was performed in 2012. However, the complexities and variability of the mitral valve anatomy and its relationship to neighboring structures have resulted in slower progress with this new therapy compared to the rapid uptake that has occurred with transcatheter aortic valve implantation (Patel and Bapat, 2017; Wyler von Ballmoos et al., 2018). TMVR can be applied to degenerated prosthetic valves and annuloplasty rings or to a wide variety of native mitral valve diseases. In cases of degenerated bioprosthetic valves, annuloplasty ring, and native valve mitral annular calcification, transcatheter heart valves designed for the aortic position can be implanted with high procedural safety and success rates. In the case of native valve mitral regurgitation, the complexities have led to the development of several TMVR systems for native valve disease with different anchoring mechanisms and geometry; all are currently investigational and none are Food and Drug Administration (FDA) approved at this time. Percutaneous mitral valve replacement has been investigated using a device similar to that used for TAVI (Webb et al., 2019).

Other percutaneous devices for the treatment of mitral regurgitation are under development or in clinical use. The MitraClip device (Abbott Laboratories, Abbott Park, IL) is a transcatheter-delivered device that reduces mitral regurgitation by fastening the anterior and posterior leaflets together in an edge-to-edge fashion (Panaich and Eleid, 2018). Approved in 2013 by the FDA, the device is composed of a polyester-covered implant that consists of two cobalt-chromium metallic arms that can be opened and closed to capture the edges of the anterior and posterior leaflets of the mitral valve (Fig. 2.5.2A.8). When the arms are closed, the leaflets are held together and the valve orifice approximates a "Fig. 2.5.2A.8" with two openings, rather than the single opening of the native valve. The polyester is macroporous, allowing for tissue ingrowth with the goal both of anchoring the device and preventing thrombosis on the foreign material. Clinical studies have been done; a recent clinical trial

of MitraClip versus medical therapy demonstrated safety and efficacy of the device in patients with heart failure due to moderate-to-severe or severe mitral regurgitation (Stone et al., 2018).

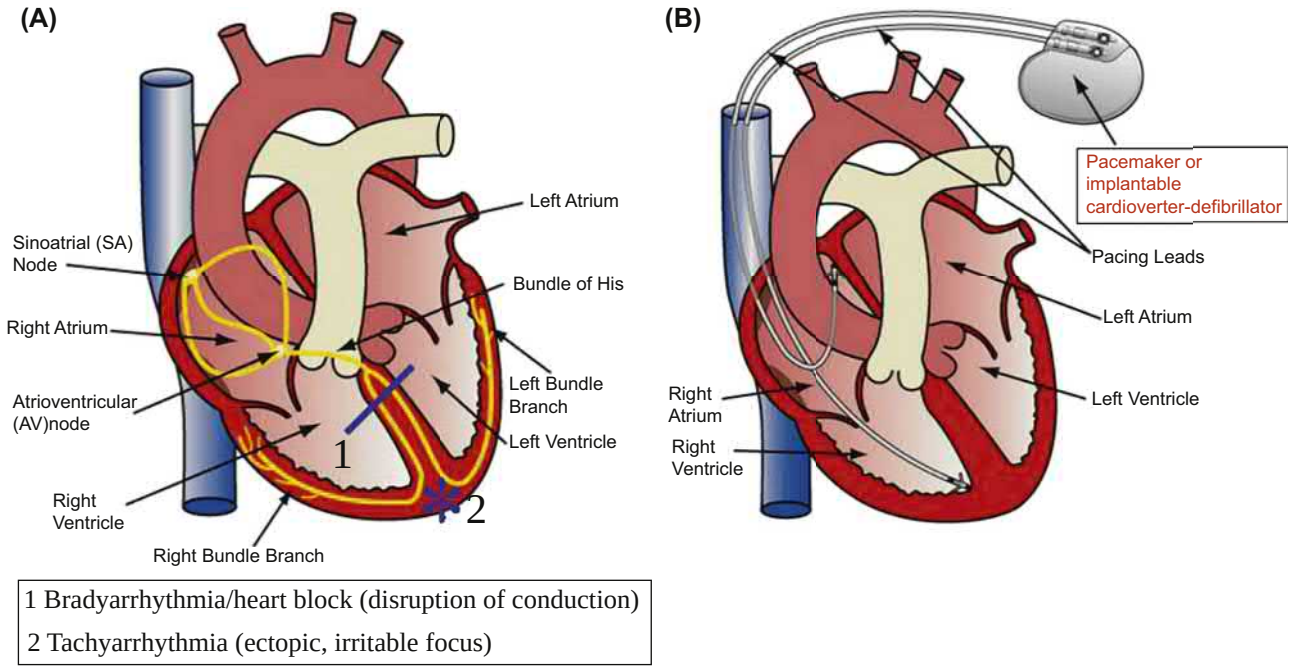
Cardiac Arrhythmias

The normal cardiac electrical cycle (Fig. 2.5.2A.9A) begins with an impulse initiated by the sinoatrial (SA) node, the heart's natural pacemaker, which is located in the right atrium near the junction with the superior vena cava. The impulse spreads through the muscle of both left and right atrial walls, causing depolarization of the cardiac myocytes that results in atrial contraction. The impulse arrives at the atrioventricular (AV) node, which is located in the posterior right atrium enclosed by the ostium of the coronary sinus, the septal leaflet of the tricuspid valve, and the membranous portion of the interatrial septum (called the

(B) Edge-to-edge approximation of the anterior and posterior leaflets of the mitral valve is achieved by deployment of the MitraClip device that is analogous to an Alfieri stitch, thereby creating a double orifice with improved leaflet coaptation. (C) Two MitraClip devices are seen attached to a portion of the mitral valve. The portion of valve and devices were removed surgically during a valve replacement necessitated by worsening mitral regurgitation. The cloth covering has facilitated tissue ingrowth into the device to help passivate the blood-contacting surface and minimize thrombosis. (D) A specimen radiograph shows the structure of the two cobalt-chromium metallic arms in the closed position. ((A) and (B) reproduced with permission from Schoen, F.J., Butany, J., 2016. Cardiac valve replacement and related interventions. In: Buja, L.M., Butany, J. (Eds.), Cardiovascular Pathology, fourth ed. Elsevier, 529–576.)

triangle of Koch). After a short delay within the AV node, the impulse passes to the bundle of His and into the left and right bundle branches, located in the intraventricular septum. The impulse spreads through the right and left ventricular myocardium causing a wave of myocyte depolarization and thereby coordinated ventricular contraction. The SA and AV nodes and the bundles of His and its right and left bundle branches are composed of cardiac muscle cells specialized for conduction.

Cardiac arrhythmias (Huikuri et al., 2001) reflect disturbances of either impulse initiation or impulse conduction. Foci of impulse-generating (automatic) cells outside the SA node, called ectopic foci, may initiate cardiac impulses that generate suboptimal ventricular



1 Bradyarrhythmia/heart block (disruption of conduction)

contractions. These arrhythmias are usually fast, i.e., tachyarrhythmias, and can result in ventricular fibrillation, which can be fatal. Intrinsic SA node dysfunction also can account for disturbances of impulse initiation. In contrast, disturbances of impulse conduction mainly consist of conduction blocks or reentry. Conduction blocks constitute a failure of propagation of the usual impulse through the specialized muscle as a result of a disease process (such as ischemia or inflammation) or certain drugs. Blocks can be complete (no impulse propagation) or incomplete (impulse propagates more slowly than normal), and can be permanent or transient. Reentry is said to occur when a cardiac impulse traverses a loop of cardiac fibers and reexcites previously excited tissue without a second impulse from the SA node. For patients in whom these cardiac arrhythmias cannot be controlled pharmacologically by antiarrhythmic drugs, two therapeutic options are available: (1) electrical therapy to control the cardiac rhythm, such as direct current cardioversion or implantable devices such as pacemakers and ICDs, and (2) interventional/surgical therapy to remove the affected tissue or interrupt the abnormal pathway such as endocardial resection, cryoablation, or radiofrequency ablation (Halbfass et al., 2018).

Cardiac Pacemakers

Cardiac pacemakers are medical devices that provide impulses to the conduction system to initiate contraction. The first cardiac pacemaker was implanted (Atlee and Bernstein, 2001) in 1958 and since then cardiac pacing has become a well-established therapeutic tool. The first pacemakers were large (40–200 cm^3) by today's standards (9–45 cm^3) and contained few of the features that are standard in current devices. Over a million patients in the United States currently have pacemakers (Fig. 2.5.2A.9B and C) and over 250,000 new permanent pacemakers are implanted each year; pacemaker placement, revision or removal is a commonly performed procedure. Most cardiac pacemakers are implanted in patients over 60 years old but they are also used in children, including infants, when necessary. The most common indications for permanent cardiac pacing are various types of conduction block. Some conduction blocks lead to bradycardia (abnormally low heart rate), while others, predominantly in the left or right bundles, will result in ventricular dyssynchrony and inefficient ventricular contraction in the setting of a normal heart rate. These conduction blocks can result in decreased cardiac output and the signs and symptoms of congestive heart failure, but can be well treated by cardiac pacing.

Modern cardiac pacing (Kusumoto and Goldschlager, 2002), either temporary or permanent, is achieved by a system of interconnected components consisting of (1) a pulse generator, which includes a power source and circuitry to initiate the electric stimulus and to sense cardiac electrical activity; (2) one or more electrically insulated conductors leading from the pulse generator to the heart, with a bipolar electrode at the distal end of each; and (3) a tissue, or blood and tissue, interface between electrode and adjacent myocardial cells. The pacemaker delivers a small current (2–4 mA) to the myocardium via the electrodes, resulting in depolarization and contraction of the heart.

Temporary pacing is most frequently used for patients with acute myocardial infarction that is complicated by cardiac conduction system disturbances that could progress to complete heart block. Leads for temporary cardiac pacing are generally directed transvenously into the apex of the right ventricle and the pulse generator is located outside the body. In the context of cardiac surgery when the epicardium is already exposed, temporary pacing is achieved by placing insulated wires with bare ends to the epicardial surfaces of the atria or ventricles with the leads emerging transthoracically from the anterior chest to permit easy withdrawal. Ultimately, the temporary pacemaker is either replaced by a permanent device or discontinued.

Permanent cardiac pacing involves long-term implantation of both pulse generator and electrode leads. The generator, usually made of a titanium alloy, is placed in a tissue pocket beneath the skin on the left anterior chest with the leads advanced transvenously through the left subclavian vein to terminate at the endocardial surface of the heart. The conducting elements are typically made of MP-35N (an alloy of nickel, cobalt, chromium, and molybdenum with excellent strength and corrosion resistance) in a composite with higher electrical conductance materials such as silver or stainless steel; these are typically insulated with an outer coating of silicone and/or urethane. The tips of the electrodes are typically placed within the right atrium and/or right ventricle depending on the pacing modality.

A single chamber pacemaker delivers a stimulus based on a programmed timing interval. The pacemaker also senses intrinsic cardiac activity and can be inhibited from providing unnecessary or inappropriate stimuli. This "demand" pacing is valuable in a patient whose problem is intermittent. A dual-chamber pacemaker with electrodes in both the atrium and ventricle delivers the sequential atrial and ventricular signals to approximate the timing of the normal heartbeat. This device also senses intrinsic atrial and ventricular depolarizations and delivers stimuli at the appropriate time to maintain proper synchrony of the chambers.

Patients with ventricular conduction delays such as left bundle branch block may suffer from heart failure due to dyssynchrony of ventricular contraction, where the right and left ventricles do not contract simultaneously. Cardiac resynchronization therapy via biventricular pacing is an intervention in which pacing electrodes are placed in the right atrium, right ventricle, and coronary sinus. The coronary sinus electrode stimulates the lateral wall of the left ventricle to allow for simultaneous excitation of the right and left ventricles, and for more uniform contraction of the entire left ventricle. Cardiac resynchronization therapy has been shown to significantly improve cardiac function in these patients (McAlister et al., 2007).

Permanent implantable pacemakers are powered by lithium-iodide batteries with a finite lifespan of 5–8 years, requiring removal and reimplantation of a new device when the battery is exhausted. In fact, the first patient to receive an implantable pacemaker in 1958 required 22 different pulse generators until his death in 2001 at the age of 86. Improving battery technology to allow for longer lifespan would minimize the number of reimplantations that a patient would require and the complications that arise from these procedures.

The interface between the electrode and depolarizable myocardial tissue is of critical importance in the proper functioning of the pacemaker (Fig. 2.5.2A.9D). Typically, a layer of nonexcitable fibrous tissue induced by the electrode forms around the tip of the electrode, which is undesirable as it increases the strength of the threshold pacing stimulus required to initiate myocyte depolarization (Fig. 2.5.2A.9E). Strategies to reduce this fibrosis include improved lead designs, and the use of slow, local release of corticosteroids to minimize the thickness of fibrous tissue formed after lead implantation (Mond and Grenz, 2004). The practical point is that, if pulse generator output is not set sufficiently high in the early postimplantation phase, loss of pacing with potentially fatal consequences can result. By contrast, maintaining output at such high levels once thresholds have stabilized greatly shortens battery life. Thus pacemakers with adjustable variations in output have been developed.

An ideal endocardial pacing lead should provide stable fixation immediately from the time of implantation, achieve and maintain a minimal threshold for stimulation, maximize sensing, and function reliably for many years. Electrode fixation to the endocardium may be active or passive. In active fixation, the electrode is designed to grasp the endocardial surface to achieve immediate fixation at implantation. A very effective aid to passive fixation is the addition of projecting "tines," or fins, in the region of the electrode tip. A different approach to improving fixation has been the development of electrodes with porous metal surfaces to foster tissue ingrowth. An endocardial pacemaker lead may require a special design if it is implanted at a particular site. One example is the J-shaped atrial lead, which is curved to facilitate placing the electrode tip in the right atrial appendage, inherently the most stable site for fixation.

"Leadless" pacemaker therapy (Della Rocca et al., 2018) is a new technology that has been introduced into clinical practice in the form of two novel devices: the Nanostim Leadless Pacing System (St. Jude Medical) and the Micra Transcatheter Pacing System (Medtronic, Inc.). These devices (Fig. 2.5.2A.9F) consist of a single capsule-like module that contains all of the functions of a traditional single-chamber pacemaker, but is implanted entirely within

the apical aspect of the right ventricle and attached to the interventricular septum via a primary fixation method involving a helical coil or tines. Implantation is performed percutaneously via a transvenous route under fluoroscopic guidance; the devices have a design feature at their proximal end such that they can be recaptured for repositioning during implantation or removal at a later date. The aim of these devices is to provide the same pacing function as a traditional transvenous pacemaker, but without the complications discussed later associated with a large subcutaneous generator pocket and associated long leads traversing the cardiac chambers and valves.

Implantable Cardioverter-Defibrillators

The first implantable cardioverter defibrillator (ICD) was placed in 1980; currently, more than 100,000 ICDs are implanted annually in the United States. The goal of ICDs is to prevent sudden death in patients with certain life-threatening arrhythmias by resetting the heart's electrical activity and stimulating a normal cardiac rhythm. ICDs have been shown to revert sustained ventricular tachycardia (abnormally high ventricular rate) and ventricular fibrillation (uncoordinated electrical/myocardial activity) in multiple prospective clinical trials. Benefit in overall mortality has been well documented (The Antiarrhythmics versus Implantable Defibrillators (AVID) Investigators, 1997).

A transvenous ICD consists of similar components to a pacemaker, namely a pulse generator and leads for tachydysrhythmia detection and therapy. The pulse generator is a self-powered, self-contained computer with one or two 3.2 V lithium-silver vanadium oxide batteries used to power all components of the system, including aluminum electrolytic storage capacitors. The devices have a service life of 3–5 years, at which point they require removal and implantation of a new device. The lead is generally placed in the right ventricle through a transvenous approach. ICD leads typically contained several coaxial conducting elements that can sense as well as deliver an appropriate shock, each conducting element may be coated in an insulator such as polytetrafluoroethylene, with all of the elements encased within silicone and coated with an outer layer of urethane insulation. The ICD constantly monitors the ventricular rate, and when the rate exceeds a certain value, provides therapy. Current devices will initially provide a short burst of rapid ventricular pacing that terminates some types of ventricular tachyarrhythmias without providing a large shock. This approach can terminate up to 96% of episodes of ventricular tachycardia without the need for a shock. If this pacing fails to break the arrhythmia, the ICD delivers a shock of 10–30 J between the electrode in the right ventricle and the surface of the pulse generator to terminate the dysrhythmic episode. These devices also keep a running record of arrhythmias and treatment results. ICDs are indicated in patients at high risk for ventricular arrhythmias (primary prevention) and in patients who have already had an episode of aborted sudden cardiac death (secondary prevention).

In contrast to the transvenous ICD, a type of ICD termed a subcutaneous ICD (S-ICD) has been developed and is in clinical use for the detection and termination of malignant arrhythmias (Willcox et al., 2016). The S-ICD uses an extravascular lead that is implanted in the subcutaneous tissue parallel to the sternum just to the left of midline in most cases. The lead is connected to the generator, which is implanted in the midaxillary line on the left side of the thorax. The lead senses a "far field" signal from the electrical activity of the heart in a manner similar to a surface electrocardiogram, and the shock is delivered by the generator in the subcutaneous tissue overlying the heart in a way similar to an external defibrillator. The S-ICD is therefore not in contact with the heart and blood and is in a more stable mechanical environment, with the hope that some of the complications noted later will be reduced.

Complications of Pacemakers and ICDs

These devices share many of the same complications, many of them requiring device removal and replacement. Like many cardiovascular devices, these are life-sustaining technologies and the implications of device failure can be fatal due to a lack of appropriate cardiac pacing (for pacemakers) or inability to sense or deliver appropriate therapy for a lethal arrhythmia (for ICDs). While normal device end-of-service from a depleted battery may not be technically considered a device malfunction, it certainly requires device replacement, and may happen prematurely due to increased fibrosis at the lead–tissue interface requiring a higher stimulus threshold. Failures of the hardware, including the battery/capacitor and charge circuit, connectors, and leads, are the most common device malfunctions, with software problems being less prevalent. Some mechanical failures include electrode dislodgment, lead fractures, electrode corrosion, and insulation failure (Fig. 2.5.2A.9G) (Zeitler et al., 2015). Complications of leads may be related to the body of the lead, as distinct from the lead–device pack interface or the electrodes. Several devices and components have been recalled in recent years for these modes of failure (Amin and Ellenbogen, 2010). Lead improvements over the years have included helical coil and multifilament designs to decrease electrical resistance and enhance flexibility and durability (Haqqani and Mond, 2009). In the past, many reports appeared on interference with pacemaker function by devices ranging from electric razors, toothbrushes, and microwave ovens at home to electrosurgical and diathermy apparatus in hospitals. Fortunately, recent generations of cardiac pacemakers have been greatly improved with regard to their resistance to electromagnetic interference.

Many complications relate to the interaction of the device biomaterials with the host tissue. These include infection, thrombosis and thromboembolism, myocardial penetration or perforation, pressure necrosis of the skin overlying the pulse generator, and migration or rotation of the pulse generator. Infection is a dreaded complication of implantable devices in general, and this is certainly true for

pacemakers and ICDs (Joy et al., 2017). The infection may originate in the subcutaneous pocket and track along the lead, which acts as a contaminated foreign body. Alternatively, it may occur by implantation of bacteria on traumatized endocardium or thrombus contiguous with the lead. The most common organisms responsible for these infections are coagulase-negative *Staphylococcus* species such as *S. epidermidis*. Septicemia may develop and septic pulmonary emboli may occur. The fundamental therapeutic principle in device-related endocarditis is treatment of the infection with antibiotics followed by removal of at least the lead and, when the pacemaker pocket is involved, the entire pacing system (Baddour et al., 2010).

ICDs contain more extensive hardware than pacemakers, and this may contribute an increased relative frequency of complications. Several additional considerations are specific to ICDs. The consequences of repeated defibrillations can cause the following effects: (1) direct effect of repeated discharges on the myocardium and vascular structures, and (2) possible thrombogenic potential of the indwelling intravascular electrodes. Another major complication of ICDs from the standpoint of the patient, other than the inability to sense or terminate an arrhythmia leading to sudden death, is an inappropriate shock. In addition to being startling and quite painful at the time of the shock, patients receiving multiple inappropriate shocks have been known to develop posttraumatic stress disorder symptoms.

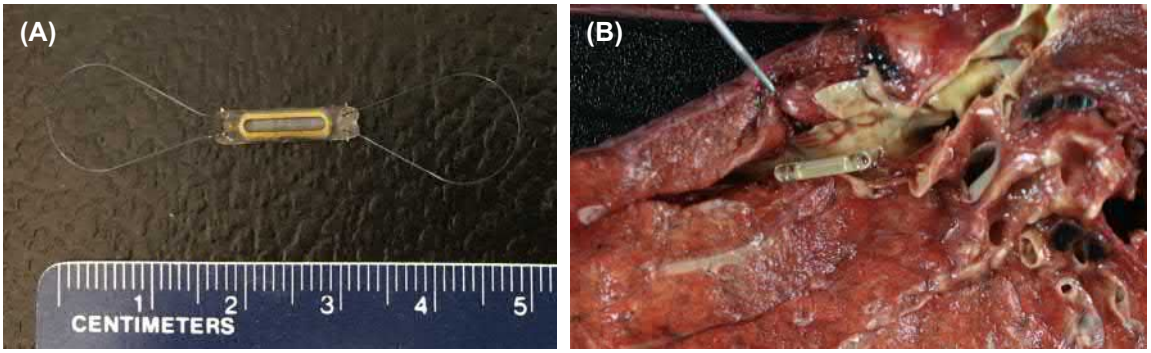
As mentioned earlier, the leads are designed to optimize their interactions with the adjacent myocardium; this can be problematic when a complication arises in which the leads must be removed. Some leads can be removed by prolonged gentle traction, but many require additional tools and techniques to free them from the venous wall through which the body of the lead travels and from the myocardium to which they are often tenaciously adherent (Krainski et al., 2018). Recourse to cardiotomy with cardiopulmonary bypass may be needed if the lead is densely incarcerated in fibrous tissue.

Congestive Heart Failure

Congestive heart failure (Jessup and Brozena, 2003) is a deficiency of the pumping function of the heart and is an extremely common condition, affecting approximately 6.2 million Americans. Each year in the United States, congestive heart failure is the principal cause of death in 60,000 individuals, a contributing factor in over 280,000 deaths, and the primary discharge diagnosis in over 1.1 million hospitalizations, all increases over previous years. Cardiac transplantation is a potential solution for some of these patients (Mancini and Lietz, 2010). However, the increasing discrepancy between the number of acceptable donor hearts (only 2500 per year) and the number of patients who might benefit from cardiac transplantation (estimated at greater than 100,000 per year) has prompted efforts toward the development of mechanical devices to augment or replace cardiac function (Baughman and Jarcho, 2007; Boilson et al., 2010; Krishnamani et al., 2010).

Congestive heart failure is the final common pathway of many specific cardiac conditions, including valvular heart disease, coronary artery atherosclerosis with resultant ischemic heart disease, and diseases that affect the cardiac muscle directly (termed cardiomyopathies). Heart failure can occur precipitously, as in myocardial infarction or viral myocarditis, or it can be a slow, progressive worsening of exercise tolerance and shortness of breath over many months or years because of ongoing deterioration of the heart muscle. It can manifest itself in the postoperative period after both cardiac surgery (e.g., valve replacement, cardiac transplantation) and noncardiac surgery (e.g., abdominal aortic aneurysm repair).

When the left ventricle is failing of whatever etiology, blood backs up into the pulmonary circulation raising the pulmonary vascular resistance and increasing the pulmonary arterial pressure necessary to overcome that resistance. Hence, the pulmonary arterial pressure can be a surrogate marker of the degree of left heart failure in patients with chronic congestive heart failure. The CardioMEMS HF System (Micro-Electrico-Mechanical HF System, Abbott Medical, Inc., Abbott Park, IL) provides hemodynamic information that can be used for the monitoring and management of heart failure (Ayyadurai et al., 2019). The device consists of a wireless sensor that is implanted in the distal pulmonary artery (Fig. 2.5.2A.10) generally via a catheter-based procedure. The sensor consists of a three-dimensional coil and pressure-sensitive capacitor encased between two wafers of fused silica, which is further encased in silicone.



• **Figure 2.5.2A.10** CardioMEMS device. (A) Unimplanted CardioMEMS pressure sensor. (B) In situ view of a CardioMEMS pressure sensor implanted in a branch of the pulmonary artery within the lung.

The coil electromagnetically couples the pressure-sensitive capacitor to the electronics system, allowing the measurement of the resonant frequency of the circuit without the need for an implanted battery. The resonant frequency is continuously converted to a pressure measurement, and the pressure waveform (including systolic, diastolic, and mean arterial pressures) and heart rate are transmitted to a receiver either in the hospital or the patient's home if they are ambulatory. The treating physician can access the data remotely and in real time to evaluate the patient and make any changes to the medical regimen. This strategy can be beneficial in certain patient groups or when used in structured programs (Dickinson et al., 2018).

As one might expect therefore, the natural history of heart failure depends on the cause and progression of the underlying disease process. For example, patients with heart failure after cardiac surgery (called postcardiotomy shock) often recover the vast majority of their cardiac function after a short period of time if they are otherwise sustained by mechanical circulatory support. In contrast, patients with dilated cardiomyopathy, one of the most common indications for cardiac transplantation, often need long-term mechanical support; studies have shown that at least 50% of such individuals would die in 3–5 years from their disease without it. One must take these clinical considerations into account when designing mechanical support systems, as different devices may best serve patients with different problems (DiGiorgi et al., 2003).

Cardiopulmonary Bypass

First used in 1953 by Dr. John H. Gibbon, cardiopulmonary bypass devices pump blood external to the body and thereby permit complex cardiac surgical procedures to be done safely and effectively. Bypass machines are useful in extracorporeal membrane oxygenation (ECMO) to assist in the transport of oxygen and carbon dioxide for patients (especially neonates and infants) with pulmonary diseases such as the respiratory distress syndrome (Alpard and Zwischenberger, 2002).

The basic operating principles of the current heart–lung machines are quite straightforward and have changed little in the past half century. Deoxygenated blood returning from the systemic circulation into the right atrium is withdrawn by gravity siphon into a cardiotomy reservoir and is then pumped into an oxygenator. The most common type of oxygenator is a membrane oxygenator, where oxygen is passed through the tube side of a shell-and-tube-type device while the blood passes through the shell side. Oxygen and carbon dioxide are exchanged via diffusion through synthetic membranes (usually polypropylene or silicone) with high permeability to these respiratory gases. The oxygenated blood is then passed through a heat exchanger to adjust the temperature of the blood and the blood is returned to the systemic circulation via the aorta. At the beginning of the procedure, the patient is anticoagulated with heparin to reduce the risk of thrombosis within the device; as the patient is weaned from bypass, the anticoagulation can be quickly reversed by the use of a drug called protamine.

During an operation, the heat exchanger lowers the temperature of the blood and therefore the core body temperature, decreasing the metabolic requirements of the body and protecting the organs (including the heart) against ischemic damage. At the end of the operation, the blood can be warmed to normal physiologic temperature as the patient is weaned from the bypass machine.

A specially trained perfusionist controls the operation of the heart–lung machine, allowing the surgeon and anesthesiologist to concentrate on their respective tasks. This device therefore provides the function of both the heart (maintaining systemic blood flow and pressure) and the lungs (oxygenating blood and removing carbon dioxide), allowing the heart to be effectively stopped for delicate surgical procedures that would be more difficult or impossible to perform on a beating, moving heart. Many improvements to the original design of cardiopulmonary bypass machines have been made since their inception. One of the problems with the original heart–lung machines was the trauma that they would cause to the blood cells. Hemolysis of red blood cells would lead to functional anemia and loss of oxygen-carrying capacity of the blood; damage to platelets would lead to thrombocytopenia (low numbers of or dysfunctional platelets), resulting in bleeding problems. The problem of blood cell damage has been largely overcome with advanced pump designs and the use of the membrane oxygenators. Roller pumps and centrifugal pumps are commonly used because they cause a lesser degree of hemolysis and shear forces; it is important in the design of these pumps to determine the optimum balance between pumping function and hemolysis/shear stress to the formed blood elements. Bubble oxygenators, which directly pass bubbles of oxygen gas through the blood, cause more hemolysis, protein denaturation, and platelet dysfunction than membrane oxygenators and are currently less frequently used. In addition, newer devices allow blood that has escaped the circulation within the sterile operating field around the heart to be processed and returned to the patient, reducing the need for blood transfusion during the procedure.

Cardiopulmonary bypass can result in many pathophysiologic changes, including complement activation from the prolonged interaction of blood with synthetic surfaces, platelet and neutrophil activation and aggregation, changes in systemic vascular resistance, and expression of other proinflammatory mediators (Levy and Tanaka, 2003). When these changes are severe, the use of the heart–lung machine can result in complications, including confusion, renal insufficiency, pulmonary dysfunction, low-grade hepatic dysfunction, and increased susceptibility to infection. Together, these manifestations are termed the postperfusion syndrome. The last decade has seen development of mini extracorporeal circuit (MECC) cardiopulmonary bypass systems (Curtis et al., 2010) with a goal of providing cardiopulmonary bypass with a reduction in this harmful systemic inflammatory response. The MECC has a greatly reduced tubing length, smaller priming volumes, reduction in the blood–air interface, and fewer components than the standard bypass systems, and utilizes heparin-coated components and centrifugal blood

pumps. These systems show a reduction in postoperative cytokine levels, organ damage, postoperative complications, and the need for blood transfusions compared to standard circuits (Vohra et al., 2009).

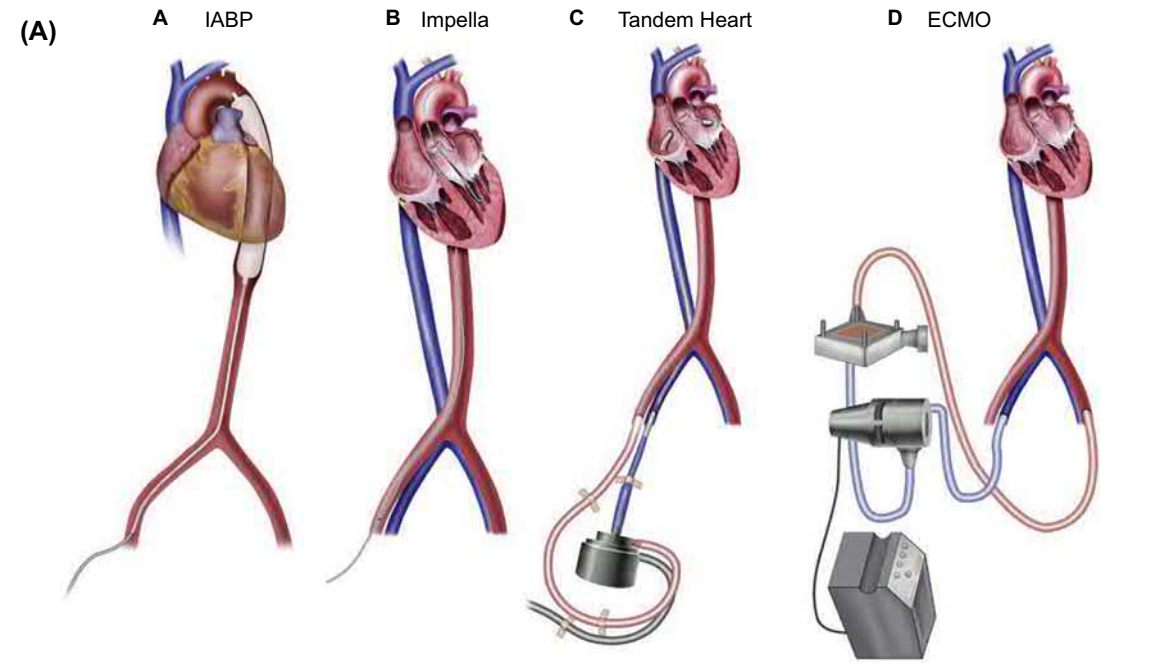
Percutaneous Mechanical Circulatory Support Devices

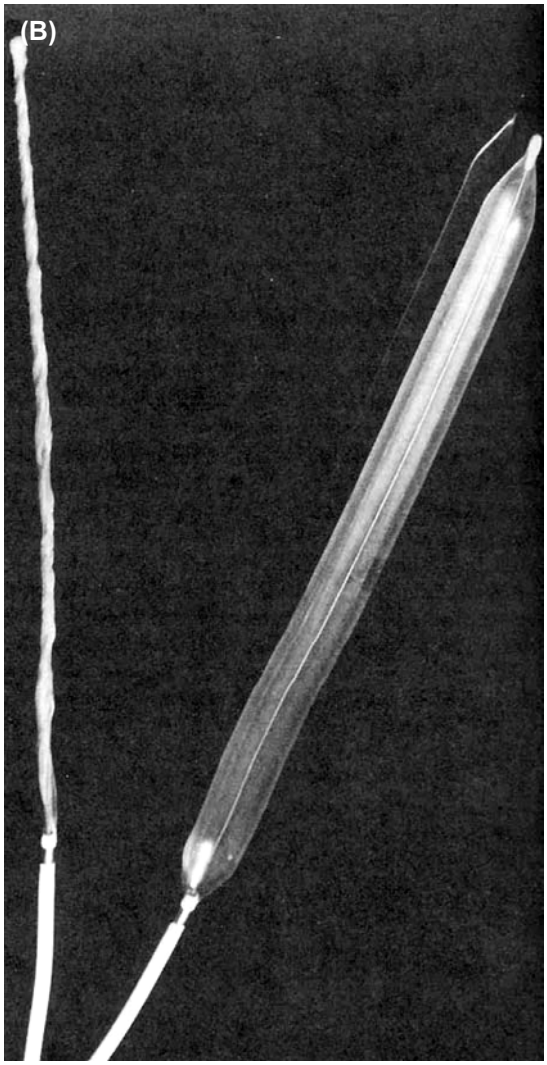
Percutaneous ventricular assist devices (VADs) (Mandawat and Rao, 2017; Miller et al., 2017) are used primarily for potentially reversible acute heart failure or cardiogenic shock, in which cardiac function is likely to recover with cardiac rest (e.g., postcardiotomy shock), or in cases of acute heart failure in which the patient needs to be stabilized quickly so that the possibilities for additional life-saving therapies (e.g., coronary artery bypass surgery, valve surgery, durable VAD placement, heart transplantation) can be assessed ("bridge-to decision"). The typical patient is critically ill with acute cardiogenic shock, mechanical complications of myocardial infarction such as ventricular septal or papillary muscle rupture, unrelenting ventricular arrhythmias, or advanced heart failure. Also, patients undergoing high-risk cardiac surgical procedures or percutaneous revascularization may benefit from the use of devices in the periprocedure period to reduce myocardial oxygen demand. Percutaneous devices (Fig. 2.5.2A.11A) used in these situations include the intraaortic balloon pump (IABP), TandemHeart (Cardiac Assist, Inc., Pittsburgh, PA), Impella (ABIOMED, Inc., Danvers, MA), and ECMO.

Since the original use of the IABP in 1968 by Kantrowitz, the basic design and function of the current device has remained relatively similar during the ensuing decades. IABPs (Fig. 2.5.2A.11B) are catheter-based polyethylene or polyurethane balloons with volumes of 25–50 mL, although smaller devices are used in the pediatric population. Helium is most often used as the inflating gas; its low viscosity allows for rapid inflation and deflation and it is rapidly dissolved in the bloodstream in the event of inadvertent balloon rupture. IABPs (Baskett et al., 2002; De Sousa et al., 2010) are generally positioned under fluoroscopic guidance in the descending thoracic aorta after percutaneous insertion via the femoral artery. They are timed to inflate during diastole (ventricular filling) and deflate during systole (ventricular contraction) using the patient's electrocardiogram or arterial pressure curve for synchronization; the devices discussed later do not have this requirement. This is termed counterpulsation (Trost and Hillis, 2006), which is out of phase with the patient's heartbeat, and causes volume displacement of blood proximally and distally within the aorta. Several beneficial effects serve to improve cardiac function. Coronary blood flow (the majority of which occurs in diastole) is increased by the rise in diastolic pressure, delivering more oxygenated blood to the myocardium. In addition, left ventricular afterload (the pressure the myocardium must attain to pump blood into the aorta) is decreased, reducing the workload and therefore the oxygen requirement of the myocardium. The combination of these two hemodynamic factors therefore improves the balance between myocardial oxygen supply and demand, and results in improved cardiac performance. The device also directly improves systemic circulation to a modest degree (approximately 10%). IABP therapy permits the heart to rest and recover enough function to support adequate circulation after the device has been removed, usually after only a few days. The major contraindications for IABP use include severe peripheral vascular disease, including aneurysms, aortic valve regurgitation, and aortic dissection (because of the need to thread the balloon through peripheral arteries and the aorta). Complications, which occurred in approximately 7% of patients with IABPs in a registry study, include limb ischemia from insertion site problems, bleeding, thrombosis with embolization, aortic dissection, balloon rupture, and sepsis.

The TandemHeart (Fig. 2.5.2A.11C) is a percutaneous VAD that supports the systemic circulation by withdrawing blood from the left atrium and reinjecting it into the abdominal aorta or iliac artery. The device has been commercially available since 2004. The pump, which sits in an extracorporeal location, is a continuous flow centrifugal pump that can provide up to 4–5 L/min of blood flow. The inflow cannula (usually 21-Fr in size) is typically inserted into a femoral vein, advanced into the right atrium and then pushed across the interatrial septum via transseptal puncture into the left atrium; when the device is withdrawn at the end of use, a small atrial septal defect remains. The outflow cannula (usually 15- to 17-Fr in size) is typically inserted into a femoral artery and advanced into the iliac artery or abdominal aorta. TandemHeart has been successfully used in a wide variety of clinical scenarios, including during high-risk percutaneous coronary interventions, bridge-to-recovery, bridge-to-decision, and bridge-to-transplant for patients with acute and advanced heart failure (Tempelhof et al., 2011; Kar et al., 2006). A modification of the TandemHeart allows it also to be used as a right VAD; a dual lumen cannula sits such that the inflow cannula of the device resides in the right atrium while the outflow cannula sits in the pulmonary artery distal to the pulmonic valve. One complication of the left-sided TandemHeart is the migration of the inflow cannula (meant to be in the left atrium) back into the right atrium. When this occurs, deoxygenated blood from the systemic venous return is drawn into the pump and returned into the systemic circulation, resulting in a right-to-left shunt. In addition, this steals blood from the right heart resulting in decreased pulmonary arterial flow leading to hypoxemic respiratory failure. The most common complication with the TandemHeart is bleeding at the cannula insertion site(s), exacerbated by the need for anticoagulation to prevent pump thrombosis.

The Impella device (Fig. 2.5.2A.11D) is a continuous, nonpulsatile axial flow pump that employs an Archimedes-screw impeller that draws blood from the left ventricular cavity and expels blood into the ascending aorta distal to the aortic valve. There are currently three versions of the device for left-sided support. The Impella 2.5 provides 2.5 L/min of flow, the Impella CP provides 3.7 L/min, and the Impella 5.0 provides





• **Figure 2.5.2A.11** Percutaneous mechanical circulatory support devices. (A) The intraaortic balloon pump (IABP) is inserted through the femoral artery and resides within the aorta. The Impella is inserted through the femoral artery and passed retrograde across the aortic valve, with the pump inflow within the left ventricle and the outflow in the ascending aorta. The TandemHeart pump is extracorporeal, with the inflow cannula tip in the left atrium and the outflow in the iliac artery or abdominal aorta. Extracorporeal membrane oxygenation (ECMO) consists of both a pump and oxygenator, drawing deoxygenated blood from the systemic venous system and returning newly oxygenated blood to the systemic arterial circulation, similar in principle to cardiopulmonary bypass. (B) Percutaneous IABP. *Left*, balloon deflated for insertion. *Right*, balloon inflated. (C) Tandem Heart pump, with the central inflow port and peripheral outflow port. Figure 2.5.2A.11 cont'd

5.0 L/min. The device is typically inserted into the femoral or axillary artery and advanced retrograde across the aortic valve so the device inlet rests in the left ventricular cavity and the outlet sits distal to the aortic valve. While the first two devices can generally be inserted purely in a percutaneous fashion, the Impella 5.0 is large enough that it often requires a surgical cut down at the arterial insertion site. By virtue of its position in the left ventricle, the Impella unloads the left ventricular pressure as well as unloading volume, which is advantageous for reducing ventricular oxygen consumption and demand. In contrast, the left atrial inlet cannula position of the TandemHeart only unloads volume without significantly changing left ventricular pressure directly. Impella devices have been extensively used for patients undergoing high-risk percutaneous coronary interventions and for patients in cardiogenic shock secondary to acute myocardial infarction. They have also been investigated as a bridge-to-decision and even as a bridge-to-transplant in appropriate patients (Cheng et al., 2018). They are contraindicated in patients who have mechanical aortic valves or left ventricular thrombi. The more common complications of the device include device migration, thrombosis/thromboembolism, bleeding, hemolysis, and damage to left ventricular cardiac structures such as the aortic and mitral valves. The Impella RP is a similar device designed for right heart failure, which is inserted in the systemic venous circulation and sits such that the device inflow is in the right heart and the outflow is in the pulmonary artery distal to the pulmonic valve.

ECMO, in contrast to the other percutaneous devices, provides the functions of both the heart (blood pressure and flow) and lungs (gas exchange) and is increasingly being used for patients with both acute cardiovascular and pulmonary diseases. The ECMO circuit is analogous to cardiopulmonary bypass in the operating room, but in a system that can be utilized at the bedside. The usual configuration is venoarterial (VA-ECMO) where systemic venous blood is removed from the patient, and passed through a continuous flow centrifugal pump, a heat exchanger, and a membrane oxygenator to provide full biventricular support and gas exchange. Cannulation can occur peripherally and percutaneously using the femoral vein and artery, or can use a surgical approach with cannulation of the right atrium and aorta in an open procedure. Just as with cardiopulmonary bypass, it is critical to have an experienced multidisciplinary team ensuring adequate functioning of the device and monitoring of the patient.

Durable Ventricular Assist Devices and Total Artificial Hearts

Durable VADs, first successfully employed by DeBakey in 1963, can replace ventricular function for extended periods, in contrast to the short-term duration of cardiopulmonary bypass, IABP, and percutaneous VADs. Durable VADs are currently used primarily in three settings: (1) for end-stage cardiac failure not likely to recover and where mechanical support will provide a "bridge-to-transplantation"; (2) for long-term cardiac support for patients with end-stage congestive heart failure that are not transplant candidates ("destination therapy") (Christiansen et al., 2008); and (3) for chronic congestive heart failure where the unloading of the left ventricle may induce myocardial changes that might lead to normalization of cardiac function and eventually allow device removal ("bridge-to-recovery"). Research in this latter area focuses on the mechanisms of cardiac recovery, identification of patients who could achieve recovery, and specifics such as the timing and duration of therapy (Maybaum et al., 2008; Birks, 2010).

The first generation of durable VADs used as bridge-to-transplant or destination therapy (Hunt and Frazier, 1998) were large, pulsatile systems, with the inflow cannula of the device generally connected to the left ventricular apex and the outflow cannula connected to the ascending aorta. The pump itself would either be implanted in the peritoneal cavity with a driveline traversing the skin to provide power and controller functions, or would remain extracorporeal with the inflow and outflow cannulae each traversing the skin. Examples of first-generation pulsatile left ventricular assist devices (LVADs) included Thoratec HeartMate XVE (Fig. 2.5.2A.12) (Rose et al., 2001) and Novacor Ventricular Assist System (Dagenais et al., 2001); the Thoratec PVAD (Farrar et al., 1990) is an example of a paracorporeal VAD. These devices generally consisted of a flexible polymer pumping bladder or diaphragm actuated by a pusher plate to allow filling and emptying of the pumping chamber. Valves on the inflow and outflow aspect of the pump ensured unidirectional flow of blood. These devices were very large and posed many challenges; nevertheless, these devices were critical in bridging patients to transplant from the 1980s into the mid-2000s. While the Thoratec PVAD is still occasionally used, the other devices are obsolete.

The second generation of durable VADs consists of implantable continuous axial flow devices, where the long

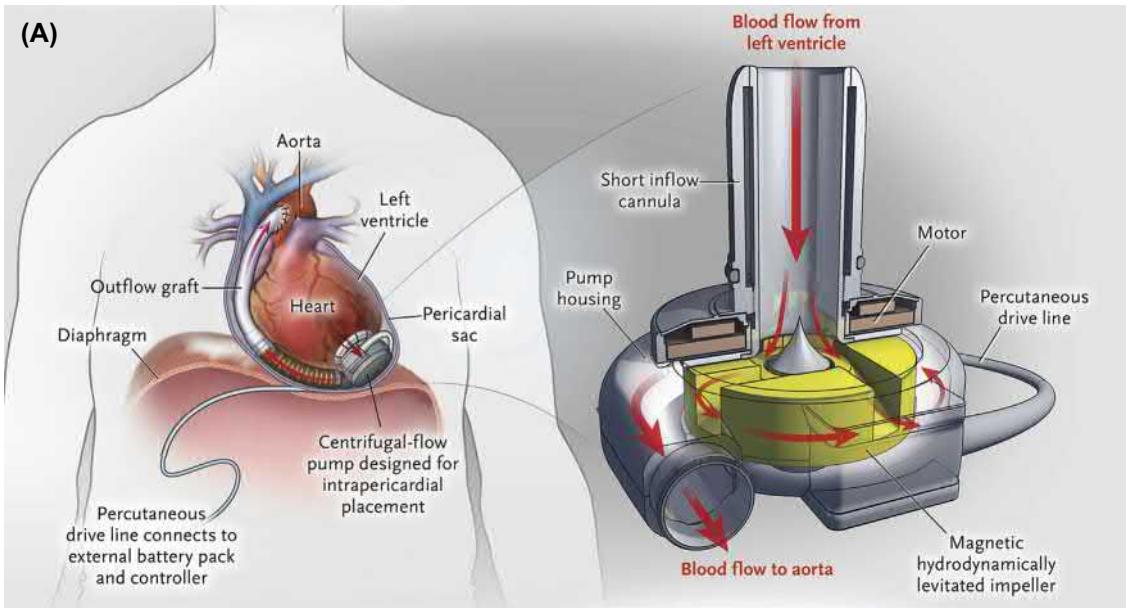
• **Figure 2.5.2A.13** (A) Diagram of the HeartMate II continuous axial flow ventricular assist device. (B) Photograph of HeartMate II and heart after removal from patient at autopsy. ((A) Reproduced with permission from Slaughter, M.S., Rogers, J.G., Milano, C.A., Russell, S.D., Conte, J.V., Feldman, D., Sun, B., Tatooles, A.J., Delgado, R.M., Long, J.W., Wozniak, T.C., Ghumman, W., Farrar, D.J., Frazier, O.H., 2009. Advanced heart failure treated with continuous-flow left ventricular assist device. N. Engl. J. Med. 361, 2241–2251.)

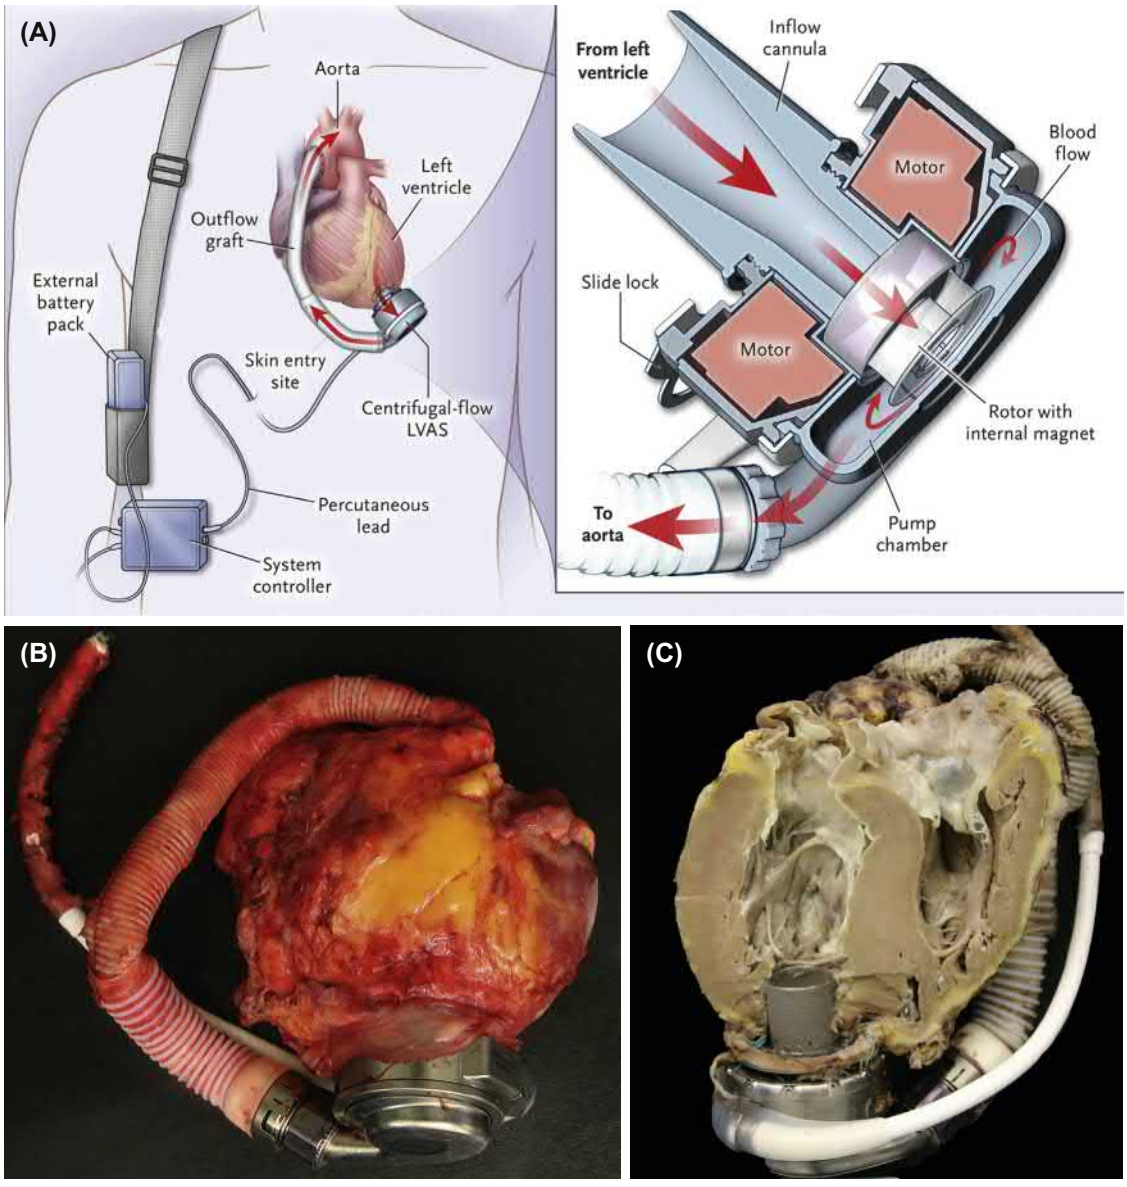
axis of the impeller is parallel to the direction of blood flow. Examples of such devices include Thoratec HeartMate II (Fig. 2.5.2A.13) (Slaughter et al., 2009), BerlinHeart INCOR (Schmid et al., 2005) (pumps reside within the peritoneal cavity), and Jarvik 2000 FlowMaker (Sorensen et al., 2012) (the pump is intraventricular). These second-generation devices are connected in much the same way as the implantable first-generation devices but are much smaller, making implantation easier and allowing smaller patients to receive them; they are also more durable than the first-generation devices. Since these are all continuous flow devices, the pumps themselves do not impart pulsatility to the blood resulting in reduced pulse pressure for the patient; this reduction of pulse pressure does not seem to have significant clinical effects. Data demonstrate lower complication rates and improved outcomes over this time, especially with newer continuous flow LVADs as compared to the first-generation pulsatile devices (Kirklin et al., 2017).

The third generation of VADs consists of implantable continuous centrifugal flow devices, where the impeller creates a centrifugal force to add kinetic energy to the flowing blood. Examples of such devices include HeartWare HVAD (Aaronson et al., 2012), Thoratec HeartMate 3 (Schmitto et al., 2015), and Evaheart LVAS (Saito et al., 2014). The use of these devices is accelerating, with a respective decline in the use of the second-generation VADs.



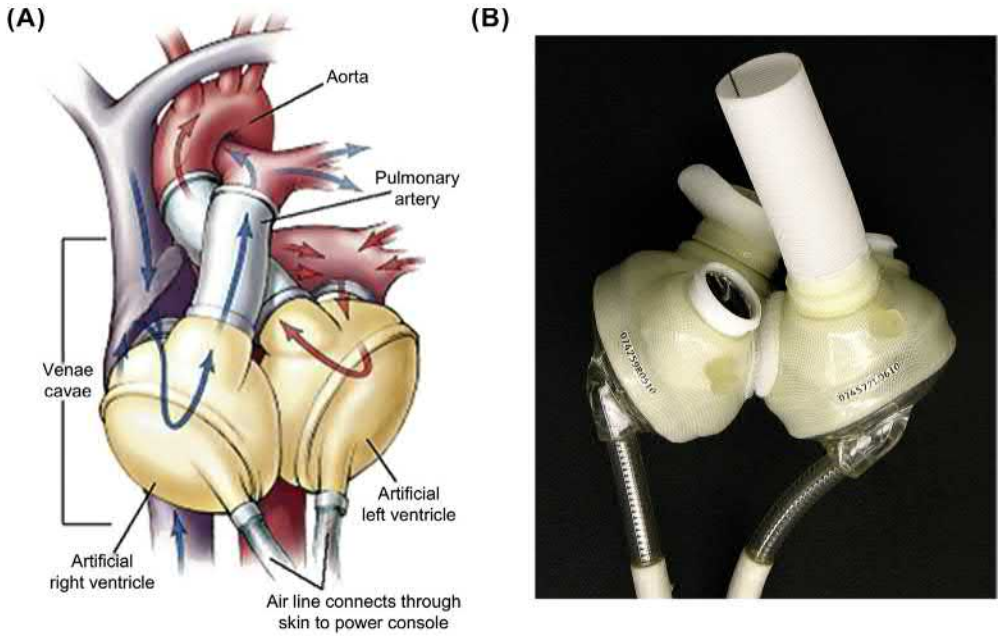
• **Figure 2.5.2A.14** (A) Diagram of the HeartWare Ventricular Assist Device (HVAD), a continuous flow centrifugal pump. (B) Photograph of HVAD and heart after surgical explantation from a patient who was bridged to cardiac transplantation with this device. ((A) Reproduced with permission from Rogers, J.G., Pagani, F.D., Tatooles, A.J., Bhat, G., Slaughter, M.S., Birks, E.J., Boyce, S.W., Najjar, S.S., Jeevanandam, V., Anderson, A.S., Gregoric, I.D., Mallidi, H., Leadley, K., Aaronson, K.D., Frazier, O.H., Milano, C.A., 2017. Intrapericardial left ventricular assist device for advanced heart failure. N. Engl. J. Med. 376, 451–460.)

The HeartWare Ventricular Assist Device (HVAD, Medtronic, Inc., Minneapolis, MN) was the first implantable third-generation centrifugal flow device available in the United States, with important design differences from the commercially available axial flow devices (Larose et al., 2010); it received CE Mark approval in 2008 followed by FDA approval in 2012. The pump is smaller and resides directly on the epicardial surface of the left ventricle (Fig. 2.5.2A.14), with the inflow cannula residing within the left ventricular cavity. The rotor produces continuous, centrifugal flow with a magnetically levitated impeller rather than the axial flow system of the Thoratec HeartMate II, for example, which requires inflow and outflow bearings to support and align the impeller. The smaller pump size and driveline, intrathoracic positioning, and flow characteristics of the HVAD are thought to be advantageous in reducing common device complications such as infection, thrombosis, and bleeding. The HVAD ADVANCE trial demonstrated noninferiority (91% patient survival at 6 months) to other commercially available devices in a bridge-to-transplant setting, and there are longer follow-up data in a postmarket registry (Streuber et al., 2014). The original HVAD inflow



• **Figure 2.5.2A.15** (A) Diagram of the HeartMate 3 Ventricular Assist Device, a continuous flow centrifugal pump. (B and C) Photograph of HeartMate 3 and heart after surgical explantation from a patient who was bridged to cardiac transplantation with this device. ((A) Reproduced with permission from Mehra, M.R., Naka, Y., Uriel, N., Goldstein, D.J., Cleveland, J.C., Colombo, P.C., Walsh, M.N., Milano, C.A., Patel, C.B., Jorde, U.P., Pagani, F.D., Aaronson, K.D., Dean, D.A., McCants, K., Itoh, A., Ewald, G.A., Horstmanshof, D., Long, J.W., Salerno, C., 2017. A fully magnetically levitated circulatory pump for advanced heart failure. N. Engl. J. Med. 376, 440–450.)

cannula had a smooth, polished titanium outer surface, which raised concerns about the increased risk of cerebrovascular accidents secondary to device-related thromboemboli (Najjar et al., 2014). A change in the HVAD inflow cannula design was therefore implemented in an attempt to promote nonthrombotic passivating tissue overgrowth by replacing the smooth, polished titanium surface with one incorporating a collar of sintered titanium microspheres (Soltani S, 2015). However, this created a discontinuity at the smooth-sintered interface on the outer aspect of the inflow cannula that appears to serve as a nidus for thrombus formation (Glass et al., 2019).The HeartMate 3 (Fig. 2.5.2A.15) is the latest third-generation centrifugal flow pump with a fully magnetically levitated motor along with active magnetic mounting (Chatterjee et al., 2018). It was first implanted in humans in 2014 by a group in Germany (Schmitto et al., 2015). The motor incorporates a contactless bearing technology and consists of the rotor with passive magnets for drive and bearing, the stator with electromagnetic coils for drive and levitation, along with distance sensors and a microcontroller. This pump is approximately one-third the size of the HeartMate I and is implanted in the pericardial space rather than in the abdominal cavity. The inflow cannula is fully sintered and resides within the left ventricular chamber, with the outflow graft anastomosed to the ascending aorta. It can deliver up to 10 L/min of flow, and can also generate an "artificial pulse" by periodically increasing and decreasing the pump speed mimicking a pulse rate of



• **Figure 2.5.2A.16** (A) Diagram of the SynCardia Total Artificial Heart. (B) Photograph of an unimplanted SynCardia Total Artificial Heart. Cardiac replacement with a total artificial heart as a bridge to transplantation. N. Engl. J. Med. 351, 859–867.)

30 beats per minute. The MOMENTUM 3 clinical trial was designed to compare the centrifugal flow HeartMate 3 with the axial flow HeartMate II in patients with advanced heart failure. The HeartMate 3 showed lower rates of pump thrombosis, stroke, and reoperation to remove or replace a malfunctioning pump compared to the HeartMate II at 2-year follow-up (Mehra et al., 2018).

In contrast to VADs where the native heart remains in place, a total artificial heart is composed of two pumping chambers that together replace the entire heart and provide both right and left ventricular function, analogous to heart transplantation (Fig. 2.5.2A.16). The SynCardia Total Artificial Heart (SynCardia Systems, Inc.; Tucson, AZ) has been implanted worldwide in more than 1000 patients with biventricular heart disease (Copeland et al., 2003; Copeland et al., 2012). The device was approved by the FDA in 2004 and has proven to be an effective and reliable device for successful bridge-to-transplant. The clinical indications for implantation have included biventricular failure, left ventricular failure with prior mechanical heart valves, left ventricular failure with severe anatomical damage (ventricular septal defect, AV disruption), intractable malignant arrhythmias, massive ventricular thrombus, cardiac allograft failure, hypertrophic or restrictive cardiomyopathy, and complex congenital heart disease. The device is an implantable, pneumatically driven pulsatile pair of pumps consisting of polyurethane ventricles, whose inflows are anastomosed to the left and right atria and whose outflows are anastomosed to the ascending aorta and pulmonary artery after complete removal of the native cardiac ventricles and all four valves. Medtronic-Hall mechanical valves on the inflow and outflow aspects of the pump ensure unidirectional flow. Systemic infection and thromboembolic or hemorrhagic events have been reported as the most common complications that prevent successful bridge-to-transplant.

The major complications of cardiac assist devices are hemorrhage, thrombosis/thromboembolism, infection, interactions with host tissue, and device component failure, including the pump and peripheral electrical systems (Fig. 2.5.2A.17). Hemorrhage continues to be a problem in device recipients, although the risk of major hemorrhage has been decreasing with improved devices, therapies, patient selection, and surgical methods. Many factors predispose to perioperative hemorrhage, including (1) anticoagulation therapy and its management along with coagulopathy secondary to liver dysfunction and poor nutritional status, (2) contact of the blood with the device resulting in intrinsic platelet dysfunction and acquired von Willebrand disease, and (3) the extensive nature of the required surgery. Nonthrombogenic blood-contacting surfaces are essential for a clinically useful cardiac assist device or artificial heart. Indeed, thromboembolism occurred in most patients having long-term implantation of the Jarvik-7 artificial heart and is a major design consideration for current devices. In the absence of adequate anticoagulation and despite the development of minimally thrombogenic blood-contacting surfaces and appropriate blood flow characteristics, thrombi can form in areas of disturbed blood flow such as connections of conduits and other components to each other and to the natural heart. The current generation of continuous flow LVADs is carefully designed to minimize thrombosis, but oral anticoagulation is still required. Pump thrombosis in the continuous axial flow HeartMate II LVAD at the inflow bearing was one of the major sources of morbidity and mortality for patients with this device. Thrombi also may form outside the

LVAD, often in association with crevices and voids as in the HeartWare HVAD discussed earlier, and in areas of disturbed blood flow such as near connections of conduits and other components to the native heart. These thrombi can detach and lead to catastrophic embolic events such as ischemic stroke. Accounting for significant morbidity and mortality following the prolonged use of cardiac assist devices, infection can occur either within the device or associated with percutaneous drive lines (Padera, 2006). Susceptibility to infection is potentiated not only by the usual prosthesis-associated factors, but also by the multisystem organ damage from the underlying disease, the periprosthetic culture medium provided by postoperative hemorrhage, and by prolonged hospitalization with the associated risk of nosocomial infections. Assist device-associated infections are often resistant to antibiotic therapy and host defenses, but are generally considered not an absolute contraindication to subsequent cardiac transplantation. Novel device designs, including alternative sites for driveline placement and the elimination of the driveline altogether with transcutaneous energy transmission technology, may play a role in further decreasing infection.

Atrial Septal Defects and Other Intracardiac Defects

In prenatal life, circulation is different than it is in postnatal life (Schoen and Mitchell, 2015). The lungs of the fetus are not providing gas exchange, so oxygenation of fetal blood is provided via the placenta and maternal circulation. This

requires two important shunts that need to close immediately after birth to separate the circulation into the pulmonary and the systemic arms. The foramen ovale, a hole in the fetal intraatrial septum, allows oxygenated blood returning to the right atrium from the placenta to preferentially pass into the left atrium. This blood passes through the mitral valve into the left ventricle and is pumped out through the aorta into the systemic circulation. The ductus arteriosus, present between the pulmonary artery and aorta, allows deoxygenated blood pumped from the right ventricle to bypass the lungs and directly reenter the systemic circulation, as the prenatal pulmonary circulation has a high vascular resistance (because of the nonexpanded lungs). After birth, these functional shunts should close to completely separate the right and left circulations; failure to do so results in a patent foramen ovale (PFO) or patent ductus arteriosus (PDA) that can allow inappropriate shunting of blood in the postnatal circulation. In addition, atrial septal defects (ASDs) or ventricular septal defects (VSDs) can also result from abnormal formation of the atrial septum or ventricular septum. While these defects can be closed via an open surgical procedure (sutures and/or fabric patches for PFO, ASD, or VSD, ligation for PDA), efforts have been made to allow closure of these defects using a minimally invasive approach. The decision to close a PFO, ASD, VSD, or PDA depends on the size of the shunt and the symptoms of the patient; the choice of technique (surgical vs. percutaneous) depends on the anatomy and structure of the defect.

Closure Devices

The first catheter-based closure of a PDA was performed in 1967 by Porstmann using an Ivalon plug to occlude flow through the ductus arteriosus. Of the many PDA closure devices that have been developed over the years, most are metal-based devices that work by causing thrombosis of the PDA with subsequent organization and fibrosis, permanently preventing flow through the residual ductus arteriosus. Three of the more commonly used devices are the Gianturco coil (stainless-steel coil containing polyester fibers to promote thrombosis), the Amplatzer Duct Occluder (ADO, a conical device consisting of Nitinol wires and a polyester fiber patch to promote thrombosis and tissue integration), and the next-generation ADO II (Baruteau et al., 2014).

Mills and King reported the first transcatheter closure of an ASD in 1976 using a double umbrella device that covered the opening from both the right and left atrial sides. Their occlusion device consisted of a skeleton of expanded polytetrafluoroethylene (ePTFE)-coated wire supporting an occluder of Dacron fabric delivered through a catheter. Improvements over the years include better device fixation methods and smaller caliber introducers. Several designs (Fig. 2.5.2A.18) of PFO/ASD closure devices are currently in use (Jung and Choi, 2018). The Amplatzer device (St. Jude Medical, St. Paul, MN) is a self-centering device that consists of double Nitinol disks filled with polyester patches connected by a small waist; the waist sits within the defect to connect the disks, which sit on either side of and are selected to be larger than the defect. The Gore Cardioform Septal Occluder (W.L. Gore and Associates, Flagstaff, AZ) is a nonself-centering device composed of a platinum-filled Nitinol wire framework, which is covered by an ePTFE patch designed to promote endothelialization. Advantages of nonsurgical closure devices such as these include shorter hospital stay, more rapid recovery, and no residual thoracotomy scar. With the experience gained in the transcatheter closure of PFOs and ASDs, this interventional technology is being extended to the closure of some VSDs, particularly in patients thought to be poor operative risks.

Several types of complications have been reported for closure devices. The most straightforward is the failure to fully close the defect resulting in residual shunting. Erosion of the device through the interatrial septum occurs in some patients with perforation and device embolization; this is thought to be secondary to the specific anatomy of the defect, but the stiffness of the device may also play a role. Inadequate fixation of the device within the defect or a device-defect size mismatch can also result in device embolization. Closure devices are effective in closing defects at least in part via thrombosis; if the thrombosis extends beyond the defect on the device, thromboemboli may result. Fractures of various device components, air embolism at the time of device deployment, infection, and development of new arrhythmias have also been reported. A number of devices are in development, with the trends being defect-specific design and minimization of the amount of foreign material left in the patient, including the use of biodegradable components (O'Byrne and Levi, 2019).

Atrial Fibrillation

AF affects more than 3 million individuals in the United States, making it the most common cardiac arrhythmia. Instead of orderly atrial contraction initiated by the SA node, rapid disorganized electrical activity in the atria causes these upper chambers of the heart to quiver or fibrillate resulting in poor contractile function and irregular flow within the chamber. As would be predicted by Virchow's triad, thrombosis may occur due to these flow abnormalities within the atria, especially within the atrial appendage. Atrial appendage thrombi are an important source of thromboemboli, explaining why patients with AF are at a fivefold greater risk for embolic stroke than individuals in sinus rhythm. Anticoagulation is effective in reducing the risk of atrial thrombosis and stroke, but this therapy has many drawbacks, including a narrow therapeutic window, variability in metabolism of the drug, interactions with other drugs and metabolites, need for frequent monitoring by blood drawing, poor patient compliance, and, most importantly, the risk of life-threatening bleeding. These side effects are reduced in a class of drugs called nonvitamin K antagonist oral anticoagulants when compared to the established vitamin K antagonists such as warfarin (Granger et al., 2011), but there is still a

bleeding risk with these newer medications. An approach for reducing the risk of thromboembolic stroke in patients with AF is to remove or ligate the left atrial appendage, first proposed in the 1930s and first performed in 1949 via a surgical approach. This approach is typically used when a patient is undergoing a concomitant cardiac surgical procedure such as valve replacement or bypass surgery.

Left Atrial Appendage Occlusion Devices

Nonsurgical device-based approaches to close the left atrial appendage have been developed, including several devices that can be deployed percutaneously to occlude the opening to the appendage and isolate it from the blood in the left atrium (Pacha et al., 2019). The Watchman (Fig. 2.5.2A.19)

left atrial appendage system (Boston Scientific, Marlborough, MA) is an FDA-approved, percutaneously deployed parachute-shaped device consisting of a Nitinol cage with a polyethylene terephthalate membrane on its surface and fixation barbs along the perimeter, which allows it to anchor in the atrial appendage. This device has been shown to be noninferior to standard warfarin therapy for prevention of embolic stroke and systemic embolization, and superior to warfarin for prevention of cardiovascular death and hemorrhagic stroke in recent clinical trials (Holmes et al., 2009; Reddy et al., 2017). The Amplatzer Amulet (St. Jude Medical, Minneapolis, MN) device is another current generation percutaneously deployed left atrial occlusion device that is currently in clinical trials (Kleinecke et al., 2017) prior to FDA approval. The Atriclip Device System (Atricure, Inc., West Chester, OH) is an occlusion device applied on the epicardial surface at the base of the left atrial appendage to close the entrance to the left atrial appendage by external compression (Ailawadi et al., 2011). The device consists of two parallel rigid titanium tubes with elastic Nitinol springs that hold the device closed.

Cardiovascular Medical Devices: Stents, Grafts, Stent-Grafts and Other Endovascular Devices

MICHAEL A. SEIDMAN[a], ROBERT F. PADERA, FREDERICK J. SCHOEN

Department of Pathology, Brigham and Women's Hospital and Harvard Medical School, Boston, MA, United States

Vascular disorders and their downstream sequelae are responsible for more morbidity and mortality than any other category of human disease. The top two causes of death worldwide, ischemic heart disease and stroke, collectively comprising approximately 13 million persons annually, more than one-quarter of all deaths in both men and women (Lozano et al., 2012), are both manifestations of vascular pathology. Additionally, aortic aneurysms and related pathologies are associated with over 175,000 deaths a year globally (GBD 2013 Mortality and Causes of Death Collaborators, 2015). Thus, the vasculature has been a longstanding and important target for both open surgical procedures and endovascular interventions using biomaterials and associated devices. The devices that have facilitated these procedures are highly specialized to the anatomic site and functional role of the segment of vascular bed targeted, and to the specific pathological processes the procedures and devices are intended to manage.

This chapter focuses on the biomaterials and devices used to manage vascular disease. However, before discussing specific device categories, we provide a brief overview of the vascular system and the key pathologic processes that affect it.

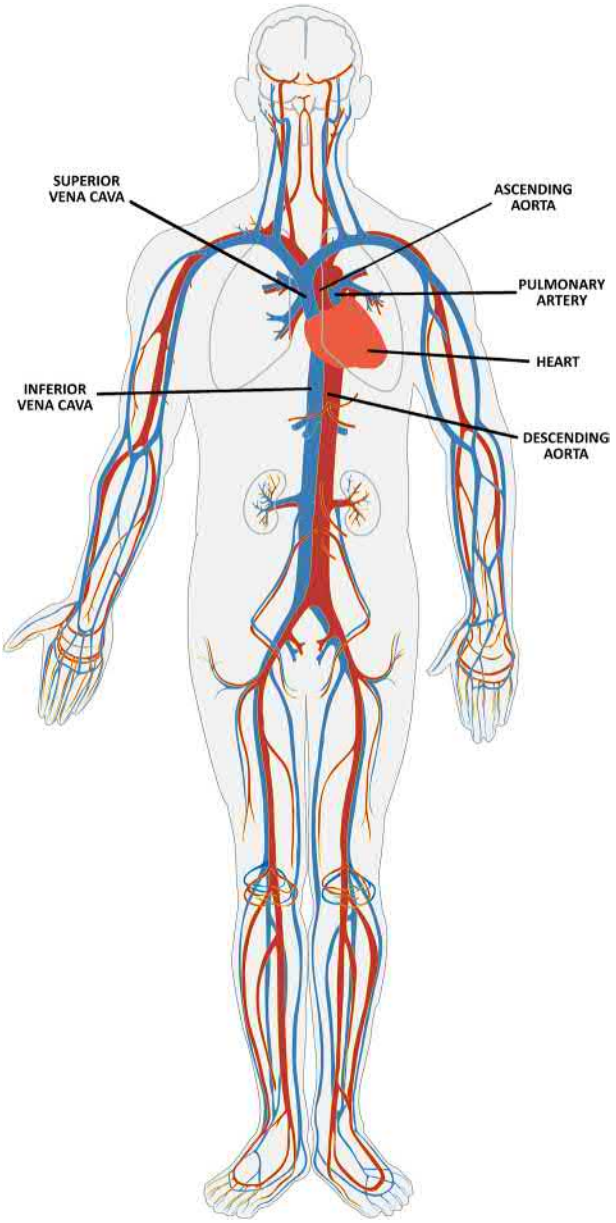
Key Concepts in Vascular Structure and Function

Architecture of the Circulation

The circulation (a.k.a. the *cardiovascular system*) transports and distributes essential substances throughout the body and helps eliminate waste products. The cardiovascular system is composed of a pump, a series of distributing and collecting tubes that carry blood away from the heart (*arteries*), vessels that carry blood toward the heart (*veins*), and an extensive network of thin-walled vessels (*capillaries*) that provide nutrient and gas exchange to the tissues and remove byproducts of metabolism (i.e., oxygen and nutrients in; carbon dioxide and other waste products out). To accomplish these functions, the cardiovascular system must regulate blood pressure and volume at all levels of the vasculature, buffer pulsatile flow in order to ensure steady and slow velocity flow in the capillaries, maintain circulatory continuity while permitting free and bidirectional exchange of substances between blood and the extravascular compartments, and control *hemostasis*, i.e., prevent clots (*thrombi*) when the circulation is intact, and prevent hemorrhage when the vessel is injured. Other functions of the circulation include regulation of body temperature, and systemic distribution of various regulating substances (e.g., hormones, inflammatory mediators, growth factors, and therapeutic substances). Moreover, the circulatory system distributes immune and inflammatory cells, and the lining cells of the circulatory system (*endothelial cells*) facilitate egress of the immune cells from the blood to the tissues in which they are needed.

The human circulation is composed of two parallel circuits with this generalized configuration (Fig. 2.5.2B.1). The *systemic circulation* originates at the aortic valve of the heart; the single lead artery, the aorta, branches into successively smaller arteries until ultimately reaching the capillaries, the level of the circulatory system at which metabolic exchange with the tissues occurs. The capillaries then "coalesce" into small and progressively larger veins, ultimately returning to the right side of the heart via the largest veins, the inferior and superior venae cavae. Similarly, and

[a]Dr. Seidman is presently affiliated with the University Health Network and the University of Toronto, Toronto, Canada.



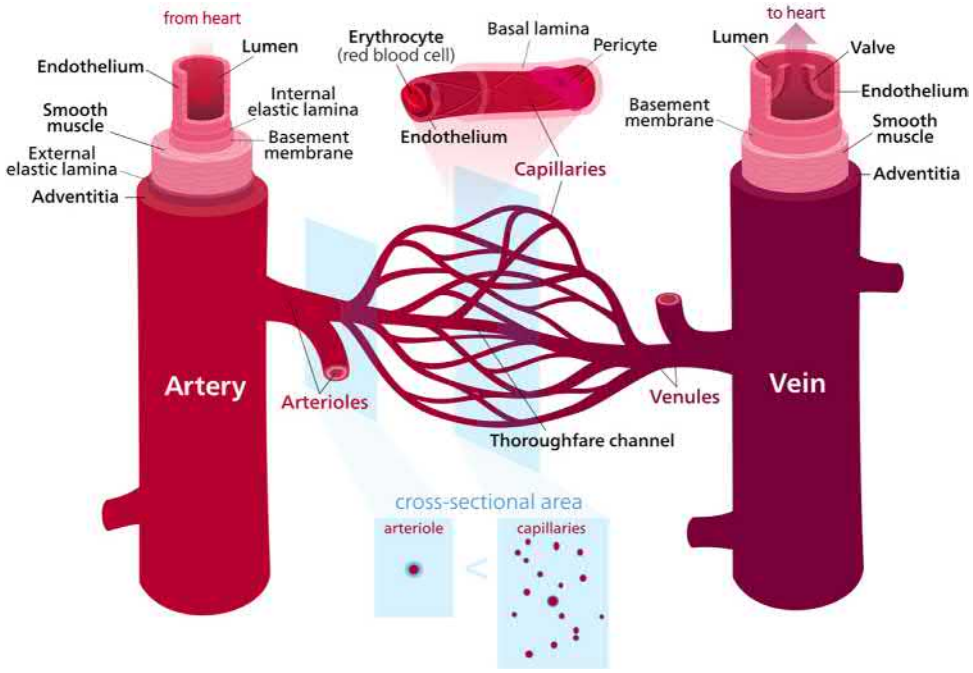
• **Figure 2.5.2B.1** The cardiovascular system. Large and medium-sized vessels carrying oxygenated (red) and deoxygenated (blue) blood are shown with respect to the heart (orange). The ascending aorta (red) and pulmonary artery (blue) carry blood away from the heart, the superior and inferior vena cavae (blue) carry blood back to the heart (the pulmonary veins, in red behind the pulmonary artery, also return blood to the heart). The descending aorta passes behind the heart but does not anastomose with it. (Reproduced from https://commons.wikimedia.org/w/index.php?curid=10005587. (Accessed 3 September 2019).)

in parallel, the *pulmonary circulation* begins at the pulmonary valve, from which arises the main pulmonary artery (the only large artery in the body which carries blood which has not yet been oxygenated). In the lung, the pulmonary artery branches successively into smaller arteries, then capillaries, and collects oxygenated blood into successively larger veins, returning blood to the left atrium via the pulmonary veins. In most organs and tissues, one or a few larger arteries bring blood in, then branch into capillaries in a manner that creates *vascular beds* within each organ. The branching structure dramatically increases the surface area available for gas and nutrient exchange at the capillary level.

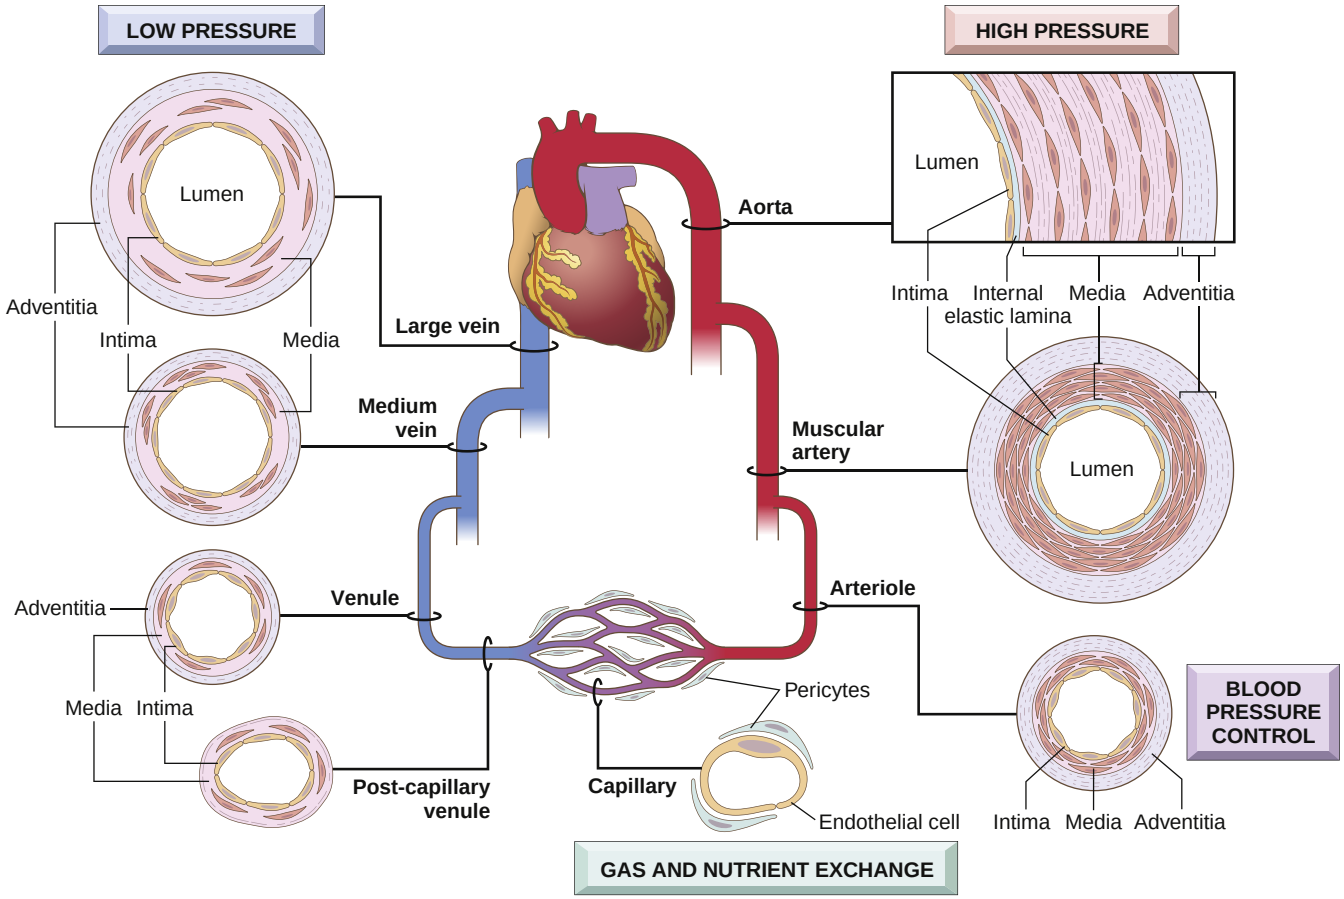
The entire cardiovascular system follows a consistent architectural paradigm with regional differences (Figs. 2.5.2B.2 and 2.5.2B.3). Three basic structural constituents comprise the walls of blood vessels: endothelium, muscular tissue, and extracellular matrix (ECM), including collagen and elastic elements. These tissues are arranged in concentric layers (called *tunica*, meaning coats): (1) the *intima*—consisting of endothelial cells (ECs), subendothelial connective tissue and the internal elastic lamina; (2) the *media*—consisting of smooth muscle cells (SMCs) and elastic laminas, including the external elastic lamina; and (3) *adventitia*—collagenous connective tissue. The histologic composition and organization, as well as the thickness of these three layers, vary characteristically with the physiologic functions performed by specific segments of the vascular system (see Fig. 2.5.2B.3). The layered structure of the blood vessels progressively undergoes segmental differentiation and adaptation to local factors, both mechanical (especially blood pressure, which determines the amount and arrangement of muscular tissue), and metabolic (reflecting the local nutritional needs of the tissues).

As emphasized above, the structure of vessels varies with their functional role. Arteries are usually divided into three major categories. In sequential order from the heart they are: *elastic arteries* (large or conducting arteries), *muscular arteries* (medium or distributing arteries), and *arterioles* (smallest arteries, <200 μm). The elastic arteries include the aorta and its largest primary branches (e.g., common carotid and common iliac arteries). The elastic components of the aorta allow it to expand during ventricular contraction (a phase called *systole*), thereby storing some of the energy of each heart contraction. Between heart beats (*diastole*), elastic recoil of the vascular wall (especially in the aorta) propels blood through the vascular system. Since diffusion of oxygen and other crucial substances from the lumen to the outer layers of the media is inadequate in all but the thinnest walled arteries, small arterioles called *vasa vasorum* course through the adventitia and send capillary twigs into the media. These small vessels provide *perfusion* (i.e., blood flow) to the vascular wall itself. The wall of an artery is generally thicker than that of the wall of a corresponding vein, in order to withstand the higher blood pressures within arteries compared with veins. Veins typically have a larger overall diameter, a larger lumen, and a thinner wall than corresponding arteries with which they course.

Although the circulation must provide high hydrostatic pressure to distribute sufficient blood throughout the body, blood in capillary beds must be delivered under low pressure to protect the capillary walls (which are necessarily thin for exchange) and low flow (to maximize residence time). These conditions of blood flow into capillary beds are facilitated by the high resistance in the arterioles (i.e., the *resistance vessels*). Arterioles are the smallest branches of the arteries, generally between 20 and 100 μm in diameter. They have a



• **Figure 2.5.2B.2** Structure of arteries and veins. Shown are the layers of an artery and vein of approximately equal size. The artery demonstrates the intima (endothelium and internal elastic lamina), media (smooth muscle and external elastic lamina), and adventitia. The vein structure is similar but lacking elastic laminae. Also shown is a cross section of an arteriole and of capillaries (bottom) to demonstrate size and structure, as well as a schematic (on a magnified scale) of a capillary structure (top). (Reproduced from https://commons.wikimedia.org/w/index.php?curid=65695195. (Accessed 3 September 2019).)



• **Figure 2.5.2B.3** Schematic of the cardiovascular system with respect to arteries and veins, demonstrating schematically regional progression of vessel sizes, composition, relationships, and different functions. (Reproduced from Mitchell, R., 2015. Blood vessels. In: Kumar, V., Abbas, A., Aster, J. (Eds.), Robbins and Cotran Pathologic Basis of Disease, ninth ed. Elsevier.)

small lumen, and a circular muscular coat with the ability to adjust the degree of contraction of such, thereby restricting lumen diameter and generating high resistance that lowers arterial blood pressure and dampens pulsatility in the downstream vessel. Therefore the capillary microcirculation experiences near-continuous low-pressure blood flow. Subsequently, postcapillary blood flows slowly into the veins, with large lumens and thin walls. Rich in connective tissue, veins are distensible and play an important role as a variable blood reservoir (*capacitance vessels*). Most of the blood volume is contained in the low-pressure circulation (i.e., approximately 75% veins, 20% arteries and 5% capillaries).

Moreover, in this conception of the cardiovascular system, the heart is considered to be a highly specialized blood vessel, i.e., a segment of the circulation, functionally adapted to pump blood, with its media represented by the *myocardium*, containing muscle specialized for rhythmic, strong contractions (*cardiac myocytes*); the *endocardium* as the intima; and the *epicardium* as the adventitia. The *coronary arteries* provide perfusion of blood to the myocardium. They comprise the vasa vasorum of the heart.

Vascular Pathology

Vascular pathology results in disease primarily via one of two principal mechanisms: (1) narrowing (*stenosis*) or complete obstruction of vessel lumens, either progressively (e.g., by intimal hyperplasia or atherosclerosis, see below) or precipitously (e.g., by either thrombosis directly or fragmentation of thrombus with downstream vessel blockage, called *embolism*); and (2) weakening of vessel walls, leading to dilation or rupture. Other forms of embolism include fat (most commonly as a result of massive tissue damage forcing extravascular tissue into the vasculature), atherosclerotic (portions of plaque dislodging from the original site and traveling downstream), mycotic (dislodging of material from a site of infection), and foreign material (e.g., from intravascular procedures or devices).

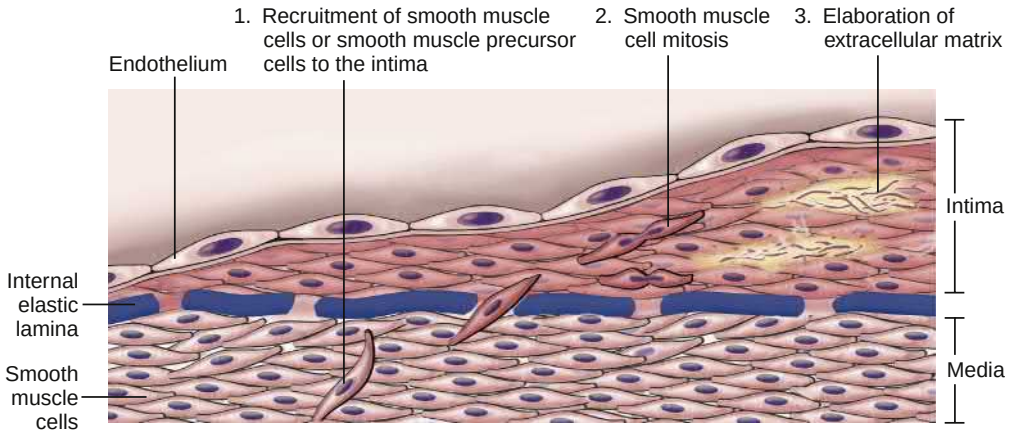
Vascular Injury and Healing

The integrated function of the cells of the vascular walls, endothelial cells (ECs) and smooth muscle cells (SMCs), is critical to the mechanisms by which the vasculature develops and responds to hemodynamic and biochemical stimuli. ECs play a role in the maintenance of a nonthrombogenic blood–tissue interface, the modulation of blood flow and vascular resistance, the metabolism of hormones, the regulation of immune and inflammatory reactions, and the growth regulation of other cell types, particularly SMCs. ECs have substantial phenotypic variability based on anatomic site and dynamic adaptation to local chemical and mechanical cues (e.g., cytokines and shear stress; Gimbrone and García-Cardeña, 2013). Thus, healthy ECs can respond to various pathophysiologic stimuli by modulating their usual (*constitutive*) functions and by expressing newly acquired (*inducible*) properties, such as expression of adhesion molecules, procoagulant and anticoagulant moieties, and major histocompatibility complex molecules, and synthesis and release of cytokines and chemokines, growth factors, vasoactive, and a variety of other biologically active products. Through the production of both relaxing factors (e.g., nitric oxide) and contracting factors (e.g., endothelin), ECs influence the vasoreactivity of the underlying smooth muscle cells. Normal endothelial function is characterized by a balance of these factors and the ability of the vessel to respond appropriately to various pharmacologic stimuli. In contrast, *endothelial dysfunction*, defined as a significantly altered (and indeed pathologic) phenotype that impairs vasoreactivity, induces a surface that is thrombogenic, or is abnormally adhesive to inflammatory cells, and thereby contributes significantly to the initiation of thrombus formation, atherosclerosis, and other vascular lesions, such as intimal hyperplasia (see below). Dysfunctional endothelium may appear normal morphologically (i.e., by conventional microscopy or scanning electron microscopy). Thus, the presence of a histologically observed structurally intact endothelium on the luminal surface of either a native vessel or a vascular replacement does not ensure that the cells comprise healthy and properly functional endothelial cells. Moreover, the demonstration of endothelial dysfunction requires functional analysis demonstrating failure to perform essential endothelial functions (most typically vasodilation and hemostasis), or by demonstration of abnormal gene expression.

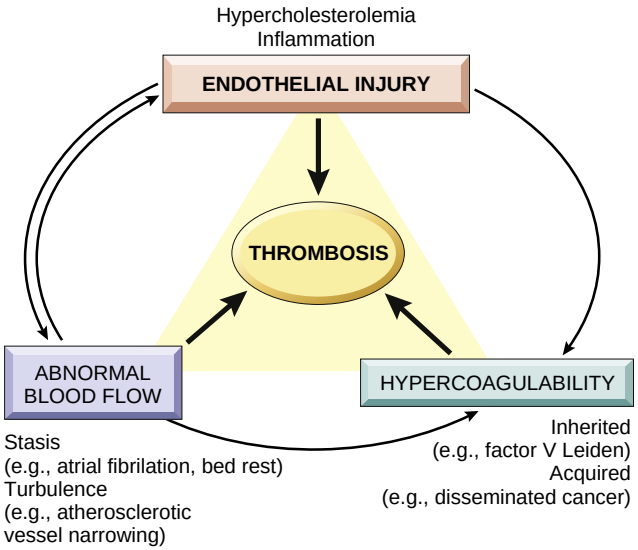
Importantly, vascular injury (whether endothelial denudation, where cells are lost from the luminal surface, or endothelial dysfunction with otherwise structurally intact cells) can stimulate SMC growth by disrupting the physiologic balance between inhibition and stimulation. This process occurs in many adult arteries, and is associated with ongoing mild vascular damage such as turbulent flow, systemic hypertension, and diabetes. Following minor vessel injury, reconstitution of the damaged vascular wall includes the formation of a neointima in which SMCs (1) migrate from the media to the intima, (2) multiply as intimal SMCs, and (3) synthesize and deposit ECM (Fig. 2.5.2B.4), causing intimal thickening. An exaggerated healing response leads to intimal hyperplasia, which, when excessive, can cause stenosis or occlusion of small and medium-sized blood vessels or grafts. Such processes contribute to clinically significant vascular pathology, as in atherosclerosis, in the coronary arteries of heart transplants, and at the junction of a vascular prosthetic graft with the natural vessel to which it is attached.

Thrombosis

Thrombosis is intravascular clot formation. Current thinking considers that the propensity to thrombosis depends on a complex interaction of three key factors, which comprise "Virchow's triad" (Fig. 2.5.2B.5): (1) the nature of the vascular luminal surface (healthy endothelium vs. endothelial injury vs. synthetic biomaterial, with or without attached biological material), (2) the quality of blood flow (laminar vs. turbulent vs. static), and (3) blood coagulation status



• **Figure 2.5.2B.4** Intimal hyperplasia following vascular injury. Smooth muscle cells (SMCs) reconstitute the damaged vascular wall by (1) migrating from the media to the intima, (2) multiplying as intimal SMCs, and (3) synthesizing and depositing extracellular matrix (ECM). The new intimal cells are shown in a different color to emphasize that they have a proliferative, synthetic, and noncontractile phenotype, distinct from medial smooth muscle cells. (Reproduced from Mitchell, R., 2015. Blood vessels. In: Kumar, V., Abbas, A., Aster, J. (Eds.), Robbins and Cotran Pathologic Basis of Disease, ninth ed. Elsevier.)



• **Figure 2.5.2B.5** Virchow's triad. The interactions of endothelial injury, abnormal blood flow, and systemic hypercoagulability in thrombus formation. (Reproduced from Kumar, V., Abbas, A., Aster, J., 2015. Hemodynamic disorders, thromboembolic disease, and shock. In: Kumar, V., Abbas, A., Aster, J. (Eds.), Robbins and Cotran Pathologic Basis of Disease, ninth ed. Elsevier.)

(normal vs. hypercoagulable vs. anticoagulated). Of note, vascular biomaterials are variably thrombogenic due to surface properties, and may alter the quality of local blow flow. These features are of less concern in large grafts (see below), such as in the aorta, where the surface thrombogenicity of the graft may be mitigated by brisk flow. However, in smaller grafts, where the anastomosis to the native circulation may promote turbulent flow, the smaller lumen is more susceptible to obstruction from thrombosis (hence patients with these devices being on long-term anticoagulation medications), and are more prone to obstruction of outflow (*run-off*).

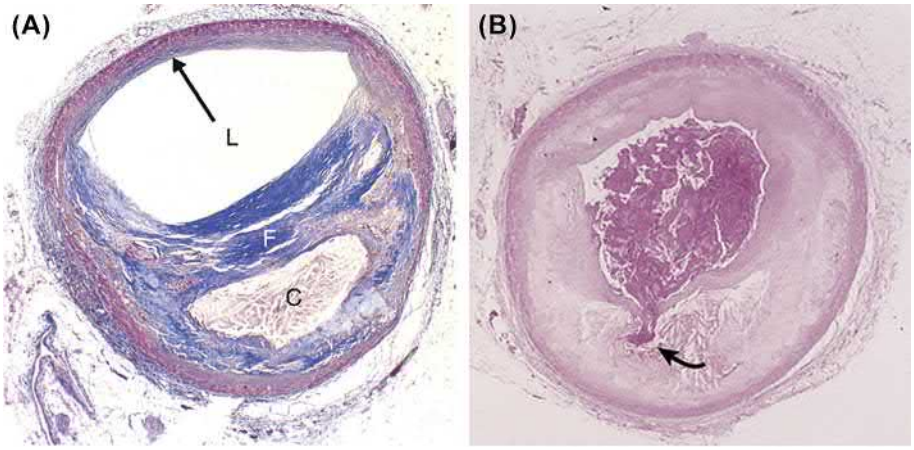
Atherosclerosis

Atherosclerosis, the most common clinically significant vascular pathology, begins in and preferentially affects the intimal layer of arteries. Atherosclerotic lesions (called *plaques*) protrude into and obstruct vascular lumens and/or weaken the underlying media to cause aneurysmal dilation, and/or thrombosis, and/or embolism (Fig. 2.5.2B.6). The early lesions of atherosclerosis comprise a thickening of the intima associated with subendothelial intimal accumulation of lipids; endothelial dysregulation of thrombosis, inflammation, vascular tone, and other functions; and inflammation, a process facilitating additional intimal thickening (Geovanini and Libby, 2018). As the plaque progresses in thickness, or if a thrombus forms, most often due to acute plaque rupture into the lumen or erosion of the overlying endothelium, downstream tissues may receive inadequate oxygen supply (*ischemia*). Ischemia of substantial degree and/or duration may result in *infarction*, i.e., ischemic death, of downstream tissue.

Atherosclerotic plaques develop primarily in elastic arteries (e.g., aorta, carotid, and iliac arteries) and large and medium-sized muscular arteries (e.g., coronary, renal, and popliteal arteries). As such, common clinically relevant sites include the heart (causing coronary artery disease, associated with myocardial infarction or "heart attack"), brain (causing cerebrovascular disease, associated with cerebral infarction or "stroke"), aorta (causing abdominal aortic aneurysm, creating a risk of rupture), kidneys (often resulting in systemic hypertension due to hormonal feedback), and lower extremities (causing peripheral vascular disease).

Aneurysms and Dissections

Aneurysms and dissection are illustrated schematically in Fig. 2.5.2B.7. An aneurysm is an abnormal dilation of a blood vessel that can promote abnormal blood flow and thrombosis. When an aneurysm is bounded by all arterial



•**Figure 2.5.2B.6** Atherosclerotic plaque in the coronary artery. (A) Overall architecture demonstrating a fibrous cap (F) and a central lipid core (C) The lumen (L) has been moderately narrowed. Note the plaque-free segment of the wall (*arrow*). In this section, collagen has been stained blue (Masson trichrome stain). • **Figure 2.5.2B.7** Patterns of vessel wall weakening. (A) Normal vessel. (B) and (C) Types of true aneurysm, where the wall bulges outward and may be attenuated but is otherwise intact. (D) False aneurysm, where the wall is ruptured, and there is a collection of blood (hematoma) that is bounded externally by adherent extravascular tissues. (E) Dissection, where blood has entered (dissected) the media of the vessel wall; although this is shown as occurring through a tear in the lumen, dissections can also occur by rupture of the vessels of the vasa vasorum within the media. (Reproduced from Mitchell, R., 2015. Blood vessels. In: Kumar, V., Abbas, A., Aster, J. (Eds.), Robbins and Cotran Pathologic Basis of Disease, ninth ed. Elsevier.)

wall components on all sides it is called a true aneurysm. In contrast, a false aneurysm (also called *pseudoaneurysm*) is a breach in the vascular wall leading to an extravascular *hematoma* (i.e., collection of blood) that communicates with the intravascular space ("pulsating hematoma") but is contained within the extravascular tissue. This is in subtle contrast to *rupture*, where the blood continues to flow outside of the vessel wall into adjacent tissue.

A *dissection* occurs when blood enters the wall of the artery with the formation of a blood-filled channel within the artery wall, called a *false lumen*, a space where the blood remains under pressure but does not usually contribute to downstream circulation. Dissections are frequently initiated by an intimal tear providing passage to the media. Dissections can also rupture.

Aneurysms and dissections typically have the greatest clinical impact when they involve the aorta. Aortic aneurysms result in about 175,000 deaths a year globally (GBD 2013 Mortality and Causes of Death Collaborators, 2015). Aortic dissections affect an estimated 2.0–3.5 people per every 100,000 every year, with incidence possibly rising (Olsson et al., 2006). Although aortic dissections are more common in men, dissections in women can occur during pregnancy (Wanga et al., 2016) and sometimes thereafter.

Atherosclerotic aneurysms occur most frequently in the abdominal aorta (*abdominal aortic aneurysm*, often abbreviated to AAA). The most important clinical consequence of an AAA is rupture, causing hemorrhage into the abdomen caused by aneurysm. The risk of rupture is directly related to the size of the aneurysm, varying from zero for a small AAA

(less than approximately 4 cm in diameter), to 33% per year for those larger than 7 cm (Sakalihasan et al., 2018). The treatment of abdominal and thoracic aortic aneurysms has been largely open surgery with a tubular textile graft. Treatment is evolving toward endoluminal approaches using stent grafts (see below) for many patients.

In contrast, aneurysms in the ascending/thoracic aorta and in many visceral sites are associated with hereditary predisposition to wall weakening through aberrant extracellular matrix metabolism or smooth muscle cell dysfunction, such as in Marfan syndrome (affecting up to 1 in 5000 individuals; National Organization for Rare Disorders, 2017), Loeys-Dietz syndrome, Ehlers-Danlos syndrome, or other forms of fibromuscular dysplasia. Ascending aortic aneurysms are also associated with bicuspid aortic valve, vascular inflammation (*vasculitis*), and prior surgery. Treatment again largely relies on surgical repair, frequently involving placement of a textile graft.

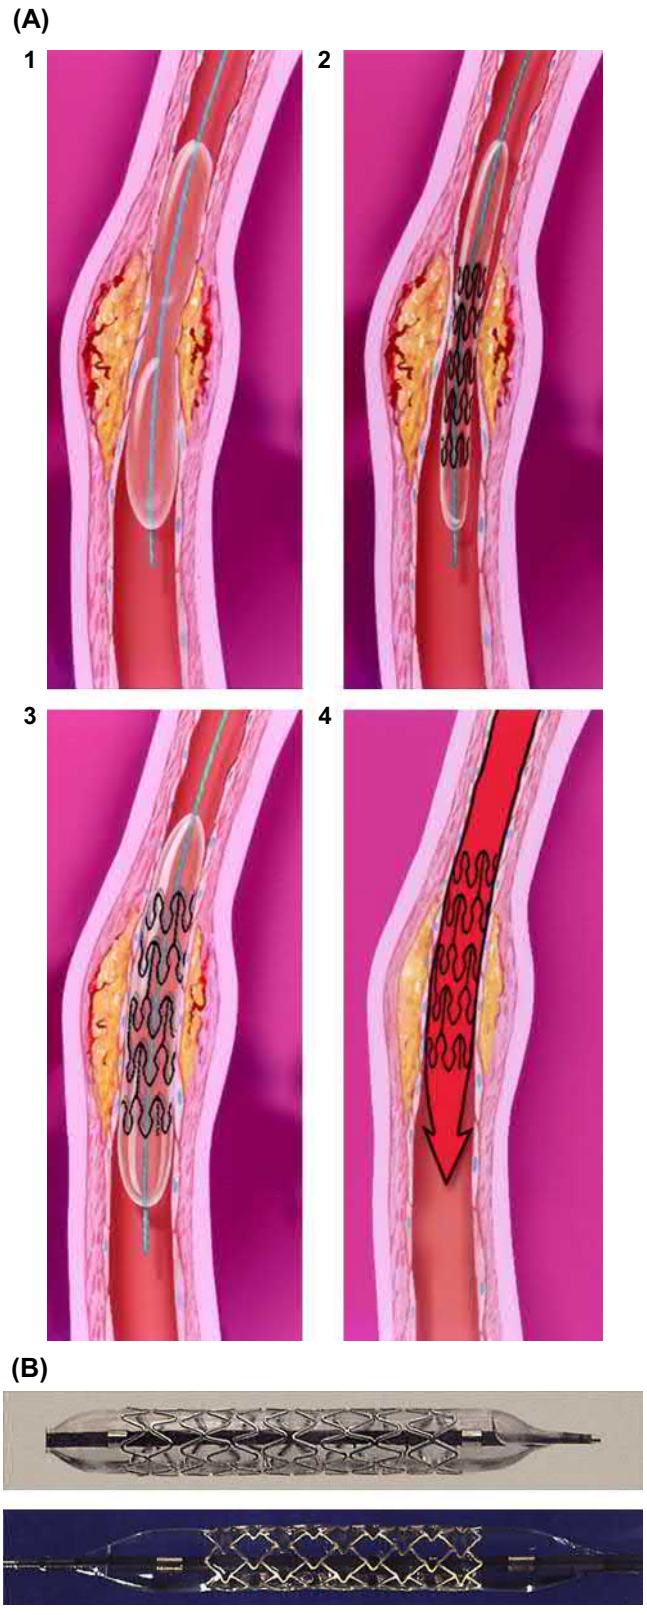
Vascular Devices and Biomaterials

To address the pathologies discussed above, a number of devices and biomaterials have been developed to restore a state that approximates normal. Many of these have focused on coronary artery disease, given the significant epidemiologic burden, but uses in other vessels are expanding rapidly.

Angioplasty and Endovascular Stents

Percutaneous transluminal coronary angioplasty (PTCA) and endovascular stents are used to restore blood flow through a diseased portion of the coronary circulation in patients with acute (typically due to thrombus) or chronic (typically due to progressive atherosclerosis) occlusion causing *stable angina* (chest pain due to cardiac ischemia occurring during exercise and resolving at rest), *unstable angina* (similar chest pain but also occurring at rest), or acute myocardial infarction (heart attack) (see Fig. 2.5.2B.8A). In PTCA, a procedure developed and implemented first by Andreas Grüntzig in the 1970s (Grüntzig and Hopff, 1974; Barton et al., 2014), a long catheter is passed retrograde from within the femoral artery up the aorta to the openings of the coronary arteries that arise from the aorta immediately distal to the aortic valve cusps. Using radio-opaque dye and fluoroscopy, areas of stenosis can be identified (called a coronary catheterization, or "cath," study). A deflated balloon is passed over a guidewire to a site of stenosis, where the balloon is inflated using progressive and substantial expansile force (~10 atm). PTCA-induced enlargement of the lumen and increased blood flow occurs by plaque reduction via compression, embolization, or redistribution of the plaque contents and by overall mechanical expansion of the vessel wall (Virmani et al., 1994).

In a minority of patients, short-term failure of this procedure (i.e., closure of the treated vessel within hours to days) occurs via one or more of several mechanisms, including



• **Figure 2.5.2B.8** Catheter-based interventions for opening occluded coronary arteries. (A) Balloon angioplasty and endovascular stenting: (1) percutaneous transluminal coronary angioplasty (PTCA); (2) stent placement at a site of prior PTCA; (3) balloon-mediated expansion of the stent; (4), balloon deflated and removed. (B) Metallic stents on expanded balloons. ((A) Reproduced by permission from Michaels, A. D. and Chatterjee, K. (2002). Cardiology patient pages. JAMA 284, 1828–1836.)

elastic recoil of the vessel wall stretched by the balloon, thrombosis at the site of angioplasty, and acute dissection (i.e., blood within the vessel wall itself) at the site of angioplasty. The major problem, however, is progressive, proliferative restenosis due to intimal hyperplasia, which occurs in 30%–40% of patients, most frequently within the first 4–6 months (Haudenschild, 1993).

In current practice, virtually all patients undergoing PTCA also receive a stent, an expandable tube of metallic mesh that splints open the vessel wall (Fig. 2.5.2B.8). Stents have been used in patients since the late 1980s. Stents preserve luminal patency by limiting elastic recoil and mechanically preventing vascular spasm. They provide a scaffold to support the disrupted vascular wall and increase blood flow, thus minimizing thrombus formation and restenosis. Endoluminal stents also provide a means of delivering any localized therapy intended to reduce restenosis, such as a pharmacologic agent or radiation (Daemen et al., 2007a,b).

Available stents range from 2.5 to 6 mm in diameter and from 8 to 50 mm in length. Deployment of a stent involves circumferential expansion of the stent in apposition to the inside surface of the coronary artery. To accomplish this, the stent is positioned across a stenotic lesion, which has usually been predilated with a balloon, with the aid of coronary catheterization. The first coronary stents developed for clinical use were bare-metal stents (BMS), composed of 316L stainless steel, which required balloon expansion, or nitinol, an alloy of nickel and titanium that is self-expanding by virtue of its "shape memory" characteristics (i.e., the stent is compressed into the delivering catheter at room temperature, and then spontaneously recovers its original, undeformed, expanded stent shape upon removal of the delivery sheath at body temperature).

Development has focused on permitting stents to become more flexible and more easily delivered and deployed to a target site, allowing the treatment of a greater number and complexity of lesions. The choice of stent is based on several factors, including the characteristics of a given plaque, such as diameter, length, and location within the coronary anatomy, and the experience of the interventional cardiologist with a particular stent. The use of BMS demonstrated that the most important early complication of stenting is thrombosis, which occurs in 1%–3% of patients within 7–10 days of the procedure (Fig. 2.5.2B.9A). This complication has largely been overcome by aggressive multidrug treatment inhibiting platelet and soluble clotting factor function. In this context, the major long-term complication of bare-metal stenting is in-stent proliferative restenosis (Fig. 2.5.2B.9B), again a form of exaggerated tissue healing and intimal hyperplasia, which occurs in as many as 50% of patients within 6 months of receiving a BMS (Virmani and Farb, 1999).

Thus, the proliferative restenosis that frequently occurs after PTCA alone was found not to be prevented by stenting with BMS. With the goal of eliminating this intimal thickening, drug-eluting stents (DESs) were developed. The first generation of DESs were stents coated with a polymer containing either rapamycin (sirolimus) or paclitaxel. Rapamycin, a drug used for immunosuppression in solid organ transplant recipients, inhibits proliferation, migration, and growth of fibroblasts and smooth muscle cells, and blocks extracellular matrix synthesis. Along with its antiinflammatory properties, this drug targets the major mechanisms of restenosis. Paclitaxel, a drug used in the chemotherapeutic regimens for several types of cancer, also has similar anti-smooth muscle cell activities. These drugs are embedded in a polymer matrix (such as a copolymer of poly-n-butyl methacrylate and polyethylene-vinyl acetate or a gelatin-chondroitin sulfate coacervate film) that is coated onto the stent. The drug is released by diffusion and/or polymer degradation over varying periods of time that can be engineered by the specifics of the polymer–drug system. Drug-eluting stents have virtually eliminated restenosis over time periods of 2 years and longer, and represent a major breakthrough in the treatment of coronary artery disease. Although early DES had a problem with late thrombotic

stenosis, newer generations of stents use thinner struts and improved polymers to significantly decrease this risk of thrombosis, while reducing the need for long-term anticoagulant medications (Torii et al., 2020). Also being investigated is the use of drug-eluting balloons in combination with bare metal stents to combine the advantages of both strategies (Richelsen et al., 2016).

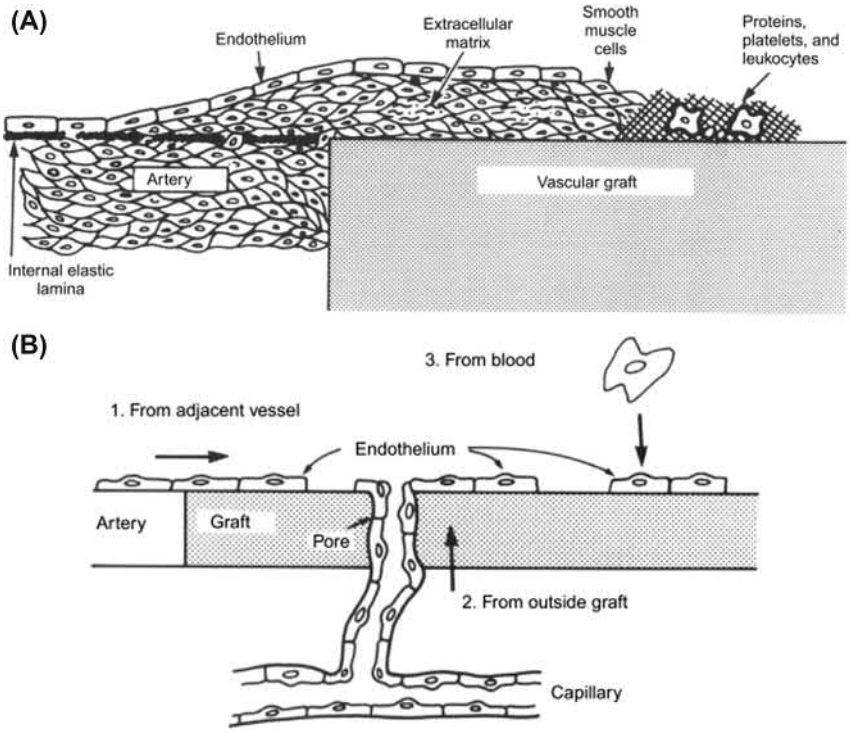
Another development is resorbable/biodegradable stents (RBSs; Hytönen et al., 2018; Lee and de la Torre Hernandez, 2018). In contrast to the permanent presence of a foreign body in BMSs and DESs, RBSs provide a scaffold to support vessel expansion and then ultimately disappear by resorption of the foreign material that may potentiate a thrombotic event. RBS designs may also incorporate the controlled release of antiproliferative agents. The eventual disappearance of RBSs obviates interference of the device on noninvasive radiologic diagnostic imaging such as cardiac magnetic resonance imaging (MRI) and computed tomography (CT). Since RBSs may potentially mitigate the problems of late thrombosis, vessel distortion, and interference with surgical coronary arterial revascularization, they have been the subject of extensive research and development efforts in recent years. Clinical trials and even regulatory approval have occurred with both degradable polymeric (e.g., poly-L-lactide) and metallic (Mg alloy) stents. One of the former stent systems (Abbott's Absorb bioresorbable vascular scaffold) has been removed from the market after regulatory approval due to low clinical adoption.

Stents are also used to manage stenosis in other arterial sites, such as the carotid artery, with many of the same principles (Morr, 2014). These approaches include use in large branch vessels of the aorta, such as the renal, celiac, and mesenteric arteries, as well as smaller vessels such as the femoral arteries in the legs. Over 1.8 million stents are placed annually in the United States alone, with over half of these being for coronary artery disease (iData Research, 2018).

Vascular Grafts

Vascular grafts provide new conduits to otherwise compromised components of the vasculature. The most important roles of such grafts are in aneurysm or dissection, particularly in the aorta; bypass of obstructed vessels, such as in the coronary or peripheral arteries; and to permit repetitive vascular access for hemodialysis. The clinical performance of a vascular graft depends primarily on its type, biomaterial, anatomic location, and diameter. In general, large-diameter (12–18 mm) synthetic fabric grafts currently used in high-flow, low-resistance locations such as the aorta, the iliac and proximal femoral arteries, and aorto-femoral bypass generally have good clinical outcomes, with 5–10-year patency rates of 90% (Clagett, 2002). In contrast, small-diameter synthetic vascular grafts (less than 6–8 mm in diameter) generally perform less well with 5-year patency less than 50%. Moreover, tissue grafts (especially autologous tissue) generally outperform synthetic grafts in small-diameter locations. The tissue graft most frequently used is a saphenous vein from the patient needing the bypass, which is surgically moved to the site needed to bypass blockages, for example, for coronary artery bypass grafting or in the extremities for femoropopliteal bypass grafting. Other natural vessels such as the internal mammary artery may be used to bypass some blockages in the coronary circulation (typically vessels <4 mm), with good results (approximately 90% patent at 10 years postoperatively).

Contemporary synthetic vascular grafts are typically fabricated from polyethylene terephthalate (PET; Dacron, DuPont), typical for larger grafts, or polytetrafluoroethylene (PTFE; Teflon, Chemours) or expanded polytetrafluoroethylene (ePTFE, Gore-Tex, Gore), typical for grafts <8 mm diameter (Fig. 2.5.2B.10). When being used to bypass a stenosis, the graft is sewn onto the native circulation proximally and distally to the blockage, creating a new branch "vessel" and providing an intact, alternate path for blood. In aneurysm and dissection, the graft is sewn proximally and distally to the pathologic segment on the inside of the vessel and passed endoluminally, limiting the flow of blood to a lumen approximating physiologic size. In the case of aneurysm, a large portion of the dilated space is now excluded from the blood flow, creating a space for hematoma, seroma, and/or infection outside the graft (see below). In the case of dissection, the graft ideally excludes further blood flow into the false lumen and/or supports the aortic wall at the site of the dissection, reducing pressure in the rupture-prone false lumen and again directing blood flow through a space approximating physiologic size. The excluded space in this event is primarily the false lumen, which will typically heal and form scar tissue in the original vessel wall. As many of these grafts are placed into large vessels such as the aorta, it is necessary to also ensure blood flow to multiple branch

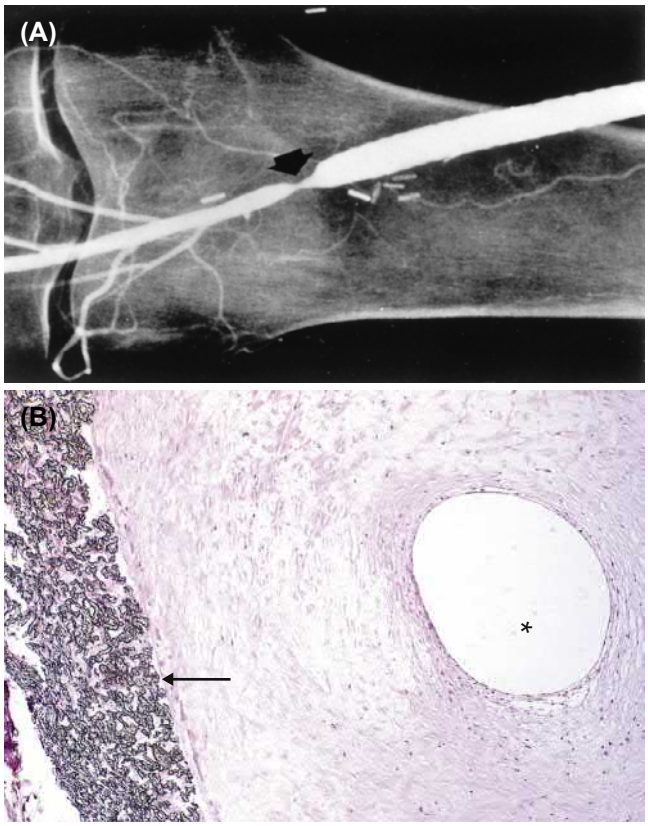


• **Figure 2.5.2B.11** Vascular graft incorporation. (A) Schematic diagram of pseudointima (platelet-fibrin aggregate, right) and neointima (smooth muscle cells and endothelial cells, left) formation at the site of anastomosis between a native artery and a graft. (B) Possible sources of endothelium on the blood-contacting surface of a microporous vascular graft. ((A) and (B) Reproduced by permission from Schoen, F.J., 1989. Interventional and Surgical Cardiovascular Pathology: Clinical Correlations and Basic Principles, WB Saunders; Philadelphia, PA.)

vessels. This is accomplished by sewing the branch vessels directly into the graft at appropriate anatomic locations, or by bridging these anastomoses with additional smaller grafts (Kuo and Han, 2017).

To ensure a high likelihood of clinical success and long-term patency, vascular grafts must have mechanical compliance consistent with that of the normal and diseased vessels to which they will be anastomosed, be resistant to thrombus to prevent occlusion, resistant to tissue overgrowth causing intimal hyperplasia (particularly at an anastomosis), have a sufficient level of suturability to facilitate placement, and be fatigue resistant (i.e., durable). When a synthetic graft is implanted and exposed to the blood, the luminal surface of the graft becomes coated with a film of plasma proteins and subsequent deposition of cellular elements and products of the coagulation cascade, as discussed in detail in other chapters of this book. With extended time in vivo, the deposition develops into a platelet-fibrin-rich layer termed a *pseudointima*. Over time, endothelial cells may coat this layer, serving as a nonthrombogenic surface, creating a *neointima* (Fig. 2.5.2B.11A). Humans have limited ability to endothelialize vascular grafts, however, with confluent endothelium covering only a 10–15 mm zone adjacent to the anastomosis in typical grafts, while the remainder of the graft will be covered only in pseudointima even after long-term implantation. A graft covered completely on its internal surface by endothelium is said to be "healed." Species differences in regenerative capacity to provide lumenal tissue coverage of vascular grafts have also been identified, something that is of high importance for the selection of appropriate animal models (Zilla et al., 2007).

One method to address lack of extensive neointima formation within most of the graft has been to create fabric grafts that have sufficient transwall porosity to foster entry of endothelial cells from surrounding small vessels in external tissues of the recipient into the entirety of the lumen (Fig. 2.5.2B.11B). To prevent early hemorrhage through these pores, however, highly porous grafts may be impregnated during fabrication with connective tissue proteins to aid clotting, or are precoated with the patient's own blood prior to implantation. However, many clinical vascular grafts are impervious in order to obviate hemorrhage (for example, the widely used ePTFE grafts typically have a limited porosity that is insufficient to permit cellular ingrowth). Thus, direct endothelial seeding of vascular grafts has been used, with some success, and there is considerable current interest in designing grafts that can best utilize the potential of circulating endothelial cell precursors to cover grafts, but this has not yet been realized (Zhang et al., 2014). Another approach is vascular tissue engineering, where ex vivo sources of cells are being explored to seed or entirely construct vascular grafts, or a porous absorbable polymer graft is implanted with the intent that endogenous (recipient) cells would replace the polymer by layered vascular structural



• **Figure 2.5.2B.12** Anastomotic intimal hyperplasia of a synthetic graft. (A) Angiogram demonstrating constriction (*arrow*). Whittemore, Brigham and Women's Hospital, Boston, MA.)

elements (Pashneh-Tala, 2016; Wissing, 2017; Song, 2018; Stowell and Wang, 2018).

The tissue reaction to synthetic vascular grafts may include the formation of exuberant fibrous tissue in the lumen of the anastomotic site as an overactive physiologic repair response (Fig. 2.5.2B.12). This reaction, called *intimal hyperplasia*, occurs in clinical and experimental vascular grafts, especially those less than 8 mm in diameter. Intimal hyperplasia results primarily from smooth muscle cell migration, proliferation, and extracellular matrix elaboration following and possibly mediated by acute or ongoing endothelial cell injury. Contributing factors include: (1) surface thrombogenesis, (2) delayed or incomplete endothelialization of the fabric, (3) disturbed flow across the anastomosis, and (4) mechanical factors (i.e., compliance mismatch) at the junction of implant and host tissues. Intimal hyperplasia tends to develop predominantly at or near anastomoses, particularly at the distal site in both synthetic and tissue vascular prostheses. In tissue grafts, intimal hyperplasia is often diffuse, leading to progressive luminal reduction of the entire graft.

An implanted graft becomes encapsulated in the surrounding connective tissue and elicits a typical foreign body reaction, which consists of a layer of foreign body inflammation containing giant cells adjacent to the material, covered by collagen, fibroblasts, blood vessels, and other cellular and extracellular connective tissue elements. This response can be exuberant, resulting in scar tissue extending into and possibly disrupting surrounding structures, inflammation eroding into surrounding structures or a space being created that can become filled with blood (hematoma) or fluid (seroma). A similar healing response can also be seen in the space excluded from an aneurysm during repair (see above), which again can develop hematoma and/or seroma. Both hematomas and seromas create sites predisposed to infection.

Prophylactic perioperative systemic antibiotics limit infection of implanted vascular prostheses generally to 6% of patients or less, and grafts are sometimes impregnated with antibiotics to further prevent infection. Early infections are typically related to contamination that occurs during the surgical procedure itself or to perioperative complications such as wound infection. Late infections usually occur secondary to seeding from the blood of the synthetic material in patients with low-grade bacteremia, often secondary to dental or gastrointestinal procedures. Since the anastomotic suture line is usually involved, an infected vascular graft may have a partially disrupted connection to the natural artery; thus, rupture with hemorrhage at the graft site may bring the patient to clinical attention. Surgical removal of an infected graft is usually necessary to address a graft infection.

Progressive deterioration of a synthetic vascular graft can cause mechanical disruption at the anastomotic site or within the body of the prosthesis leading to aneurysm formation or the formation of an external collection of blood due to rupture (called a false aneurysm; see Fig. 2.5.2B.7). The incidence of long-term graft deterioration is small but unknown. Delayed failure is associated with chemical, thermal, or mechanical damage to polymeric yarn materials during manufacture, fabric defects induced during manufacture (e.g., dropped stitches) or during insertion (even "atraumatic" vascular clamps can damage yarn fibers), and potentially postoperative biodegradation of graft material.

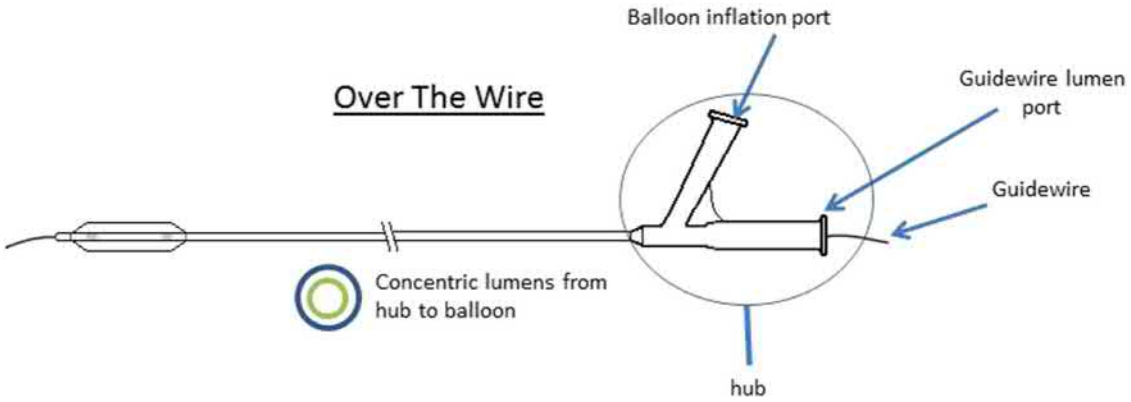
Worthy of a separate mention, grafts are also used in hemodialysis, which helps maintain a majority of patients with end-stage renal disease. This requires repeated access to the patient's circulation (Scott and Glickman, 2007; Lee and Misra, 2016). In the United States alone, an estimated 468,000 patients were on dialysis in 2016 (National Institute of Diabetes and Digestive and Kidney Diseases, 2016). The major approaches to repetitive vascular access are the biological arteriovenous fistula (AVF) or the synthetic arteriovenous graft (AVG). Owing to high rates of AVF maturation failure and recurrent stenosis of AVGs (owing to thrombosis, intimal hyperplasia, or infection), as well as the paucity of effective therapies for these two major problems, vascular access dysfunction remains a major cause of morbidity and mortality in hemodialysis patients, often resulting in subsequent surgery to repair the site. Hemodialysis is also discussed in Chapters 2.5.3 and 2.6.6.

• **Figure 2.5.2B.13** Stent grafts. (E) Original courtesy of Jagdish Butany, MD, University of Toronto.)

Endovascular Stent-Grafts

Mortality rates of abdominal aortic aneurysm surgery vary from less than 10% for nonruptured aneurysms and up to 80% for leaking or ruptured aneurysms. This high mortality led to the development of less invasive methods for treatment of aortic aneurysms and other aortic abnormalities, especially for patients who are not good candidates for conventional open surgery. Endovascular aneurysm repair (EVAR) performed through percutaneous vascular access can provide effective and durable repair, improved morbidity and mortality relative to open surgical correction, and reduced hospital costs, particularly for intact aneurysms (Patel, 2016). Originally developed for treatment of abdominal aortic aneurysms, EVAR has been extended to thoracic endovascular aortic graft repair.

EVAR uses an endovascular device, often called a stent-graft, which consists of a metallic stent covered by a cloth sleeve that resembles a vascular graft (Fig. 2.5.2B.13). These stent-grafts are generally constructed of a stainless steel or nitinol frame covered by polyester or ePTFE, either on the luminal or abluminal (outside) aspect of the metallic stent. Stent grafts are deployed endovascularly either as self-expanding units or over an inflatable balloon. The stent used for a given application is selected by the diameter, length, and geometry of the lesion and location of side



• **Figure 2.5.2B.14** Over-the-wire balloon catheter structure. The guide wire passes through the center of the catheter lumen, and the balloon is passed over the wire, still within the catheter lumen. (Image adapted from https://commons.wikimedia.org/wiki/File:OTW_Vs._Rx.jpg.)

braches or branch points. These stents hold the graft in place via tension against the vessel wall and/or by metallic hooks that become embedded into the vessel wall, removing the requirement for sutures. The fabric provides a mechanical barrier to prevent intravascular pressure from being transmitted to the weakened wall of the aneurysm, thus excluding the aneurysm from the flow of blood, just as with surgically implanted grafts. Stent-grafts may be straight, typically with both ends anchored to the aorta; bifurcated, with the proximal end typically attached to the aorta and the graft limbs fastened to the iliac arteries; or branched in more complex fashion using carefully placed fenestrations and iterative placement of stent-grafts (Kuo and Han, 2017; Pearce et al., 2017; Lindström et al., 2019).

Although EVAR has been a significant advance in aneurysm management for some patients, complications continue to occur and EVAR technology development is ongoing (Belvroy, 2018). Complications related to the device include (1) thrombosis; (2) obstruction owing to device twisting, kinking, or oversizing; (3) infection; (4) graft dilation or structural failure with tear or fracture; (5) device migration or change in alignment; (6) erosion of the graft into/through the arterial wall; and/or (7) aneurysm expansion or rupture. These complications may be further associated with *endoleak*, the persistence of blood flow outside the lumen of the endoluminal graft but within the aneurysm sac. This may result from an incomplete "seal" between the endograft and the wall of the aorta, inadequate connection between components of modular prostheses (i.e., failed prosthesis-to-prosthesis anastomosis), fabric defects or porosity, or retrograde blood flow from patent aortic sidebranches. This may further promote aneurysm enlargement, graft damage, and graft migration. Many of these can warrant immediate or delayed conversion to an open surgical repair, with the further risks and complications of that procedure.

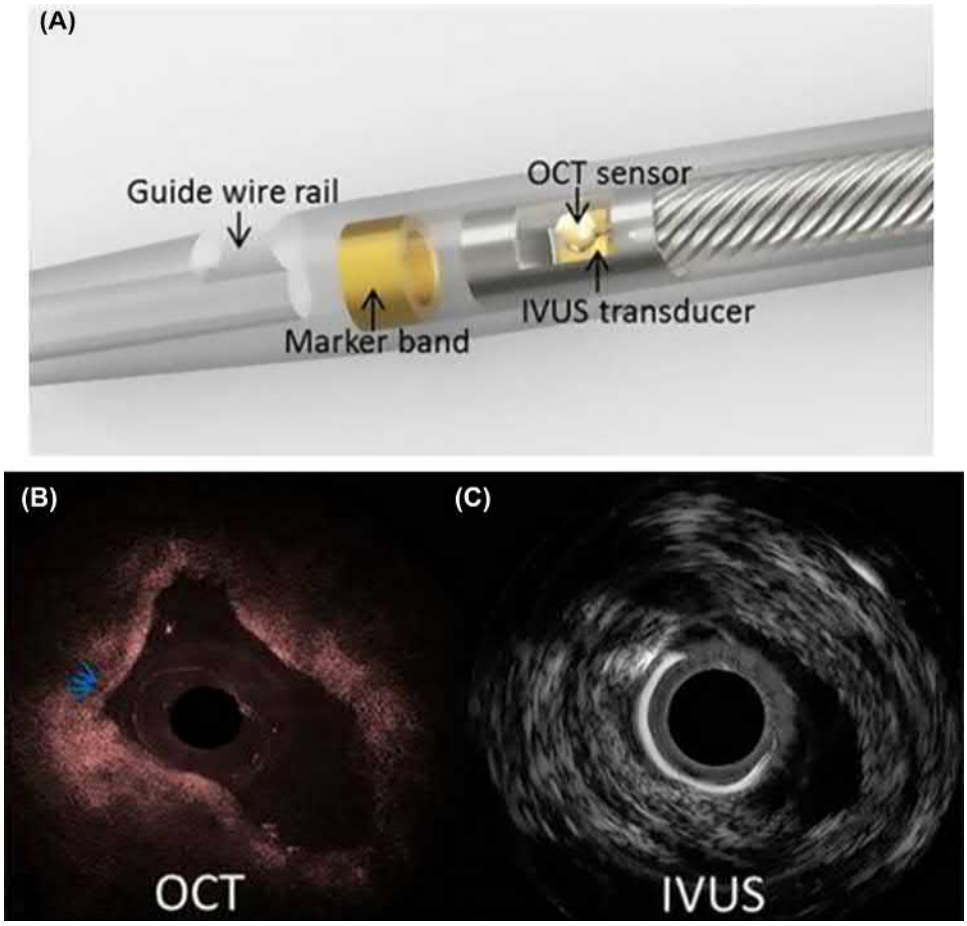
Other Vascular Devices

Endovascular Catheters

Perhaps the most ubiquitous vascular medical device, catheters, mentioned numerous times above and in other chapters, are tubes of various types, in this context specifically for communicating with the vascular space. As such, they are small-diameter, typically flexible devices, generally made of polymers, most commonly polyurethanes or silicone. They are often passed through an outer sheath to facilitate entry into the vasculature, and are typically guided by a steerable wire, or *guide wire*, passed through the catheter lumen (Fig. 2.5.2B.14). As needed, this guide wire can be removed while leaving the catheter in place. The inner lumen, where the guide wire is or was, can be used to deliver varying materials, such as nutritional or metabolic (e.g., salt) support, medications (such as agents to promote thrombus regression or vascular dilation), other medical substances, or additional devices. These catheters are typically left in the body for only a very short duration (minutes to days), except in critically ill patients in whom central venous lines may be indwelling for longer duration. The major complication in such patients is catheter-based infection (Bell, 2017).

Diagnostic Catheters

Catheters may be used in combination with sensors as diagnostic devices, such as to measure blood pressure, temperature, or oxygenation of sites not directly accessible by ex vivo devices. Catheters can also be used to deliver radiocontrast agents to facilitate improved visualization of vascular structures; as vessel wall thickness is typically below the resolution of ex vivo imaging techniques, these contrast agents facilitate detailed imaging of the vessel lumen. Common techniques include fluoroscopy (a continuous real-time X-ray-based technique), computed tomography (CT, an X-ray technique to visualize in three dimensions), or magnetic resonance imaging (MRI, a radiofrequency technique also used to image in three dimensions). When specifically applied to vessels, terminology for these techniques is often adapted to use the term angiography, such as with CT angiography (CTA) or magnetic resonance angiography (MRA). These techniques allow for vessel lumens to be assessed for absence of flow into expected regions (e.g., occlusions or narrowing of vessel lumens) as well as to identify blood passage into inappropriate sites,



• **Figure 2.5.2B.15** Combined optical coherence tomography (OCT)/intravascular ultrasound (IVUS) catheter. (A) Magnified view of the catheter probe. (B) OCT image generated from the device. (C) IVUS image generated from the device. (Reproduced by permission from Li, J., et al., 2015. Ultrafast optical-ultrasonic system and miniaturized catheter for imaging and characterizing atherosclerotic plaques in vivo. Sci. Rep., 18406.)

such as extravascular space. These techniques are the basis for diagnostic coronary catheterization, cerebrovascular imaging, and other diagnostic procedures. Although more often administered peripherally, radioactive tracers can also be delivered in a similar manner.

Coronary imaging has started routine use of more advanced intravascular imaging, where the imaging device itself is passed through the catheter (Fig. 2.5.2B.15), but these are also starting to see use in other vascular beds. As blood itself is opaque to visible light, preventing direct visualization of vessel walls, the two most common techniques that have emerged are intravascular ultrasound (IVUS) and optical coherence tomography (OCT). In IVUS, the catheter is adapted to have an ultrasound probe on the tip that is designed to provide circumferential radial imaging. This allows ultrasonic assessment of the vessel wall that, as the catheter is passed through the course of the vessel, can be used to construct a three-dimensional image of a short vascular segment. The depth of penetration of the IVUS image is up to 200 μm into the vessel wall, albeit with relatively low resolution. In contrast, OCT catheters are infrared light-based probes, including both source and sensor, typically based through the catheter lumen. These only have penetration of up to 20 μm, and thus typically only capture one side of the vessel wall, but provide higher resolution imaging (with adaptations, called micro-OCT, being developed with cellular level resolution). Combined IVUS-OCT devices exist to facilitate combined imaging.

Therapeutic Catheters

Therapeutically, catheters can be used, as mentioned above, to deliver medical therapies systemically or locally. In fact, intravenous access sites are, in effect, simply short catheters. Similarly, "central lines" are catheters designed to deliver medications to the large vessel circulation rather than peripherally. Hemodialysis catheters, absent fistula or graft sites (described above), are paired catheters, inserted at a single, typically large-vessel site that includes one port to remove blood from the patient to the dialysis machine, and one catheter to return the filtered blood. Catheters can also be used to aspirate thrombus from obstructed vessels.

Some medical devices have been specifically developed to provide intravascular therapy in combination with catheters. One of the simplest types of these is inflatable

balloons, as described above, often constructed of polyethylene terephthalate (PET) or nylon. Devices have also been designed to remove atherosclerotic plaque (*atherectomy*) without surgical intervention (Figs. 2.5.2B.16A; Chambers et al., 2016). *Directional atherectomy* uses a device that is repeatedly passed over the plaque to scrape away material. *Rotational atherectomy* uses a rotational device (often over 100,000 rpm) to bore through plaque, which, while requiring fewer passes of the catheter to obtain a larger end lumen diameter, does result in small fragments of plaque that may cause clinically relevant downstream embolism and occlusion. Similar risk exists with *ultrasonic atherectomy* using ultrasonic waves instead of mechanical force. *Transluminal atherectomy* modifies the rotational technique using a smaller bore and lower speed rotational device (approximately 2000 rpm) associated with suction to retrieve the resulting plaque fragments. *Laser atherectomy* uses a laser (typically 355 nm) to burn away plaque, resulting in less embolization risk.

Transcatheter lasers have also been employed to burn away fibrous adhesions between other intravascular devices and the vessel wall. One of the most common applications of this technique is when electrophysiology leads become adherent to the superior vena cava but require extraction. The laser is used to carefully burn away the pathologic fibrous tissue, but this does carry a risk of perforating the vessel wall. A similar tissue dissolution process may be used for destroying other pathologic tissues sites, for example in ablating foci of aberrant electrical activity (i.e., arrhythmia) in the heart atria.

Endovascular Coils

One catheter-delivered strategy that warrants special mention is the use of metallic coils and related devices used to ablate small vascular spaces, typically small aneurysms (such as so-called *berry aneurysms* of the cerebrovascular circulation) or inappropriate vascular connections (e.g., patent ductus arteriosus) (Jia, 2018; Agrawal, 2019). As an alternative to open surgical obliteration of the structures, these metallic coils (radio-opaque for visualization and often made from platinum) are specifically intended to induce a clotting reaction, with the thrombus that forms occluding the space. Over time, this thrombus will organize and form durable fibrous tissue to close off the space. There are also similar techniques combining metal and fabric components. Of note, coiling can be utilized to occlude blood vessels serving tumors (typically benign ones), resulting in a way to specifically infarct the pathologic tissue, potentially negating the need to remove the lesion surgically.

Vascular Filters

Venous thromboembolic disease is a significant cause of morbidity and mortality, largely due to the potential complication of pulmonary embolism (PE). The most common scenario is for a thrombus to form in the deep venous system of the lower extremities (so-called deep venous thrombus, DVT), become detached from the wall of the vein, travel through the inferior vena cava to the right side of the heart and lodge as an embolus in one of the large branches of the pulmonary artery. Therapy for patients with DVT or PE usually involves anticoagulation with warfarin and/or low-molecular-weight heparin. However, when anticoagulation is contraindicated due to active or threatened bleeding, or when there is recurrent DVT/PE despite adequate anticoagulation, placement of an inferior vena cava (IVC) filter is indicated.

Prior to the development of these devices, surgical ligation of the IVC during an open abdominal operation was performed. Following a period when filters were placed surgically, interventional radiologists began to place filters using a minimally invasive percutaneous approach in the 1980s. There are five types of filters commonly used in current clinical practice whose common design elements include metallic wires in a configuration to catch emboli in the bloodstream, a mechanism to anchor the device securely to the wall of the IVC and an ability to be deployed through a catheter

percutaneously (Fig. 2.5.2B.17). These devices are made variably from titanium, stainless steel, nitinol, and other metal alloys (Ha and Rectenwald, 2018). Complications of these devices include thrombosis at the insertion site, thrombi forming on the filter itself, thrombosis and obstruction of the IVC, migration or tilting of the device, and penetration of the IVC wall. Many of these complications are rare and/or without clinical consequence. As these devices have become safer and more effective, the indications for their use have expanded. Current research involves creating devices with a lower profile to make insertion easier and reduce insertion site thrombosis, designing removable devices and continuing to evolve the devices with the goal of catching potentially lethal emboli while maintaining adequate vena caval blood flow (Magnowski, 2017; Kaufman, 2018).

A similar concept is used in catheter-based interventions where there is a likelihood of creating embolic particles, such as cerebral emboli with transcatheter valve technologies (Nombela-Franco, 2018). In these settings, a cage-like device is deployed through the catheter to a position distal to the treatment site, facilitating capture of the most clinically relevant emboli.

Vascular Closure Devices (VCDs)

The very nature of nonsurgical vascular interventions necessitates that a vascular wall has been punctured to pass the device into the circulation. In small entries, particularly in the low-pressure venous circulation, these will close and heal without further medical intervention, although possibly associated with a small hematoma that typically resolves. Larger interventions require at a minimum that pressure and bandaging be applied to ensure proper closure of the vessel site. In the case of access to a large artery by a large-bore device, such as with many of these transcatheter technologies described above, surgical ligation had been the standard of care. However, percutaneous VCD, typically utilizing the same catheter as the original intervention, has been developed to close the defect at the end of the intervention (Bechara et al., 2010; van Wiechen et al., 2019).

A number of strategies for these VCDs have been developed. Devices such as Prostar XL and ProGlide (Abbott Vascular) utilize precise suturing methods. Others utilize titanium or nitinol clips or discs, such as the StarClose (Abbott Vascular), Angiolink EVS (Medtronic), and Boomerang (Cordiva). A third strategy is the use of biological collagen plugs to seal the access site, such as with the MANTA (Essential Medical) and the Angio-Seal (St. Jude Medical). The InSeal VCD (InSeal Medical) membrane-based device consists of a nitinol frame, a biodegradable patch, and a polyglycolic acid (PGA) tether. The PerQseal (Vivasure Medical) D consists of a bioresorbable patch and scaffold.

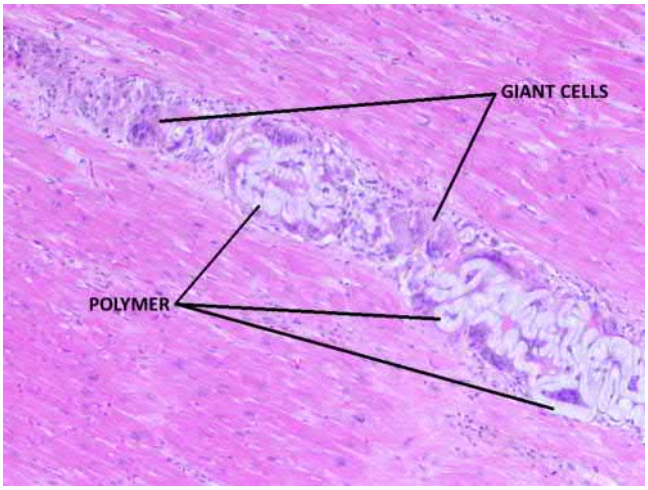
Unintended Embolic Biomaterials

One additional complication of virtually all endovascular procedures is the possibility for small fragments of foreign material to break off the device and travel through the vasculature. Although metallic devices are rarely associated with such failures, degeneration of other materials, particularly plastics, has been described to have such long-term complications. Furthermore, catheter delivery systems rely on the use of polymer lubricants such as compounds including polyethylene glycol, hydroxyethyl cellulose, and hydroxypropyl methylcellulose, to ensure smooth passage of the various components, and these gel-like substances are emerging as a source of embolic material found throughout the systemic vasculature (Fig. 2.5.2B.18; Chopra et al., 2017). At this time, the clinical significance of these emboli is uncertain, but ongoing research is evaluating the relative risk as several cases have been correlated with ischemic events.

• **Figure 2.5.2B.17** Vena cava filter with clot.

Ex Vivo Evaluation

To facilitate quality assurance, quality control, and quality improvement, any vascular device that is recovered must be



• **Figure 2.5.2B.18** Intravascular foreign material (pale blue) in the heart of a patient that received an intravascular procedure, consistent with hydrophilic polymer emboli (HPE). There is an associated foreign-body inflammatory reaction characterized by multinucleated giant cells.

evaluated properly. Removal might be encountered in the context of device explant (typically removed due to mechanical failure or infection), organ or large-tissue resections containing the device (for example, heart explant at the time of transplantation), or autopsy. In fact, quality control of this type and device retrieval is one of the most compelling arguments for performance of a medical autopsy. Relevant findings may be primary mechanical device failure, overgrowth of tissue onto the device surface restricting function (pannus), occlusive thrombosis, dehiscence (detachment of the device from the biologic substrate), and infection.

The evaluation of these devices upon recovery requires cooperation between individuals with expertise both in the tissue biology and evaluation, such as pathologists, as well as individuals that are expert in the appropriate engineering principles, most notably biomedical engineers. This facilitates a precise understanding of the intrinsic human pathology, the device functioning after being exposed to the human environment, and the events stimulated by the interaction of the device with the human. Proper evaluation is best facilitated by a combination of ex vivo imaging of the device and tissue (e.g., device X-ray, CT, or MRI), expert dissection, and device functional evaluation. Some of the techniques used by pathologists for this evaluation include electroelution of stents (Bradshaw et al., 2009), plastic embedding and diamond cutting of tissue with the device in site, novel imaging techniques (many of which are also being applied in vivo, such as microprobe ultrasound and OCT), and devices such as borescopes to visualize the internal aspects of devices and vascular lumens.

Conclusions

The core principles evident in this chapter for developing endovascular biomaterials are maintenance of the vascular integrity, prevention of thrombus and excessive tissue healing, and resistance to device-centered infection. Future advances will focus on improving these features in existing applications, and will almost certainly see new devices for solving additional biological challenges, focusing on the same principles.

Extracorporeal Artificial Organs and Therapeutic Devices

REI UKITA[1], ALASTAIR CAMPBELL RITCHIE[2], ANGELA LAI[1], KEITH E. COOK[1]

[1]Department of Biomedical Engineering, Carnegie Mellon University, Pittsburgh, PA, United States

[2]Department of Mechanical, Materials and Manufacturing Engineering, University of Nottingham, Nottingham, United Kingdom

Introduction

Artificial lungs and kidneys are commonly used for short-term support during either acute organ failure or chronic organ dysfunction. When using both devices, blood is pumped from major blood vessels, through the artificial organ and back to the patient. For efficient mass transfer, both artificial lungs and kidneys utilize densely packed bundles of hollow fibers to transfer nutrients to and wastes from blood. As a result, both feature a high degree of blood–biomaterial interaction, protein adsorption, cellular adhesion, and activation of inflammation and coagulation. On the other hand, artificial lungs and kidneys transfer different substances and have different periods of use, and thus use different base materials for mass transfer and different approaches to reducing activation of coagulation and inflammation. Artificial lungs are expected to act continuously for several days to months at a time, while artificial kidneys are typically used for less than 6 h. As such, blood–biomaterial interactions in artificial lungs are sustained, and the biomaterials requirements are more stringent. Thus, the area of extracorporeal respiratory support has been a more fertile ground for device and biomaterials innovation recently.

Extracorporeal Respiratory Support

Pulmonary Disease—Incidence, Causes, and Mortality

More than 190,000 people in the United States suffer from adult respiratory distress syndrome (ARDS) each year (Matthay and Zemans, 2011). Typical causes of ARDS are sepsis, pneumonia, aspiration of gastric contents, and major trauma (Rubenfeld et al., 2005). These diverse causes all lead to damage to the alveolar capillary membrane, typically through a neutrophil-mediated inflammatory reaction, causing increased pulmonary vascular permeability and leakage of proteinaceous exudate into the alveoli. This fluid leakage leads to increased diffusional resistance between alveolar gas and capillary blood, increased alveolar surface tension, alveolar collapse, and ultimately reduced oxygen and carbon dioxide transfer in the lungs. Most clinicians in this setting try to overcome the gas transfer deficit by increasing inspired oxygen fractions and alveolar recruitment with increased tidal volumes and airway pressures. Despite short-term gains in gas exchange, these ventilator settings can further damage the lung over the long run, worsening long-term gas exchange, systemic inflammation, and thus increasing mortality. For these reasons, low tidal volumes (<6 mL/kg) and low airway pressures (<30 cm H_2O) are desired. While these settings have decreased ARDS mortality rates to around 30%–40% (ARDS Network et al., 2000; Li et al., 2011), sufficient gas exchange may not be possible for patients with severe ARDS without support via artificial lungs.

Over 12 million Americans also suffer from chronic lung diseases such as chronic obstructive pulmonary disease (COPD), cystic fibrosis (CF), and interstitial lung disease (ILD) (American Lung Association 2008). Patients with COPD, CF, and ILD all experience a gradual decline in respiratory function over a period of years coupled with acute exacerbations that lead to a transient, but dangerous, worsening of dyspnea, hypoxia, and hypercapnia (Hyzy et al., 2007), hospitalization within the ICU, and death. In the United States, there are over 6.9 million emergency room visits (CDC, 2014), 700,000 hospital discharges per year and approximately 180,000 deaths. Lung transplantation is the only restorative treatment for these patients, but there are only approximately 2300 transplants in the United States

each year (Valapour et al., 2018). As a result, the vast majority of these patients will suffer for years with life-threatening exacerbations and will never receive a lung transplant.

Chronic lung disease patients undergoing acute exacerbations receive oxygen therapy in a form of noninvasive or invasive ventilation. Noninvasive ventilation (NIV) uses a facemask, positive pressure, and elevated inspiratory oxygen fractions to improve lung ventilation and gas exchange. If NIV cannot provide sufficient gas exchange, invasive mechanical ventilation with endotracheal (ET) intubation is required. Like ARDS, however, invasive ventilation is associated with many serious health risks, including ventilator-induced lung injury, lower respiratory tract infection, and diaphragmatic atrophy (Powers et al., 2002). As a result, prolonged duration of mechanical ventilation is also associated with higher hospital mortality (Loss et al., 2015), and it is not well-suited for long-term support.

Extracorporeal Membrane Oxygenation (ECMO)

Due to the insufficient, often harmful nature of prolonged mechanical ventilation, extracorporeal membrane oxygenation (ECMO) was developed. The goal of ECMO is to supply the majority of a patient's oxygen requirements and remove nearly all of their carbon dioxide (CO_2) production using a blood-processing extracorporeal circuit. This should allow patients with respiratory dysfunction to be supported on either gentle mechanical ventilation, noninvasive ventilation, or better yet, normal respiration.

During routine ECMO, cannulas are inserted into two major blood vessels for blood drainage and blood reinfusion. Venous blood is then pumped from the body, through the ECMO circuit, and then back to the patient at flow rates typically ranging from 60 to 100 mL/kg/min for adults. Typical ECMO circuits consist of drainage and reinfusion cannulas, the oxygenator, a pump, medical-grade Tygon tubing (S-50-HL), and polycarbonate connectors to connect everything together (Fig. 2.5.3.1). Modern circuits typically employ a centrifugal pump with a spinning, plastic, impeller to drive blood flow. However, roller pumps can still be used. In these devices, the circuit tubing is placed within the pump raceway, where rollers compress the tubing to peristaltically drive blood flow.

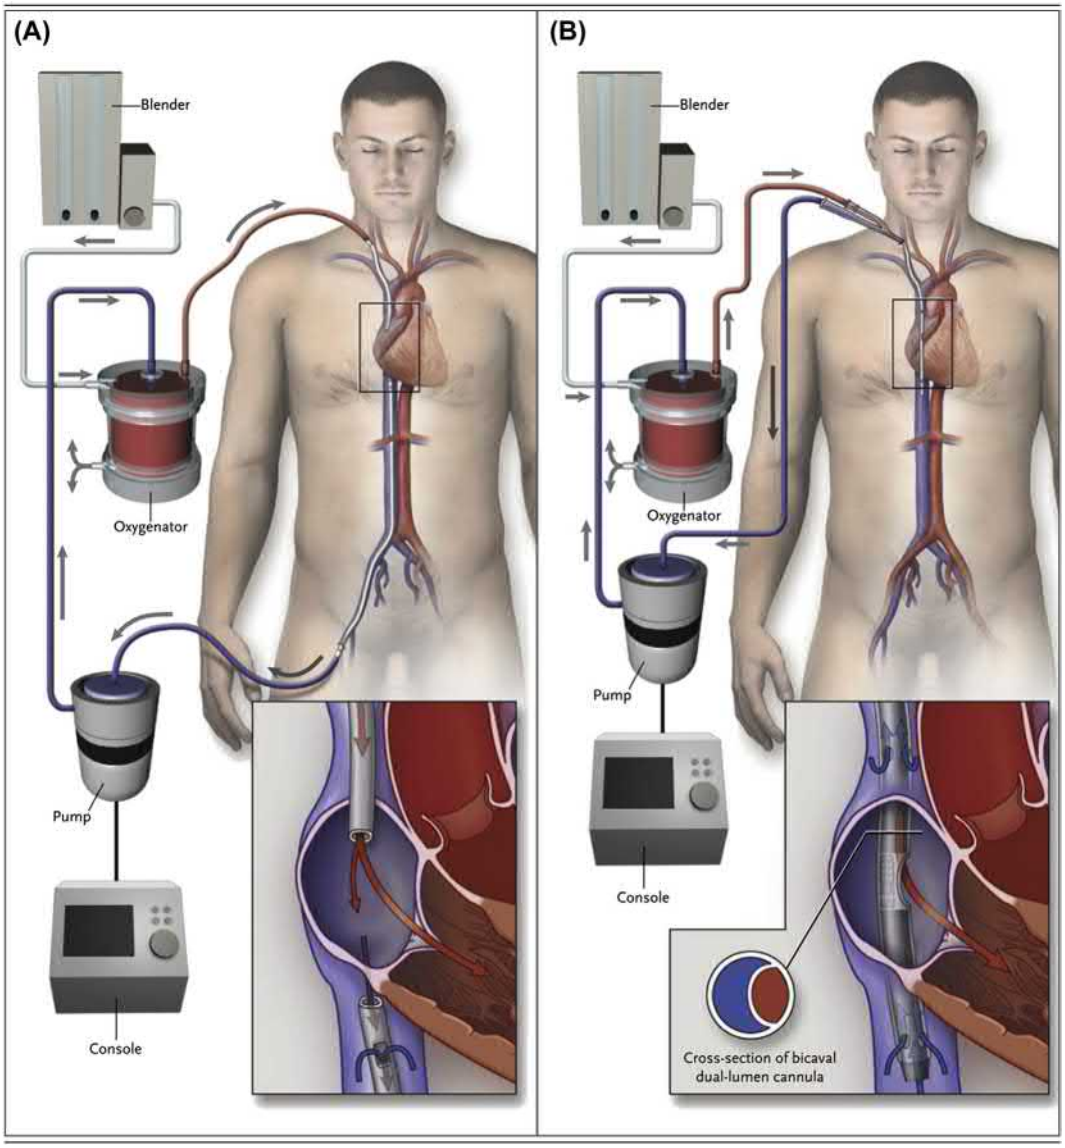
ECMO gas exchangers are typically called oxygenators. However, these devices are also highly efficient at transferring CO_2 and would more accurately be called artificial lungs. Early ECMO oxygenators utilized flat sheets of silicone rubber as the gas transfer membranes, but modern oxygenators all utilize bundles of polymethylpentene (PMP) hollow fibers (Fig. 2.5.3.2). These fibers have micropores throughout the fiber wall for excellent gas diffusion, and a 1–2 μm, solid outer skin to eliminate any leakage of plasma through the fiber wall. All current devices employ 380 μm outer diameter (OD) fibers that are woven together in gauzy fiber mats using multiple strands of polyethylene terephthalate (PET) filaments. Fiber mats are then wound around cores into fiber bundles and fixed within polycarbonate housings using polyurethane potting material. Typical fiber bundle surface areas are around 1.8 m^2 for adult oxygenators, representing over 90% of the total blood-contacting surface area of the ECMO circuit. Other fiber materials, such as solid PDMS or PDMS-coated porous polypropylene have been tested but have been largely used in experimental devices.

The most common ECMO attachment modes are veno-venous (VV) and veno-arterial (VA). During veno-venous ECMO, blood is drained from a large vein and returned to another large vein (Fig. 2.5.3.1). The drainage cannula is typically inserted in the jugular vein and down into the larger vena cava near the right atrium for easier blood drainage. In an earlier era of ECMO, during which patients were sedated and bed-bound, femoral vessels were frequently used for drainage and reinfusion. During more modern, ambulatory ECMO, a single, dual-lumen catheter is typically used to drain blood from the inferior and superior vena cava and reinfuse it directly into the right atrium. This keeps drainage away from the femoral vessels and allows for greater patient mobility. Veno-arterial ECMO also drains blood from the vena cava but returns oxygenated blood to a large artery, typically the carotid artery. By pumping blood around the heart and into the arterial system, VA ECMO thus provides both respiratory and cardiac support. However, pumping blood into the high-pressure arterial system requires higher pump speeds, leading to greater blood shear stress, red blood cell damage, and platelet activation, and a greater risk of bleeding from the arterial cannulation site (Lukito et al., 2016). It is thus utilized only in patients who require cardiac support.

Regardless of support mode or system, ECMO patients must be supported in the intensive care unit. This is due primarily to the respiratory deficits of the patients. However, once appropriate respiratory support is established, continuing biocompatibility issues such as systemic inflammation, bleeding and thrombotic complications, and multiorgan dysfunction continue to plague the patient requiring continuous, close care and monitoring (see Oxygenator Biocompatibility Challenges: Coagulation and Inflammation).

AMBULATORY ECMO

During its initial application, all ECMO patients were sedated and bed-bound. However, it has been recognized that patients recover more effectively if they can be mobilized, and unique dual-lumen cannulas have been invented that allow veno-venous ECMO via the jugular vein. This eliminates femoral cannulation that can interfere with walking. Now, ambulatory ECMO is being applied when possible to allow patients to walk while being supported during ECMO, particularly when ECMO is used as a bridge to lung transplantation (Lehr et al., 2015; Garcia et al., 2010). The circuits utilized during ambulatory ECMO are still cumbersome, however, and there is a trend toward creating more compact ECMO systems that allow patients to walk. Additionally, circuits are now being attached via vascular grafts during VA ECMO for greater safety when long-term support is envisioned. Further refinements, including better biomaterials, may allow these patients to leave the ICU altogether.



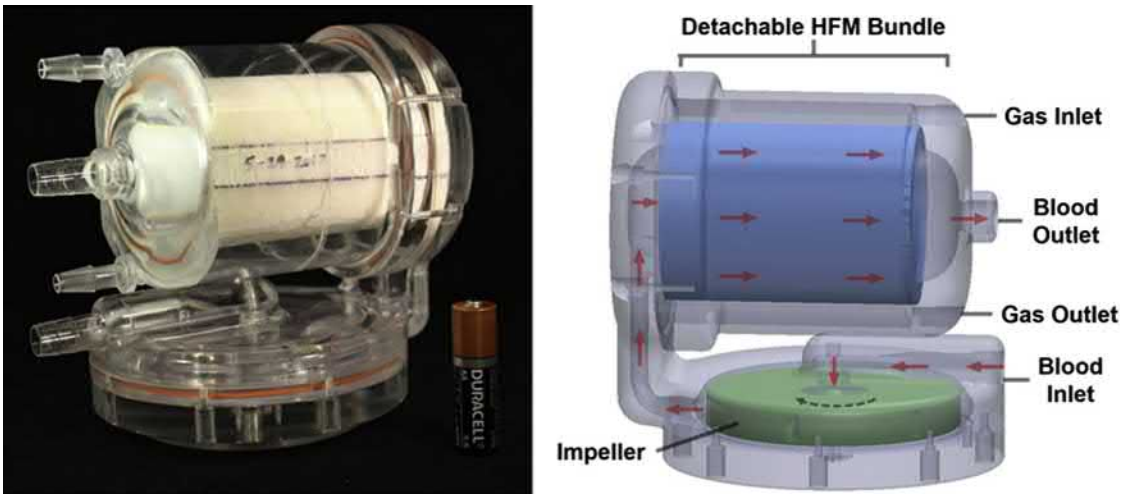
• **Figure 2.5.3.1** Venovenous (VV) extracorporeal membrane oxygenation (ECMO) using either (A) jugular and femoral access or (B) a single dual-lumen cannula. (Reproduced from Brodie D, Bacchetta M. 2011. Extracorporeal Membrane Oxygenation for ARDS in Adults. N. Engl. J. Med. 365, 1905–1914.)

Alternative Extracorporeal Gas Exchange Devices

Although ECMO is the mainstay for clinical respiratory support, a number of other devices are currently under development to support patients with acute or chronic lung disease. These devices offer different means of generating blood flow or gas exchange, leading to specific advantages such as smaller circuits and greater mobility, less blood damage and activation, simpler deployment, or better unloading of the right ventricle.

The desire to allow patients to live more normally while on ECMO, including ambulation, has motivated the development of various combined pump-lung systems (Fig. 2.5.3.3). Circuit modifications may be as simple as closely connecting the pump, pump console, and oxygenator to reduce circuit volume, as in the clinical Maquet

• **Figure 2.5.3.2** Artificial lung fiber bundle prior to incorporation into a full device.



• **Figure 2.5.3.3** ModELAS pump-lung, showing the full device as well as the blood flow paths in the gas exchanger and pump.

Quadrox system, or actually combining the pump impeller and the oxygenator fibers within one housing, as with the University of Maryland (Wu et al., 2012b; Wei et al., 2016) and University of Pittsburgh pump-lungs (Madhani et al., 2017c). In either case, these systems are smaller and lighter than traditional ECMO systems and thus offer greater portability.

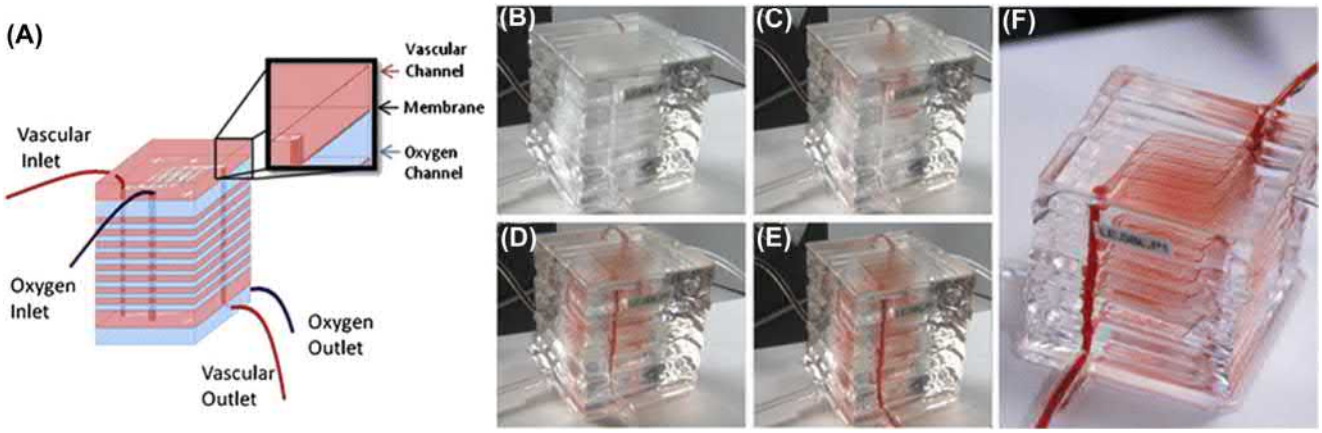
Extracorporeal carbon dioxide removal, or $ECCO_2R$, also attempts to reduce circuit size and complexity by focusing support solely on CO_2 removal. $ECCO_2R$ can be performed using a smaller membrane oxygenator and blood flow rates of 0.5–1.0 L/min because CO_2 is 20 times more blood-soluble than O_2 and thus far easier to transfer. $ECCO_2R$ is ideal in situations where CO_2 transfer is the primary problem, such as acute exacerbations of COPD. Because of the lower blood flow requirement, the device can even be attached without a pump in an arteriovenous configuration. Novalung's interventional lung assist (iLA) device is the only commercial device specifically designed for this purpose and is used clinically during arteriovenous carbon dioxide removal ($AVCO_2R$) via femoral artery and femoral vein cannulation (Zimmermann et al., 2009). A pumped, veno-venous $ECCO_2R$ system, Alung Technology's Hemolung Respiratory Assist System, has also been developed and is currently undergoing clinical trials. This ultralow-flow system is frequently referred to as "respiratory dialysis."

Thoracic artificial lungs (TALs) are also under development as either a bridge to lung transplantation or as permanent respiratory support for patients with chronic lung disease (Fig. 2.5.3.4) (Schewe et al., 2012a; Skoog et al., 2017). TALs attach to the pulmonary circulation, with blood flow coming from the proximal pulmonary artery (PA) and returning to the left atrium. The right ventricle (RV) drives blood flow through the TAL, and thus no mechanical pump is necessary. As a result, like $AVCO_2R$, the TAL circuit is compact. In addition to providing respiratory support, the TAL can eliminate

• **Figure 2.5.3.4** Compliant thoracic artificial lung (cTAL). (Reproduced from Schewe RE, Khanafer KM, Arab A, Mitchell JA, Skoog DJ, Cook KE. 2012. Design and In Vitro Assessment of an Improved, Low-Resistance Compliant Thoracic Artificial Lung. ASAIO. J. 58, 583–589.)

pulmonary hypertension (PH) and improve RV function by creating a second, low-resistance pathway around the diseased natural lungs (Akay et al., 2010). However, to accomplish this, a TAL must be designed with a very low resistance, similar to that of a healthy natural lung. The low blood-flow resistance, low shear stresses, and the lack of a pump, heat exchanger, and reservoir cause a reduction in coagulation, inflammation, and damage to formed elements in blood as compared to ECMO (Cook and Mockros, 2002). Thus, unlike ECMO, no blood products need to be given during use (Skoog et al., 2017), and devices such as the MC3 Biolung and the compliant TAL (cTAL) caused no significant hematological, hemodynamic, or organ function deficits during 14–30 days of testing (Skoog et al., 2017).

Lastly, there are growing efforts to design oxygenators that utilize thin 20–200 μm-tall channel gas transfer membranes, known as microchannel lungs (Fig. 2.5.3.5) (Thompson et al., 2017; Shin et al., 2004; Potkay, 2014; Kovach et al., 2015; Hoganson et al., 2011, 2010; Burgess et al., 2009). These devices are fabricated with soft lithography using PDMS, which has high gas permeability. To increase gas exchange efficiency, these channels are thin, have short diffusional distances, and high surface area to blood volume ratios. Therefore, they have the

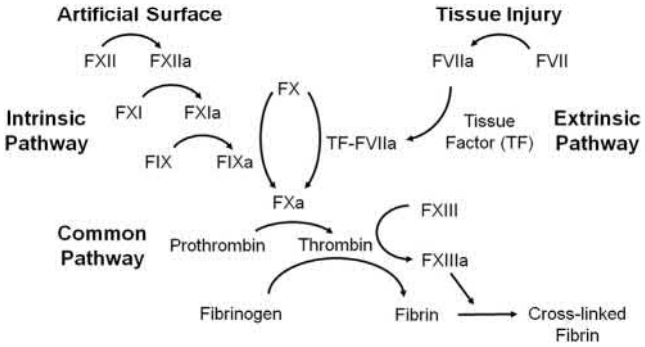


• **Figure 2.5.3.5** Microchannel artificial lung featuring multiple, interconnected layers of microchannel networks (A). Sequential images (B–F) demonstrate the blood entering the layers during priming. (Reproduced from Kniazeva T, Hsiao JC, Charest JL, Borenstein JT. 2011. A microfluidic respiratory assist device with high gas permeance for artificial lung applications. Biomed Microdevices 13, 315–323.)

potential to have higher gas exchange efficiencies than conventional hollow fiber devices and smaller device sizes. However, these small channels create new design challenges. First, blood flow must be distributed from a single, large feeder tube such as a vascular graft or cannula down to the small microchannels and back without numerous generations of branching channels, large amounts of additional device volume, or abrupt shifts in channel dimensions that lead to flow recirculation, accelerated clot formation, and increased blood flow resistance. Second, these devices have useful lifetimes of a few hours, using standard clinical anticoagulation protocols prior to occluding due to thrombus formation. The high surface area to volume ratio and small channel heights lead to rapid clot formation, as it only takes a small amount of clot to plug the entire channel. Thus, previous in vitro and in vivo whole-blood microchannel studies used higher levels of anticoagulation than ECMO (activated clotting time, ACT > 500 s) (Plegue et al., 2018; Kovach et al., 2015), and these devices will not be practical until less thrombogenic surfaces are developed. Current development focuses on using various surface coatings to reduce thrombosis (Kovach et al., 2015; Plegue et al., 2018). A possible solution to this issue may be the use of microchannel lungs constructed from biological tissue (Comber et al., 2019). These devices are endothelialized to reduce clot formation with their collagen-based structures promoting normal endothelial cell growth and function. Although promising, these devices will require several years of development to achieve full-scale designs suitable for preclinical testing.

Oxygenator Biocompatibility Challenges: Coagulation and Inflammation

All artificial lungs are composed of a variety of hydrophobic materials including polypropylene (PP), polymethylpentene (PMP), and polydimethylsiloxane (PDMS) gas exchange



• **Figure 2.5.3.6** Coagulation cascade demonstrating the intrinsic pathway, which is activated by artificial surface contact; the extrinsic pathway, which is activated by tissue factor; and the common coagulation pathway.

fibers, polyvinyl chloride (PVC) in tubing, polycarbonate housings, and polyurethane "potting" that separates the blood and gas space. The fiber bundle is the predominant site of clot formation in artificial lungs due to its large, densely packed surface area (Fig. 2.5.3.2). Coagulation and inflammation are initiated by protein adsorption onto their hydrophobic surfaces, changing protein conformations and exposing either binding or active sites that lead to further procoagulant reactions (Cook and Mockros, 2002). Adsorption of two proteins is predominantly responsible for clot formation. First, FXII adsorption to the biomaterial surface causes its activation to FXIIa, leading to activation of the intrinsic branch of the coagulation cascade (Fig. 2.5.3.6). This leads to generation of proinflammatory molecules via the kallikrein–kinin system and thrombin by the common coagulation pathway (Renne et al., 2012). Thrombin formation then causes conversion of fibrinogen to fibrin, thus forming the solid clot, and platelet activation, which accelerates the process. The second pathway causing clot formation is direct platelet binding to proteins adsorbed on the biomaterial surface. The predominant protein causing this is fibrinogen, which undergoes a conformational change upon

adsorption, allowing platelet binding via its GpIIb/IIIa ($\alpha_{IIb}\beta_3$ integrin) receptor. Platelet binding initiates activation, releasing numerous procoagulants and causing platelet aggregation and acceleration of clot formation(Cook and Mockros, 2002).

The gold standard for reducing clot formation in artificial lungs is continuous, intravenous (IV) infusion of unfractionated heparin. Heparin is a carbohydrate with molecular weights ranging from 3 to 30 kDa. Heparin is cleared from the systemic circulation by the kidney and has a half-life of 60–90 min, so it must be continuously administered during ECMO to maintain anticoagulation. When in plasma, heparin inhibits the common coagulation cascade (Fig. 2.5.3.6) by forming a complex with antithrombin III (ATIII) and inactivating Factor Xa (FXa) and thrombin. Thus, heparin inhibits coagulation initiated by both the intrinsic and extrinsic branches within the artificial lung and the patient, respectively, and serious bleeding issues can occur during ECMO even with careful anticoagulant management. These complications are further exacerbated by platelet and coagulation factor consumption by the artificial surfaces and pump.

In a study of pediatric ECMO, bleeding complications occurred in 33% of neonates and 45% of pediatric patients. Thrombotic complications occurred in 29% of neonates and 33% of pediatric patients(Dalton et al., 2015). As a result, bleeding and thrombosis complications were associated with a 40% and 33% decrease in survival, respectively. In another recent study (Mazzeffi et al., 2016), serious bleeding events occurred in 56.1% of adult patients, causing a 2.22 crude odds ratio for in-hospital mortality. Thus, both thrombosis and bleeding are significant risks during ECMO.

Alternative approaches to systemic anticoagulation have been examined in an attempt to reduce these complications. These include use of direct thrombin (Jyoti et al., 2014) and FX inhibitors (Weitz and Gross, 2012) and various types of platelet inhibitors, particularly aspirin (He et al., 2014; Staudacher et al., 2016; Esper et al., 2015). Like heparin, these inhibitors all inhibit coagulation at artificial surfaces and in the tissues, so their benefits to reducing bleeding and thrombotic complications are minimal. An anticoagulation approach gaining promise is to selectively inhibit the intrinsic pathway alone. The rationale is to focus on the upstream portion of the intrinsic branch while leaving the extrinsic branch unaffected to minimize bleeding complications. A complete lack of intrinsic branch activity is safe naturally; a genetic deficiency in plasma FXII or prekallikrein does not lead to an increase in spontaneous or injury-related bleeding in tissues (Renne et al., 2012; Schloesser et al., 1997). Therefore, a highly selective intrinsic branch inhibitor could significantly reduce clot formation at artificial surfaces while having little to no effect on clot formation within the patient's tissues. Moreover, an overdose of this inhibitor would not cause bleeding complications, and thus one could err on the high end of inhibition and reduce monitoring requirements. These inhibitors, therefore, might allow for safer and simpler management of anticoagulation.

This approach is not new (Wachtfogel et al., 1998). The challenge, however, has been finding an intrinsic branch inhibitor that is both potent and highly selective. This is a significant challenge, as FXIIa is a trypsin-like serine protease, and plasmin and most coagulation factors are also serine proteases. Thus, FXIIa inhibitors found in plants, insects, and bacteria also significantly inhibit trypsin, the extrinsic or common coagulation cascade, and plasmin. One synthetic, kallikrein inhibitor, nafamostat mesilate, has been tested during ECMO. However, a large, well-controlled study demonstrated that nafamostat has a bleeding complications rate that is significantly *greater* than that of heparin (Lim et al., 2016), presumably due to its concurrent inhibition of thrombin, plasmin, and ADP-induced platelet aggregation (Sundaram et al., 1996). Poor selectively has thus motivated the development of a new generation of synthetic, highly selective inhibitors. This includes RNA aptamers (Woodruff et al., 2013), FXIIa antibodies (Worm et al., 2015; Larsson et al., 2014), and bicyclic peptides (Middendorp et al., 2017; Zorzi et al., 2017). Their applications in artificial lungs have so far been at a preclinical stage but have shown promising results.

Blood contact with the artificial surfaces of artificial lungs also activates the immune system, leading to a "whole body inflammatory response." The predominant causes are surface-activated contact factors and complement fragments. Neutrophil and monocyte binding to adsorbed proteins on the extracorporeal circuit may also contribute to their activation. Studies of leukocyte activation during ECMO are quite limited, but they suggest significant inflammation during the first 24 h of extracorporeal circulation, at which point activation subsides (Fortenberry et al., 1996). This indicates that, while coagulation in artificial lungs is progressive, surface-induced inflammation subsides over time and is a lesser concern during use of artificial lungs.

NATURAL ORGAN VERSUS ARTIFICIAL ORGAN ANTICOAGULATION

The blood vessels in our bodies are all lined with endothelial cells that actively anticoagulate blood under normal conditions using multiple, cooperative means of anticoagulation that primarily act at the endothelial surface (van Hinsbergh, 2012). This includes a benign surface that does not activate the clotting cascade and multiple types of platelet and coagulation cascade inhibitors. Our historic approach with artificial organs, however, has typically featured large, systemic doses of the coagulation cascade inhibitor, heparin, creating patient-wide anticoagulation. This approach is changing, however, through the combined application of surfaces that both passively and actively inhibit local clot formation coupled with lower doses of systemic anticoagulants (Wu et al., 2007; Amoako et al., 2016).

Organs coated with endothelial cells have been examined as well, although maintaining cells on artificial surfaces for long periods poses significant challenges (Wiegmann et al., 2016; Pflaum et al., 2017; Polk et al., 2010).

Surface Coatings

Two general types of surface coatings have been designed with a primary goal of reducing artificial surface coagulation: surface immobilization of anticoagulant molecules and surfaces that repel nonspecific protein adsorption and ensuing activation of thrombosis. Table 2.5.3.1 outlines the specific types of commercial coatings and their polymeric compositions. In assessing the value of these coatings, one must be extremely careful to examine the conditions under which the testing occurs, including the substrate for the coating (an idealized surface versus hydrophobic polymers commonly used in artificial lungs), the geometric complexity of the test device (flat surface versus full artificial lung), the test media (single protein solution versus whole blood), the test setting (in vitro versus in vivo), and lastly the duration of testing.

We will focus our discussion of these coatings when they are applied to the densely packed, hydrophobic surfaces of full artificial lungs and exposed to whole blood. Together, this represents perhaps the most challenging setting for these coatings. If possible, we would prefer to discuss their use during long-term use of artificial lungs during ECMO, but there are few to no data in this setting. Thus, the majority of this discussion of coatings will focus on animal or clinical cardiopulmonary bypass (CPB). In analyzing these results, one must keep in mind that CPB only lasts on the order of hours and is a far more complex setting than ECMO, with several factors that confound the ability of the coating to reduce clotting and inflammation. These include significant soft- and hard-tissue trauma from the surgery itself, blood damage and activation by the pump, and the air–blood interface in an open-air blood reservoir. The effect of coating may, therefore, be too small compared to the extent of the other sources of blood activation during the procedure, and this could cause an underestimation of the true effect of the coating.

Heparin Coatings: Heparin coatings have the longest history as cardiovascular coatings and are most commonly used today. The initial rationale for surface heparin coating was to immobilize heparin for localized inhibition of FXa and thrombin. However, their long, flexible carbohydrate chains also exert a steric hindrance effect and repel protein adsorption (Weber et al., 2002; Amiji and Park, 1993), and this can be further enhanced by adding hydrophilic spacer groups, such as polyethylene oxide, between the surface and the heparin molecule (Amiji and Park, 1993; Byun et al., 1995).

Heparinized coatings were first applied using ionic attachment, but these bonds were found to be unstable, and these coatings leach heparin over long-term use (Noishiki and Miyata, 1985). Hence, covalent grafting supplanted this due to its higher stability. Heparin could either be attached at a single point (end-point) or at multiple points along the chain (multipoint), but end-point grafting has better bioactivity compared to the multipoint (Larsson et al., 1987) and is the more common method of heparin coating (Weber et al., 2002). Some of the notable examples of commercial coatings making use of end-point grafting are Carmeda BioActive Surface (CBAS) from Medtronic and Maquet's Bioline. CBAS consists of depolymerized, lower molecular weight heparin covalently grafted to surfaces by aminating the base matrix, which consists of positively charged polyethyleneimine and negatively charged dextran sulfate (Biran and Pond, 2017). Bioline coating is a combination of heparin and albumin with both ionic and covalent linkages to the surface.

Studies have shown that the Bioline and CBAS heparin coatings can reduce inflammatory responses during short-term artificial lung use, as occurs during CPB (Sohn et al., 2009). However, the ability of these coatings to reduce coagulation is likely poor, with studies indicating an inability to slow thrombin or fibrin formation. It is thus hypothesized that surface-bound heparin has a limited

TABLE 2.5.3.1 Commercial Oxygenator Coating Materials and Their Mechanisms

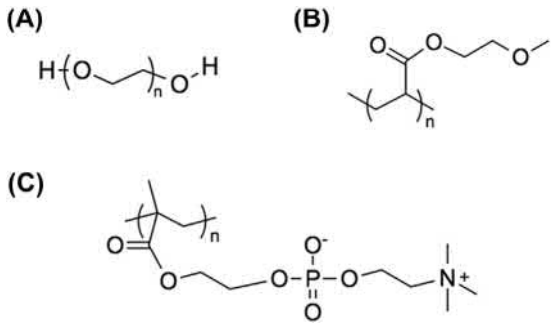
Polymer Type	Mechanism	Commercial Brand (Company)
Heparin	Inhibition of FXa and thrombin, antiadsorptive (Liu and Pedersen, 2007; Weber et al., 2002; Amiji and Park, 1993)	Carmeda Bioactive Surface (Medtronic), BIOLINE (Maquet), Duraflo II (Baxter), Trilium (Medtronic)
Albumin	Bioinert surface, antiadsorptive (Amiji and Park, 1993)	Safeline (Maquet), BIOLINE (Maquet)
Polyethylene glycol (PEG)	Hydration layer (hydrogen bonding) antiadsorptive (Jeon et al., 1991; Alcantar et al., 2000)	Trilium (Medtronic)
PMEA	Hydration layer (hydrogen bonding), antiadsorptive (Tanaka et al., 2000b, 2002; Chen et al., 2010)	X-coating (Terumo)
Phosphorylcholine	Hydration layer (electrostatics), antiadsorptive (Ishihara, 2000; Hatakeyama et al., 2010)	P.h.i.s.i.o. (Sorins), Agile (Eurosets)
Carboxybetaine & sulfobetaine	Hydration layer (electrostatics), antiadsorptive (Cao and Jiang, 2012)	None

bioavailability relative to its soluble counterpart and only provides mild benefit in reducing coagulation via inhibition of thrombin or FXa (Savannah et al., 2014). Rather, the efficacy of heparinized coating may be due to changes in protein adsorption and conformational changes (Weber et al., 2002).

Albumin Coatings: Albumin solutions have long been used to prime CPB and ECMO circuits in order to preadsorb relatively benign albumin, limit fibrinogen adsorption, and in theory, reduce thrombus formation (Mulvihill et al., 1990). After initiating blood flow through the circuit, however, IgG and fibrinogen will displace albumin and bind to the surface (Vroman and Adams, 1986). Thus surface passivation with albumin is only a short-lasting solution and not sufficient for long-term artificial lung use (Vroman and Adams, 1986). Different approaches have thus been taken to more stably anchor albumin using covalent grafting (Kasálková et al., 2014; Kamath and Park, 1994), irradiation (Kamath and Park, 1994; Sivaraman and Latour, 2010), and cross-linking (Amiji et al., 1992). Albumin has thus been incorporated into commercial coatings such as Safeline and, as discussed previously, Bioline. Safeline utilizes covalently attached human albumin, while Bioline contains both heparin and albumin in the coating. The effectiveness of Bioline was discussed previously, and studies comparing the two suggest they have similar, limited effectiveness (Zimmermann et al., 2007).

Polyethylene Glycol (PEG) Coatings: Polyethylene glycol (PEG), also referred to as polyethylene oxide (PEO), is commonly used as a biocompatible material in various biological applications including low-fouling coatings (Alcantar et al., 2000; Kovach et al., 2014; Ding et al., 2012), biomolecule stabilization (Roberts et al., 2002), and stealth particles (Jokerst et al., 2011). The polymer commonly is a linear polyether chain (Fig. 2.5.3.7). When there are about 10 or fewer repeat units, it is referred to as oligo-ethylene glycol (OEG).

The effects of PEG on reducing protein adsorption and platelet fouling have been demonstrated in vitro mainly by exposing surfaces to single-protein solutions or plasma (Alcantar et al., 2000; Ma et al., 2004; Prime and Whitesides, 1993). While these results were promising, the in vivo results have been mixed. Kidane et al. coated polyethylene, silicone rubber, and expanded polytetrafluoroethylene tube surfaces with triblock PEG copolymer coatings and exposed them to a fibrinogen solution and platelet-rich plasma in vitro (Kidane et al., 1999). The same coating that reduced fibrinogen by 70% in vitro did not significantly reduce platelet adhesion in an ex vivo canine shunt model. Similarly, plasma-deposited PEG on a fluorinated ethylene propylene surface reduced fibrinogen adsorption from a single protein solution to < 10 ng/cm^2, and yet the coated surface had more polymorphonuclear leukocyte adhesion relative to the uncoated control when exposed to whole blood or plasma (Shen et al., 2002). When the same coated materials were also implanted subcutaneously in rats, there were signs



• **Figure 2.5.3.7** (A) Polyethylene glycol (PEG), (B) 1,2-polymethoxyethyl acrylate (PMEA), and (C) 2-methacryloyloxyethyl phosphorylcholine (MPC).

of surface degradation after 1-day and 4-week implantation, and the authors suggested that the degradation was due to reactive oxygen species secreted by the leukocytes (Shen et al., 2002). Other studies have reported that PEG may not be stable for long-term in vivo applications, as discussed in other chapters in this book. PEG can be metabolized by the body and broken down into organic acids (Herold et al., 1989). Additionally, PEG can undergo oxidative degradation in the presence of oxygen or transition metal catalysts (Ulbricht et al., 2014).

The most well-known commercial PEG coating is Medtronic's Trillium, which combines PEG, heparin, and sulfonate groups. In short-term CPB settings, the coating has demonstrated anywhere from mild to no benefits compared to no coating. Trillium showed a similar benefit in preserving platelet counts as the heparin CBAS coating or albumin precoating via the prime (Palanzo et al., 1999, 2001). However, others have shown no difference in adhered platelets, leukocytes, or fibrin (van den Goor et al., 2006), or inflammatory response and blood loss compared to an uncoated control during CPB (Ereth et al., 2001). This may have been caused, in part, by the lack of coating in the rest of the circuit (Ereth et al., 2001; van den Goor et al., 2006). The reports on PEG's in vivo hemocompatibility in the setting of oxygenators are thus mixed, and there is clearly a discrepancy between its promising in vitro results and mixed in vivo results. The sum of these results suggest that this material is unlikely to be of significant benefit to long-term artificial lungs. There is, to date, no long-term study demonstrating a reduction in clot formation or inflammation.

1,2-Polymethoxyethyl Acrylate (PMEA) Coatings: PMEA consists of a hydrophobic alkyl carbon backbone with pendant hydrophilic groups (Fig. 2.5.3.7). It has primarily been explored as an antithrombogenic coating for cardiovascular devices, including membrane oxygenators, by the Terumo Corporation branded as Xcoating. The low-fouling property of PMEA is attributed to high bound water content near the surface that is stabilized by hydrogen bonds with the polymer chains (Tanaka et al., 2000a,b, 2002; Tanaka and Mochizuki, 2010).

In vitro blood circulation studies show that platelet adhesion, activation, and fibrin deposition were reduced

with PMEA coating compared to uncoated polypropylene (Gupta et al., 2014) and PVC surfaces (Yoshizaki et al., 2005). Several CPB studies concluded that PMEA coating offered benefits by preserving platelet count and reducing platelet activation and blood loss compared to its uncoated control (Zimmermann et al., 2004). On the other hand, there are contradictory results regarding PMEA's ability to reduce coagulation relative to heparin coatings during CPB or simulated CPB (Veysel et al., 2006), and a general trend toward similar or greater activation of complement and inflammation with PMEA (Veysel et al., 2006). Unfortunately, the limited number of studies and the variability in the type of heparin coating and test methods make these results difficult to interpret. Furthermore, the long-term benefit of PMEA coating are completely untested.

Phosphorylcholine Coatings: Current research on phospholipid-like coatings began with interesting observations about cell surfaces: their phospholipid composition was asymmetric across the membrane, such the inner membrane was largely made up of negatively charged species like phosphatidylserines and the outer part was made up of species like phosphatidylcholines that have a balanced, overall neutral charge (Zwaal et al., 1977). Furthermore, the charged inner layer was highly thrombogenic, whereas the outer, neutral layer was much more thromboresistant (Zwaal et al., 1977; Zwaal and Hemker, 1982). This led to the development of the phospholipid-like antithrombogenic coating known as phosphorylcholine (PC), characterized by the negative phosphate group and the positive ammonium group. The balanced positive and negative charges categorize PC as a zwitterionic polymer. Commonly, 2-methacryloyloxyethyl phosphorylcholine (MPC, Fig. 2.5.3.7) is used as the monomer for a coating (Wang et al., 2014; Tateishi et al., 2014). Poly-MPC chains consist of an acrylate backbone with PC branches. Because MPC is highly water-soluble, it is common practice to copolymerize it with a hydrophobic moiety, such as n-butyl methacrylate, for better adsorption to surfaces (Ishihara, 2000; Ishihara et al., 1992). Currently, the P.h.i.s.i.o. PC coating from Sorin is the only commercially available zwitterionic coating for oxygenators for CPB and ECMO in the United States. In Europe, EUROSETS.A.L.ONE from Italy is also commercially available.

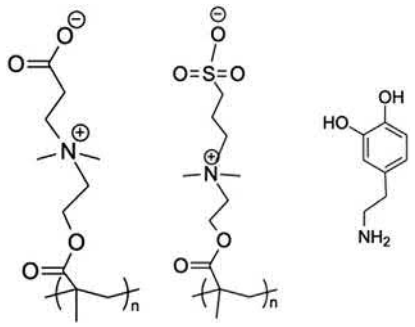
The mechanism for PC's low-fouling property is like that of PEG and other hydrophilic coatings. The charged moieties present in the polymer electrostatically attract water molecules to create a hydration layer. Because these charge interactions are stronger than hydrogen bonding, the hydration layer is much stronger and harder to disrupt by protein adsorption (Hatakeyama et al., 2010; Morisaku et al., 2008).

In vitro PC coating has been applied to various surface types including polyethylene (Ishihara et al., 1991), magnesium alloy (Ye et al., 2013), gold (Emmenegger et al., 2009), and PDMS (Goda et al., 2006). These reports generally show success in reducing protein and platelet fouling when tested in single-protein solutions and platelet-rich plasma (Tateishi et al., 2014). Animal and clinical studies of PC-coated oxygenators have shown good biocompatibility, though the amount of available data is small. A 2-hour canine extracorporeal study with cross-linkable PC coating on PP hollow-fiber membrane oxygenators demonstrated reduced platelet activation and clot formation (Wang et al., 2016). Clinical PC studies also showed reduced platelet activation but no reduction in thrombin activation or overall clot formation (De et al., 2002). On the other hand, one adult CPB study reported that the PC-coated oxygenator from Sorin had a lower increase in transoxygenator pressure drop compared to the uncoated control, indicating decreased thrombus formation (Lorusso et al., 2009). Therefore, PC coating of clinical CPB circuits had mixed results in comparison to its successes in vitro, but the long-term efficacy on artificial lungs is still under investigation. One downside that may limit application is that MPC synthesis is challenging due to the sensitivity to moisture, which may cause variations in batch quality (Zhang et al., 2006).

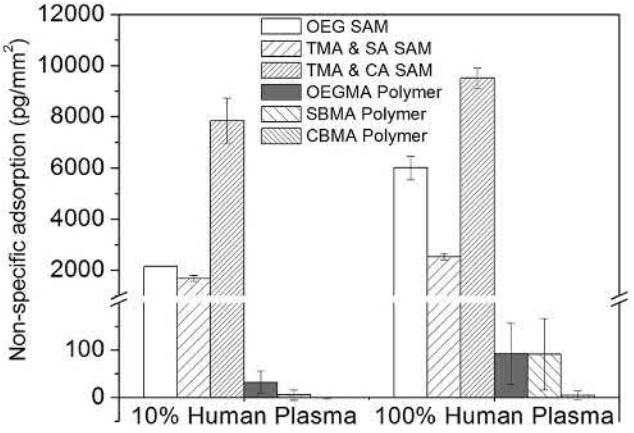
Sulfobetaines and Carboxybetaine Coatings: Recently, other types of zwitterionic polymers have been developed and tested. Polycarboxybetaine (pCB) and polysulfobetaine (pSB) have been the most successful examples (Fig. 2.5.3.8), and thus represent one of the most active areas of investigation for nonfouling coatings. These polymers bear similar structure to PC, but their negative moieties are different; carboxybetaine has a carboxylate group, and sulfobetaine has a sulfonate group. Furthermore, both pSB and pCB, much like PC, are bioinspired materials. SB is similar in structure to taurine, which is an amino acid abundantly present in the body (Zhang et al., 2006), while CB structurally resembles glycine betaine, a molecule that is believed to have osmoregulatory and protein-stabilizing functions in many species including humans (Papageorgiou and Murata, 1995).

Evidence suggests that pCB and pSB coatings create a waterlike layer that both repels proteins while maintaining their conformations (Keefe and Jiang, 2012; Abraham et al., 2011). Both pCB and pSB have been tested to examine the extent of protein adsorption, and pCB has particularly shown excellent in vitro performance. Ladd et al. reported a protein fouling study with surface plasmon resonance (SPR) that compared the efficacy of various polymer brushes over a gold substrate, including poly-oligo-ethylene methacrylate (pOEGMA), polysulfobetaine methacrylate (pSBMA), and polycarboxybetaine methacrylate (pCBMA). When 100% plasma flowed over the surface, only pCBMA showed protein fouling of $<10\,pg/mm^2$ versus $\sim100\,pg/mm^2$ for pOEGMA and pSBMA (Fig. 2.5.3.9) (Ladd et al., 2008). Another SPR study demonstrated that only pCB coating had protein adsorption below the detection limit of $6\,pg/mm^2$ when exposed to 33% human plasma for 30 min, whereas PEG, pSB, and PC all had measurable amounts of 1200, 3200, and $4600\,pg/mm^2$, respectively (Emmenegger et al., 2009). Thus, pCB is currently the least fouling material tested and has great potential toward long-term artificial lung applications.

Many approaches to pCB and pSB coating have been examined. Like PEG and PC coating, copolymerizing pCB and pSB with hydrophobic or amphiphilic moieties is a simple yet effective graft-to approach (Li et al., 2012). The loss of stability and leaching are the main points of concern for this approach. Another common graft-to approach makes use of 3,4-dihydroxyphenylalanine (DOPA), a bioinspired adhesive molecule found naturally in byssal threads of mussels (Fig. 2.5.3.8). These threads can attach securely to various types of surfaces in a wet, tidal environment because of DOPA's unique chemistry (Herbert, 1983). On organic surfaces, the hydroxyl groups present on DOPA are oxidized and covalently attach themselves to the surface, whereas the same hydroxyls can attach via hydrogen-bonding to inorganic surfaces (Lee et al., 2006). DOPA is hence a versatile and powerful adhesive over a wide range of surface types. Sundaram et al. utilized DOPA's property to design a simple, one-step dip-coating or wash-through methodology for grafting pCB polymers to a variety of surfaces including PDMS, PVC, and PP (Fig. 2.5.3.10) (Sundaram et al., 2014). The simple approach and broad application across polymers make this an attractive option for the diverse materials within artificial lungs and ECMO circuits. The challenge with this approach is that a high grafting density may not be achieved due to the steric effects imposed by the long, bulky polymer chains.



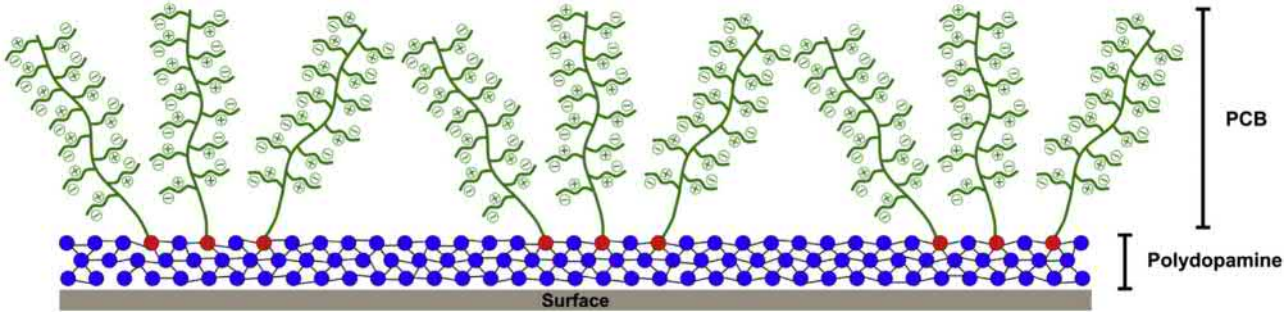
• **Figure 2.5.3.8** Polycarboxybetaine (PCB), polysulfobetaine (PSB), and 3,4-dihydroxyphenylalanine (DOPA).



• **Figure 2.5.3.9** Protein adsorption levels on a variety of antiadsorptive surface coatings, including polyoligoethylene methacrylate (pOEGMA), polysulfobetaine methacrylate (pSBMA), and polycarboxybetaine methacrylate (pCBMA). (Reproduced from Ladd J, Zhang Z, Chen S, Hower JC, Jiang S. 2008. Zwitterionic polymers exhibiting high resistance to nonspecific protein adsorption from human serum and plasma Biomacromolecules 9, 1357–1361.)

Graft-from approaches have also been investigated. This approach, however, requires premodification of the surface with an initiator for polymerization but, theoretically, allows for greater grafting density. Surface-initiated atom transfer radical polymerization (SI-ATRP) of pCB on PDMS (Hong et al., 2017), SI-ATRP of pSB on polysulfone membranes (Yue et al., 2013), and single electron transfer-living radical polymerization of SB and CB brushes over a flat polymethylpentene sheet have all been demonstrated (Obstals et al., 2018). Mussel-derived peptides were also used as initiators for polymerizing pSBMA over metal oxides, gold, and polycarbonate (Kuang and Messersmith, 2012). Higher grafting density should yield reduced fouling; however, the scalability of this approach for larger specimen, such as full-scale artificial lungs, remains a challenge (Sun et al., 2017).

All of these approaches are currently being examined for application to artificial lungs. A DOPA-pCB coating on PDMS sheet demonstrated a 77% reduction in platelet binding over the control following 8 h of in vitro citrated platelet-rich plasma recirculation (Amoako et al., 2016), while an identical study using PMEA coatings demonstrated only a 17% reduction (Gupta et al., 2014). A pSB



• **Figure 2.5.3.10** Polycarboxybetaine (pCB) coating using 3,4-dihydroxyphenylalanine (DOPA) to attach pCB to the device surface. (Reproduced from Sundaram HS, Han X, Nowinski AK, Brault, ND, Li, Y, Ella-Menye, J-R, Amoako, KA, Cook, KE, Marek, P, Senecal, K, Jiang, S. 2014. Achieving One-Step Surface Coating of Highly Hydrophilic Poly(Carboxybetaine Methacrylate) Polymers on Hydrophobic and Hydrophilic. Surfaces Adv Mater Interfaces 1(6), 2014.)

copolymer-coated PMP hollow-fiber membrane achieved an 80%–95% reduction in platelet deposition from citrated whole blood following a 3 h incubation (Malkin et al., 2018). Ultimately, however, the true test of pCB and pSB coatings is their long-term function in contact with whole blood. A lightly cross-linked pCBMA hydrogel was used to coat glucose sensors, and the sensors showed high measurement sensitivity and accuracy after 42 days, while the control failed after 2 days (Yang et al., 2012). This suggests an elimination of bulk clot formation. Studies demonstrating that pCB coatings can be applied to full-scale artificial lungs and reduce coagulation during long-term testing are only now emerging but have been promising. A sheep VV-ECMO study was conducted by Ukita et al. to determine the optimal grafting method for pCB coating in a miniature artificial lung (Ukita et al., 2019). The parallel, head-to-head testing demonstrated that DOPA-pCB was the most effective grafting strategy over SI-ATRP or copolymerization approaches. Moreover, the same DOPA-pCB approach was used to coat a small artificial lung circuit tip-to-tip and was tested in a rabbit VV-ECMO model for 4 hours. This model demonstrated that the coating reduced clot formation by 59%.

Nitric Oxide Surface Flux

Another approach to reducing thrombosis is to actively provide anti-platelet activity at the material surface via surface nitric oxide (NO) flux. Nitric oxide is normally produced by endothelium in the vasculature, causing both vasodilation and platelet inhibition. Nitric oxide is small, lipophilic, and is thus able to diffuse easily through platelet membranes. Inside the platelet, it activates guanylyl cyclase, inhibits phosphoinositide 2-kinase, impairs calcium influx, reduces binding to platelet agonists such as thrombin, ADP, and thromboxane, and reduces GpIIb/IIIa receptor expression. Nitric oxide thus limits platelet activation, adhesion, and aggregation. Importantly, the robust antiplatelet effect of NO is localized to where it is released due to its short, 0.05–2 ms half-life in whole blood (Thomas et al., 2001). Thus, NO can be used to create localized anti-thrombotic activity at a biomaterial surface, including those of artificial lungs. When released from or generated at a biomaterial surface, NO inhibits platelets near the surface, but those same platelets return to normal function while flowing back to the patient. Therefore, NO flux in extracorporeal devices does not cause bleeding like systemic anticoagulants. On the other hand, binding of NO to hemoglobin in red blood cells results in methemoglobin (MetHb) formation. MetHb is a form of hemoglobin that cannot effectively deliver oxygen. Therefore, at high concentrations, MetHb will decrease oxygenator efficiency and cause tissue hypoxia (Stepuro and Zinchuk, 2006). As a result, NO flux rates must be limited.

NO has been used as a surface anti-platelet agent in three ways: (1) release from NO donors located within circuit polymeric materials (NOrel), (2) generation from endogenous donors in blood (NOgen), and (3) NO delivery via the artificial lung sweep gas. In general, surfaces with NO flux rates greater than the endothelium ($>0.5\times10^{-10}$ mol/min/cm^2) reduce platelet consumption and clot formation, and this inhibition is linearly related to NO flux during short-term (<4 h) in vitro or in vivo (Amoako and Cook, 2011). Blood clotting time at a PDMS surface, for example, is 2–4 times normal at NO flux rates of $1.4–3.6\times10^{-10}$ mol/min/cm^2.

NO release is not the best choice for an artificial lung, as artificial lung fibers are thin, and the NO payload would not be sufficient for long-term use. On the other hand, NO release has been tested extensively in the polymer tubing used to connect devices in the ECMO circuit. Platelet losses are typically reduced from 60% to 25% when NO is released from Tygon tubing during short-term (4 h) in vivo extracorporeal circulation studies using tubing-only circuits (Zhang et al., 2003; Major et al., 2010; Handa et al., 2013; Amoako et al., 2012). Unfortunately, tubing represents < 10% of the typical surface area of artificial lung circuits, is less thrombogenic than the oxygenator, and is thus a lesser player in circuit coagulation.

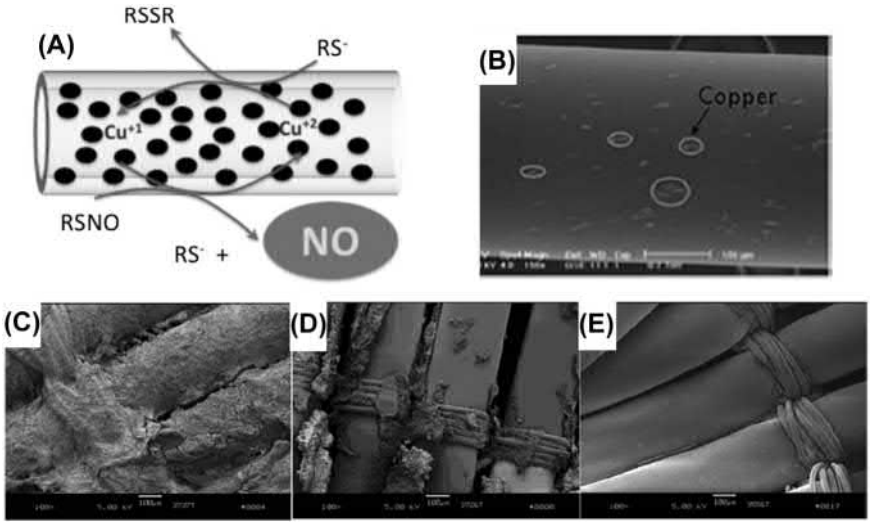
The simpler and more common mode of NO delivery in oxygenators is via the artificial lung sweep gas. Published studies using less than 100 ppm in the sweep gas demonstrate either small or no platelet inhibition (Keh et al., 1999), while use of 500–1000 ppm significantly reduced platelet adhesion to the oxygenator (Sly et al., 1996). Unfortunately, these higher concentrations also increased metHb to almost 9%. The ideal range is thus likely between 100 and 500 ppm. Concentrations of 100 and 200 ppm do not increase metHb levels significantly, but 500 ppm increases their levels to approximately 5% (Demarest, 2017). The benefit to platelet binding, however, is small in this range (Amoako et al., 2016; Demarest, 2017) in part due to conversion of NO to nitrates when delivered with oxygen in the sweep gas.

The last means of supplying NO is generating it from donors that are already in blood and/or supplied intravenously. This method can provide a constant supply of surface NO that is less diminished by formation of nitrates and nitrites. The most common method for NO generation is incorporating copper (Cu) particles in the biomaterial surface as a catalyst to decompose NO donors in the blood (Noble et al., 1999; Wang et al., 2002). As a stoichiometric reaction (Eqs. 2.5.3.1 and 2.5.3.2), the rate of NO release can be controlled with the availability of NO donor and how much Cu is exposed to the donor:

$$Cu^{+} + RSNO = Cu^{2+} + RS^{-} + NO \qquad \textbf{(2.5.3.1)}$$

$$Cu^{2+} + 2RS^{-} = 2Cu^{+} + RSSR \qquad \textbf{(2.5.3.2)}$$

This reduction–oxidation reaction can cycle indefinitely if there is a supply of NO donors. For artificial lung fibers, this has been accomplished by incorporating Cu nanoparticles in polydimethylsiloxane (PDMS; Fig. 2.5.3.11) (Amoako et al., 2013; Amoako and Cook, 2011; Lai et al., 2019).



• **Figure 2.5.3.11** Nitric oxide (NO) generating polydimethylsiloxane (PDMS) surface applied to artificial lung hollow fibers, including (A) mechanism of NO generation, (B) copper nanoparticles in the fiber wall, (C, (D) typical clot formation on control fibers without copper, and (E) typical clot formation on NO-generating fibers. (Reproduced from Amoako K A., Montoya PJ, Major TC, et al. 2013. Fabrication and in vivo thrombogenicity testing of nitric oxide generating artificial lungs J Biomed Mater Res Part A 101, 3511–3519.)

Surface NO generation was catalyzed via copper nanoparticles within PDMS gas exchange fibers in a 4-h, pumpless arteriovenous ECMO rabbit model using a continuous infusion of S-Nitroso-N-acetylpenicillamine (SNAP) as the NO donor (Amoako et al., 2013). This study demonstrated a markedly lower increase in blood flow resistance and less clot formation on NO-generating hollow fibers. Additionally, the surface-generated NO did not create an increase in metHb over the 4 hours. NO-generating fibers also showed significantly reduced blood flow resistance, increased device lifespan, and reduced clot formation on the hollow fibers when compared to standard PMP fibers in a 72-hour, pumped veno-venous ECMO sheep model (Lai et al., 2019). However, this method is limited in two ways: (1) copper leaches off fibers into the vasculature, and this could lead to excessive copper delivery and resulting toxicity, and (2) the copper is likely to reduce the gas permeability and gas transfer. Despite these negatives, this method of NO delivery has the most experimentally demonstrated benefit.

Renal Replacement Therapies and Therapeutic Apheresis

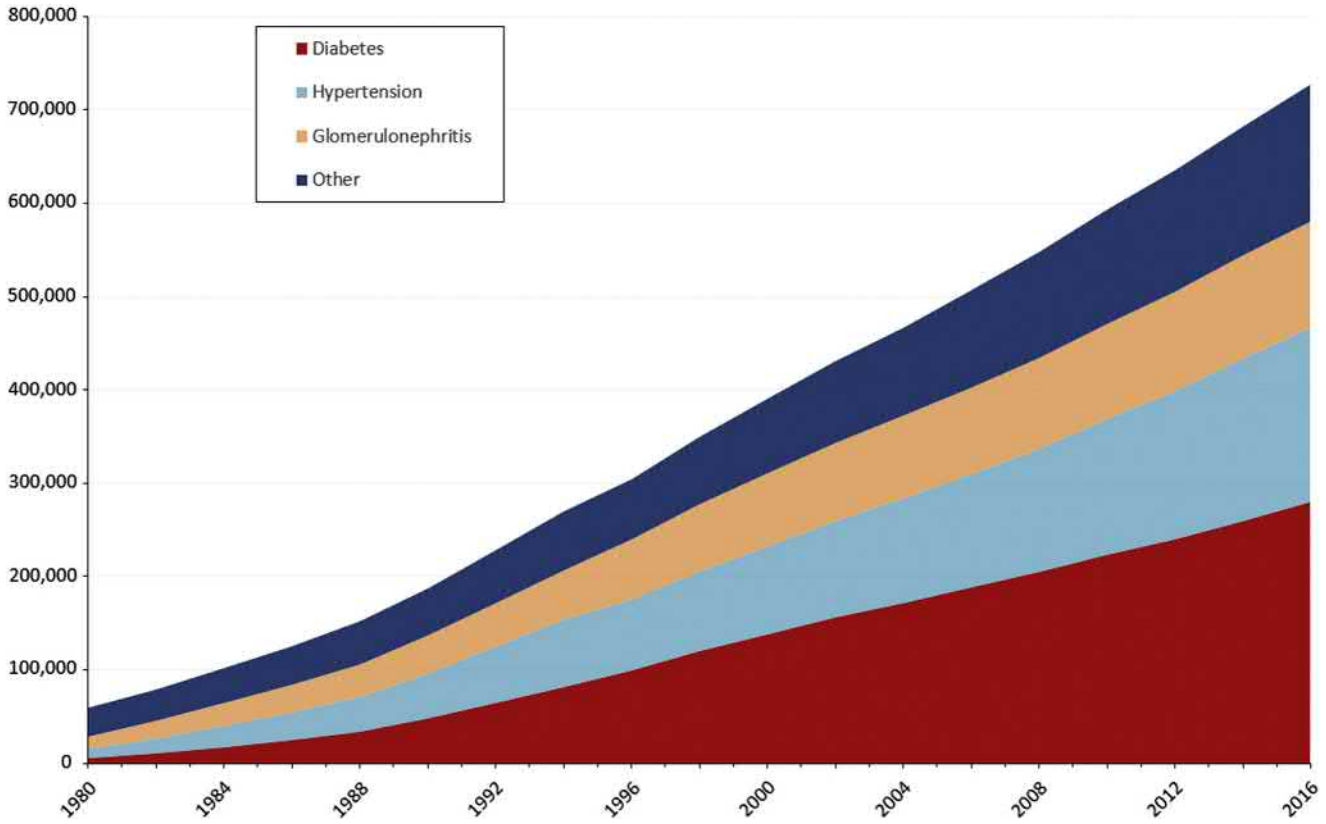
Introduction

The purpose of renal replacement therapies and therapeutic apheresis is to remove toxins and metabolic waste products from the blood and to maintain the volumetric and osmotic balance of the patient. The vast majority of these procedures are performed intermittently, or as a temporary partial or total replacement. All these procedures involve the contact of blood with biomaterials, mechanical pumping of the blood, and mass transfer to and from the blood. As with artificial lungs, blood-biomaterial compatibility is essential to the success or failure of a procedure.

Renal Replacement Therapy

Renal replacement therapy describes treatments such as peritoneal dialysis, hemodialysis, and hemofiltration, used to detoxify blood in cases of renal insufficiency. Renal insufficiency may be caused by: acute renal failure, typically of rapid onset and due to external causes; or chronic renal failure, usually due to damage to the tissues of the kidneys. Chronic renal failure may be caused by infection, toxins, or hypertension, and may also arise as a complication in diabetes mellitus. The number of prevalent (i.e., alive and receiving treatment) patients with end-stage renal disease in the United States between 1980 and 2016 is given in Fig. 2.5.3.12 (USRDS, 2009, 2018). As can be seen from the graph, the incidence of chronic renal failure has risen steadily since 1980, and diabetes has become the prominent cause of renal failure, accounting for some 38.5% of all cases in 2016, followed by hypertension, and glomerulonephritis. Of the 726,331 surviving ESRD patients listed by the United States Renal Data System in that year (USRDS, 2009, 2018), 215,061 (29.6% of the total) had received a transplant that was still functioning. The other patients were dependent upon renal replacement therapy.

In 2016, there were 511,270 patients receiving renal replacement therapy in the United States, of whom 89.6% received hemodialysis treatment. Blood may be treated by extracorporeal hemodialysis (familiarly known as dialysis), peritoneal dialysis, and extracorporeal hemofiltration (a form of plasmapheresis). Fig. 2.5.3.13 shows the numbers of patients treated by blood purification therapies in the United States between 1980 and 2016 (USRDS, 2009, 2018). As can be seen, as the patient population has increased, the number and proportion of patients treated by hemodialysis has increased similarly. The number of patients treated by peritoneal dialysis has remained at around 10% of the total, with 51,057 in 2016. The proportion



• **Figure 2.5.3.12** Prevalence and causes of chronic renal failure in the USA, 1980-2016. Source: United States Renal Data System (USRDS) Annual Data Reports, 2009 and 2018. Data is as at December 31st of stated year.[1]

of patients treated by hemofiltration is very small, as this is predominantly used in intensive care medicine, particularly in the treatment of multiple organ failure (Coles and El Nahas, 2000).[1]

Function of the Kidney

The kidney is responsible for maintaining the osmotic and water balance of the body; for detoxification and the removal of metabolic waste; and endocrine functions. It operates by a combination of filtration, selective reabsorption, and active secretion. The functional unit of the kidney is the nephron, of which there are approximately one million in each kidney. Fig. 2.5.3.14 shows a schematic representation of a nephron, and its associated specialized blood vessels.

In the glomerulus, the whole blood is filtered. The filtrate contains water and solutes with a molecular weight below 60,000 (small proteins, amino acids, glucose, urea, and ionic solutes), of similar composition to blood plasma. Approximately 10% of the blood volume entering the glomerulus is filtered here. The remaining blood passes into the peritubular capillaries and vasa recta while the filtrate enters the proximal convoluted tubule. Within the remaining structures of the kidneys, water, small proteins, and solutes are reabsorbed by active and passive processes, while certain metabolites are secreted directly into the tubular fluid. These processes result in a net reabsorption of approximately 98%–99% of the water filtered, and total reabsorption of glucose, proteins, and amino acids from the filtrate. A healthy individual will excrete 1–2 L of concentrated urine per day, on average.

In addition to its excretory function, the kidney also has regulatory and endocrine functions. It controls the acid–base balance of the blood, and the water balance of the body, through selective secretion of H^+ into the urine to control pH, and the action of antidiuretic hormone, which controls the urine concentration. The kidney plays a role in the regulation of blood pressure through secretion of renin and tissue hormones (prostaglandins). The kidney also secretes erythropoietin, which promotes red blood cell formation in the bone marrow.

Treatment of Renal Failure

In its initial stages, chronic renal failure (end-stage renal disease, or ESRD) is treated conservatively. As the disease progresses, blood purification is needed to remove toxins from the blood (Wing and Jones, 2000). The severity of chronic renal failure may be reduced by restricting a patient's protein, potassium (K^+), and water intake through carefully managed diets, and the administration of bicarbonate supplements to maintain a healthy blood pH. Erythropoietin supplements are given to maintain the patient's hematocrit (Coles and El Nahas, 2000). As the disease progresses, some form of renal replacement therapy becomes necessary.

[1]The data reported here have been supplied by the United States Renal Data System (USRDS). The interpretation and reporting of these data are the responsibility of the author(s) and in no way should be seen as an official policy or interpretation of the U.S. government.

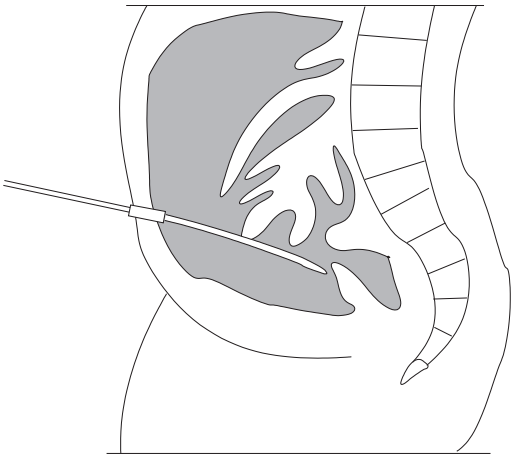
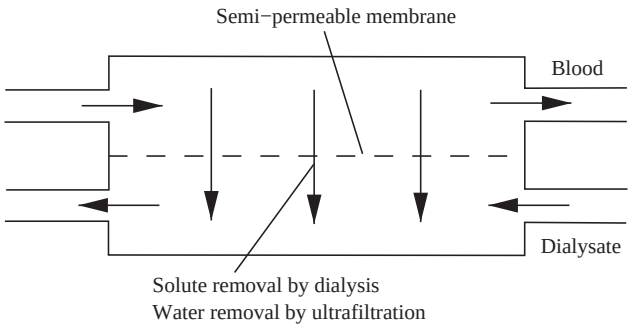
Peritoneal Dialysis

Peritoneal dialysis uses the peritoneum, the membrane lining the walls of the abdominal cavity, and the abdominal organs for mass exchange. Dialysate is introduced into the peritoneal cavity through a catheter, as shown in Fig. 2.5.3.15. While in the peritoneal cavity, metabolic wastes such as urea and creatinine, toxins, and excess solutes (K^+, for example) are transferred from the blood into the dialysate by dialysis, while water is removed by osmosis (Sargent and Gotch, 1996). Used dialysate is then removed.



• **Figure 2.5.3.15** Positioning of catheter in peritoneal cavity for peritoneal dialysis.



• **Figure 2.5.3.16** Principle of dialysis.

Peritoneal dialysis is dependent on a number of factors. The rate of solute removal is dependent on the blood flow in the capillaries of the peritoneum and its permeability, as well as on concentration gradients between the blood and the dialysate. In addition, the suitability of a patient for treatment by peritoneal dialysis is often dependent on the amount of residual renal function.

There are two principal forms of peritoneal dialysis therapy. *Continuous ambulatory peritoneal dialysis* (CAPD) is the most commonly used form, particularly in younger patients who can manage their own therapy. In this treatment method, the dialysate is infused into the peritoneal cavity, allowed to dwell for a set length of time, then drained and replaced with fresh dialysate. Typically, a patient would perform between five and six exchanges per day (Malchesky, 2004). It has the advantage that it offers patients a certain amount of independence, as they are not tied to any equipment for the majority of the time.

In *automated peritoneal dialysis* (APD), also known as continuous cycler-assisted peritoneal dialysis (CCPD), a machine (cycler) performs the exchanges, usually at night while the patient is sleeping. APD can increase the clearance of metabolites considerably, particularly in patients with rapid rates of exchange between the peritoneum and the dialysate (high or fast transporters). In APD treatment, the cycler will perform several complete exchanges in a night, with a complete cycle of infusion, dwell, and drainage being completed in 30 min or less, and treatment for 8–12 h in total. APD is sometimes referred to as *intermittent peritoneal dialysis*, if the APD is only performed at night. Many patients use a combination of CAPD during the day and APD at night.

Toxin removal in peritoneal dialysis is the sum of the patient's residual renal function and the toxin removal by hemodialysis, The overall removal of toxins, metabolites, and water must be sufficient to keep the patient healthy. As water removal is dependent on the osmotic pressure of the dialysate, dialysate is supplied in three different strengths: 3.86% glucose, 2.27% glucose, and 1.36% glucose. All three strengths are hypertonic and will result in water transfer to the dialysate, the rate of transfer is dependent on the osmotic gradient. A more concentrated dialysate will increase the ultrafiltration rate, and hence the removal of solutes as well as water will be enhanced; however, the stronger dialysate concentrations are only used when necessary, and most transfers are performed using the standard (1.36%) dialysate strength.

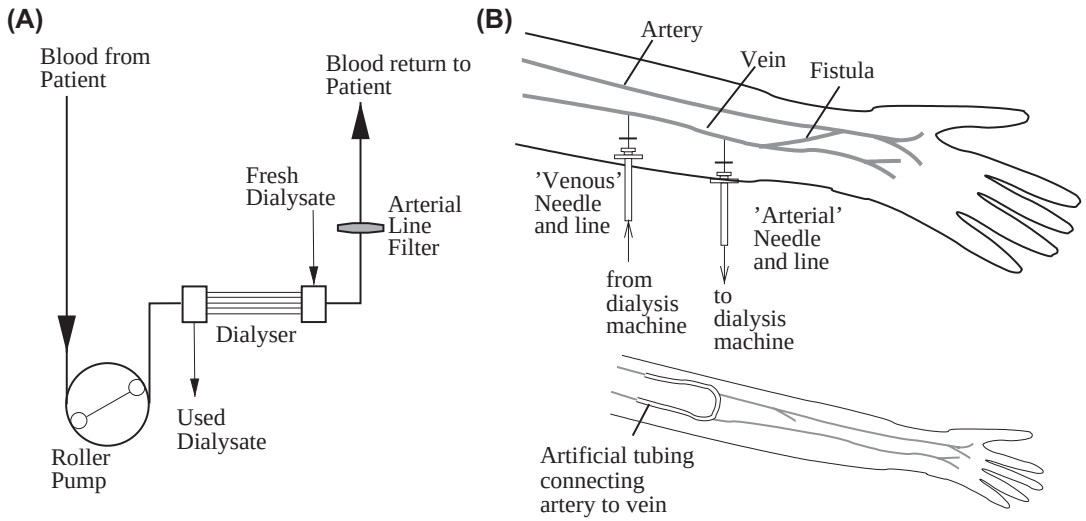
Peritoneal dialysis has the advantage that the patient's blood does not come into contact with any artificial surfaces, hence there is no need for anticoagulation. It has the disadvantage that the dialysate has to be infused into a body cavity, with the attendant risk of infection (Malchesky, 2004). It is vital to ensure the sterility of the dialyzing solutions and to prevent infections at the access site. The most common complication of peritoneal dialysis is peritonitis, and this is also the most common reason for the discontinuation of PD. In most cases where peritoneal dialysis has to be discontinued, patients will begin treatment by hemodialysis.

Hemodialysis

Dialysis is the process of solute transfer across a semipermeable membrane, and is similar in principle to diffusion. It is a passive process, with solute molecules that are small enough to pass through the membrane traveling from an area of high solute concentration to an area of low solute concentration. Typical hemodialyzers use membranes with a molecular weight cut-off between 5000 (low-flux membranes) and 20,000 (high-flux membranes) (Boure and Vanholder, 2004) and a surface area of between 0.5 and 2.1 m^2.

In the hemodialyzer, blood flows through membrane hollow fibers, with dialysate flowing in countercurrent fashion, as shown in Fig. 2.5.3.16. Metabolic wastes such as urea and creatinine are transferred from the blood into the dialysate, due to the concentration gradient. The dialysate must be carefully formulated to ensure that normal concentrations of glucose and blood solutes are maintained. The blood and dialysate are osmotically balanced, hence any solute removal is by ultrafiltration, due to the differential pressure ($P_B - P_D$) between the blood and dialysate compartments.

Hemodialysis is an intermittent therapy, and is typically administered every 48 h, with sessions lasting up to 6 hours at a time (Malchesky, 2004). The limiting factor for hemodialysis session duration is the rate of water removal, as water can only be drawn out of the blood plasma, and rates of fluid transfer from the intracellular fluid and interstitial



• **Figure 2.5.3.17** (A) Circuit for hemodialysis. (B) Hemodialysis access from arteriovenous fistula (top) and from a graft (bottom) (Wing and Jones, 2000).

• **Figure 2.5.3.18** Hollow fiber dialyzer (Terumo Clirans C061) with end cap removed to show arrangement of hollow fibers.

fluid pools to the plasma (plasma refilling) must be sufficient to maintain normal blood pressure.

Fig. 2.5.3.17A shows a typical hemodialysis circuit, incorporating a blood pump, dialyzer, and arterial line filter. Blood is drawn from a dialysis access (Fig. 2.5.3.17B), usually located in the arm, and pumped through the dialyzer (Fig. 2.5.3.18) at rates varying between 50 and 400 mL/min, depending on the condition of the patient, particularly the blood flow and blood pressure within the access vessel and the required solute clearance and ultrafiltration rates. The dialysate is either prepared in batches, or continuously, typically by mixing concentrate and processed mains water. Dialysate flow rates vary within the range of 300–800 mL/min, with most procedures performed at 500 mL/min. A higher dialysate flow rate will increase the clearance of solutes from the blood, but this increase in performance has to be balanced against the increased cost of the dialysate used.

Dialyzer Materials and Coatings

Dialyzer materials are chosen based on two main characteristics: waste clearance and biocompatibility. The ideal fiber has well controlled pore sizes to create a sharp drop in the permeability at a specific molecular weight. Low-flux dialyzers remove low-molecular-weight solutes (<500 Da), including urea (60 Da), creatinine (113 Da), and phosphate (134 Da). High-flux dialyzers are designed to also allow the loss of middle- to high-molecular-weight solutes (500–15,000 Da) and protein-bound uremic toxins (>15,000 Da) (National Kidney Foundation, 2013). In an attempt to mimic the human kidney, the Japanese Society of Dialysis Therapy (JSDT) recommends that pore sizes allow less than 3 g of albumin (66,000 Da) lost per session with a blood flow rate of 200 mL/min and a dialysate flow rate of 500 mL/min (Saito, 2011).

The first dialyzers utilized cellulose membranes, but these are no longer used due to issues with biocompatibility. In particular, the cellulose surface contains hydroxyl groups that bind complement fragment C3b, slowing its inactivation by plasma inhibitors. This allows activation of the alternative complement pathway, neutrophil and monocyte activation, and inflammation (Cook and Mockros, 2002). As a result, cellulose was chemically modified to replace the hydroxyl group with acetate to form cellulose acetate, diacetate, or triacetate. Despite this improvement, greater flux and biocompatibility were desired, leading to the development of other hollow-fiber materials. Current dialyzers thus utilize polysulfone (PS), polyethersulfone (PES), polyester polymer alloy (PEPA), polyacrylonitrile (PAN), and polymethylmethacrylate (PMMA) fibers (National Kidney Foundation, 2013; Ahmad et al., 2014). The PS, PES, and PEPA membranes are hydrophobic and thus are all mixed with polyvinylpyrrolidone (PVP) to achieve surface hydrophilicity. This improves waste transport and filtration during hemofiltration, and reduces protein adsorption and platelet adhesion (Kokubo et al., 2015a,b).

The AN69 PAN membrane possesses a significantly negative charge, and this leads to increased activation of FXII, the contact system, and generation of bradykinin. Bradykinin is known to cause increased capillary permeability and blood vessel vasodilation. Under normal circumstances, bradykinin is deactivated by angiotensin-converting enzyme (ACE). However, in patients taking ACE inhibitors to control blood pressure, bradykinin deactivation is insufficient and patients can develop a dangerous anaphylactic-like response leading to severe hypotension. In order to remedy this, the AN69ST fiber utilized a polyethylenimine (PEI) polycation spacer molecule. The addition of this polycation thus changes the adsorptive character of this surface, resulting in significant increases in the adsorption of cytokines (Shiga et al., 2014), fibroblast growth factor (Yamato et al., 2016), and anticoagulants such as heparin and nafamostat mesilate (Hirayama et al., 2017; Nakamura et al., 2017).

The ability of AN69ST to adsorb heparin has been used in an attempt to reduce or eliminate systemic heparin when dialyzing patients with a history of bleeding issues. In initial studies, the circuit was prerinsed with a heparin solution to adsorb the heparin and then used normally. Unfortunately, studies examining the frequency of circuit failure due to clot formation showed no significant improvement over polysulfone fibers (Brunet et al., 2011). One small study, however, has demonstrated the ability to reduce rather than eliminate systemic anticoagulation (Sanchez-Canel et al., 2012). Subsequently, heparin has begun to be preadsorbed during the manufacturing process, leading to the HeprAN membrane (Thomas et al., 2011). A study of 45 dialysis patients demonstrated that the HeprAN fiber allowed for a reduction in systemic heparin anticoagulation in 67% of patients (Kessler et al., 2013).

Heparin coating has also been employed on unmodified cellulose fibers (Lee et al., 2004) and, more recently, polysulfone fibers. The poor biocompatibility of cellulose fibers likely halted further research on their surface coating (Kessler et al., 2015); the polysulfone coatings appear promising (Ren et al., 2013), but there has been no evaluation of their clinical benefits.

Vitamin E coatings are also applied to dialysis membranes. One of the complication of dialysis over long-term treatment is amyloidosis and atherosclerosis. Both are thought to be caused by repeated oxidative stress imposed over time by hemodialysis. To combat this, vitamin E-coated PS membranes have been developed. In small studies, these membranes have demonstrated reduced oxidative stress (Satoh et al., 2001; Clermont et al., 2001), reduced activation of the contact system of the coagulation cascade, and platelet surface binding (Sasaki, 2006).

In addition to the membranes of the hemodialyzer, the blood will also come into contact with the tubing and connectors used in the extracorporeal circuit. Commonly used materials for blood tubing include poly(vinyl chloride) (PVC), polyurethane, and silicone rubber (PDMS, polydimethyl siloxane). However, the area of these materials, and the exposure time, is much lower than for the functional membrane surface.

Coagulation and Inflammation During Hemodialysis

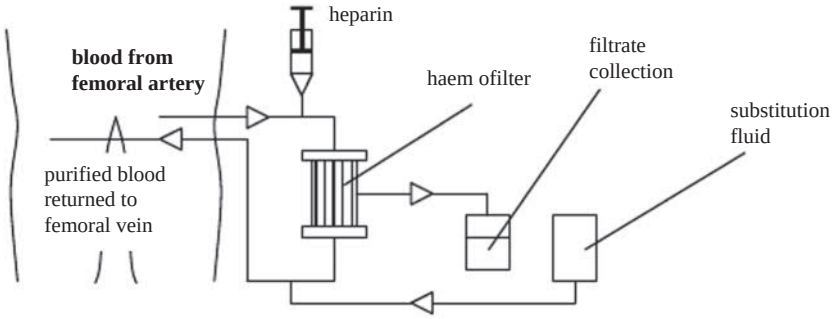
Much like artificial lungs, the large, densely packed artificial surfaces of dialyzers cause significant protein adsorption, direct activation of the coagulation cascade and complement, platelet adhesion and activation, and white cell activation. As a result, clot forms rapidly on the dialyzer surface unless significant anticoagulation is used, and the patient is exposed to repeated systemic activation of coagulation and inflammation during each treatment. All blood returning to the patient is filtered to ensure that thromboemboli cannot enter the patient's bloodstream.

To combat coagulation, heparin is the anticoagulant of choice. In the United States, unfractionated heparin is typically used, whereas in Europe, low-molecular-weight heparin is recommended by the European Best Practice Guidelines (Kessler et al., 2015). Unlike ECMO, there is no "typical" heparin dose: heparin doses are tailored based on experience with patients' bleeding propensity during hemodialysis and vary widely from dialysis facility to facility (Davenport et al., 2014). Heparin is delivered as an initial bolus and may then be followed by either a continuous drip, hourly heparin boluses, or no additional heparin at all. Although there is no standard, an example of the former method would be to deliver an initial bolus of 2000 U, followed by 1200 U/h. When repeated boluses are given, 500–750 U may be given hourly (Davenport et al., 2014). In places that reuse dialyzers, heparin doses are increased to limit the formation of clot and loss in dialyzer function. Unlike ECMO, the degree of anticoagulation is typically not monitored due to the short duration, relatively low bleeding complication rate during hemodialysis, and cost.

In addition to heparin, several other anticoagulants have been attempted to decrease the relative risks of dialyzer coagulation and patient bleeding. These include direct platelet inhibitors (prostacyclin) and other systemic inhibitors of the coagulation cascade, such as heparinoids (danaparoid, fondaparinux), direct thrombin inhibitors (hirudin, argatroban, melagatran, lepirudin, bivalirudin), and the broad-spectrum serine protease inhibitor nafamostat mesilate. Like heparin, these anticoagulants inhibit both surface-induced coagulation as well as tissue-based coagulation and thus offer little advantage over heparin. One attempted solution to this problem is regional citrate anticoagulation (RCA). In this method, citrate is used to chelate calcium and thus anticoagulate blood just prior to the dialyzer blood inlet. Calcium is then added back to the blood prior to it returning to the patient. Although offering some potential benefits, this method is cumbersome, complicated, and thus costly to employ (Kessler et al., 2015). Therefore, this also has not supplanted heparin use.

Extracorporeal Hemofiltration

Extracorporeal hemofiltration is mostly used in the treatment of acute renal failure, particularly where renal failure is accompanied by fluid overload. The toxins and excess water are removed by ultrafiltration, and fluid balance is maintained by addition of an isotonic substitution fluid "downstream" of the filter (see Fig. 2.5.3.19). This method is particularly effective in the removal of toxins, although as the substitution fluid is mixed directly with the blood,



• **Figure 2.5.3.19** Schematic showing access and extracorporeal circuit for hemofiltration.

and hence enters the body directly, it is very expensive to prepare. Its principal advantage over dialysis is the enhanced removal of solutes from the blood, of particular importance in cases of poisoning and multiple organ failure.

The most modern hemofiltration techniques use pure hemofiltration (convective transfer) in combination with dialysis (diffusive transfer) to achieve the desired blood purification. This technique is usually referred to as hemodiafiltration or high-flux dialysis; the set up is similar to that for conventional dialysis, although the vascular access is still arterio-venous (Malchesky, 2004).

Hemoperfusion

The term hemoperfusion applies to the direct perfusion of whole blood over a sorbent bed or reactor. The sorbent used may be activated charcoal, nonionic or ionic resins, or immunosorbents, while reactors may contain enzymes, cells, or tissues. The purpose of the treatment is either to remove specific toxins or metabolites, or to carry out specific biochemical reactions. Issues with biocompatibility, safety, and immunological isolation have limited the application of hemoperfusion to the use of charcoal and resins as sorbents (Kambic and Nose, 1993).

Sorption of the solute into the sorbent is based on chemical affinity, rather than molecular size. Due to the nature of the sorbent granules, the surface area for sorption is very high, but it also makes it possible for particulates to be released from the reactor into the blood. The nonspecific nature of charcoal sorption can also lead to the removal of beneficial compounds from the blood. For these reasons, hemoperfusion has largely been superseded by plasma treatment (plasma perfusion) and sorbent dialysis, which will have a similar therapeutic effect with fewer potential hazards. The very large surface area of sorbents also leads to extensive blood–biomaterial contact, resulting in complement activation and initiation of the coagulation cascade. These events will cause a reduction in leukocyte and platelet levels in the blood.

Therapeutic Apheresis

"Apheresis" describes any technique in which a fraction of the blood (platelets, plasma, red blood cells, leukocytes) is removed, and the remaining blood is returned to the donor. This can be divided into "donor apheresis," in which volunteers give blood fractions for the treatment of others, and "therapeutic apheresis," where blood fractions are selectively removed to achieve a therapeutic result.

Therapeutic apheresis can be used to treat diseases where abnormal blood proteins or cells are present in the bloodstream, and these proteins or cells are implicated in the condition's progression. In plasmapheresis, the plasma is separated and either replaced (plasma exchange), or treated prior to recombination with the blood (plasma treatment). In cytapheresis, one or more of the cellular components of the blood is selectively removed. Cytapheresis is overwhelmingly used as a donation procedure, for collection of blood proteins, platelets, and immune cells, with only 0.8% of the 1562 patient cases (13 cases) studied in the 2007 International Apheresis Registry[2] treated with therapeutic cytapheresis.

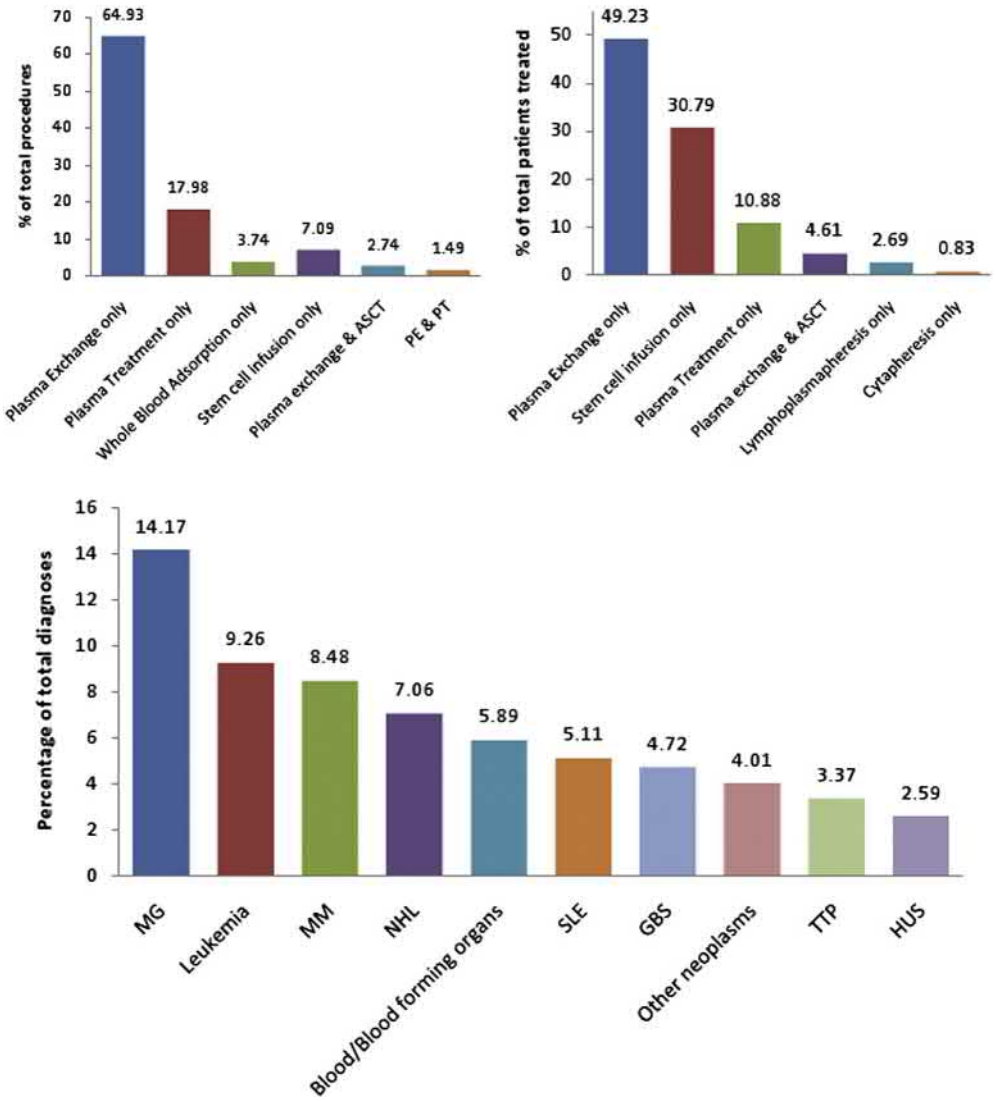
Plasmapheresis

Plasmapheresis has been used with considerable success in the treatment of a number of conditions, notably myasthenia gravis, leukemia, multiple myeloma, non-Hodgkins lymphoma, and other disorders affecting the blood and blood-forming organs (Kambic and Nose, 1993). Plasmapheresis is also used in the management of possible rejection of transplanted tissue due to ABO mismatch. Fig. 2.5.3.20 gives a breakdown of the number of treatments, number of patients treated by therapeutic apheresis, and the type of treatment used in the 2007 International Apheresis registry (Malchesky et al., 2009). Note that stem cell infusion was recorded in the survey although it is not an apheresis technique. Myasthenia gravis was the most common condition treated, both in terms of the number of patients and the number of treatments (it is a chronic condition, hence repeated treatments would be necessary), followed by leukemia (this figure does not include Hodgkins disease and non-Hodgkins lymphoma), multiple myeloma, and non-Hodgkins lymphoma.

Plasma Separation

Plasma separation can be achieved by centrifugal or membrane methods. Centrifugal methods can be batch or continuous. In a batch method, anticoagulated blood is removed from the patient, and then centrifuged to separate the plasma, red blood cells, and buffy coat (lymphocytes and platelets). In a continuous process, shown schematically in Fig. 2.5.3.21, blood is fed

[2] The 2007 International Apheresis registry is drawn from 20 participating centers offering apheresis treatment; these numbers should not be taken as estimates of the total number of patients worldwide.



• **Figure 2.5.3.20** Modes of treatment and conditions treated by apheresis, from the 2007 International Apheresis Registry (Malchesky et al., 2009). ASCT = Autologous Stem Cell Therapy; GBS = Guillan-Barre Syndrome; HUS = Hemolytic Uremic Syndrome; MG = Myasthenia Gravis; MM = Multiple Myeloma; NHL = Non-Hodgkins lymphoma; PE & PT = Plasma Exchange and Plasma Treatment; SLE = Systemic Lupus erythematosus; TTP = Thrombotic thrombocytopenic purpura.

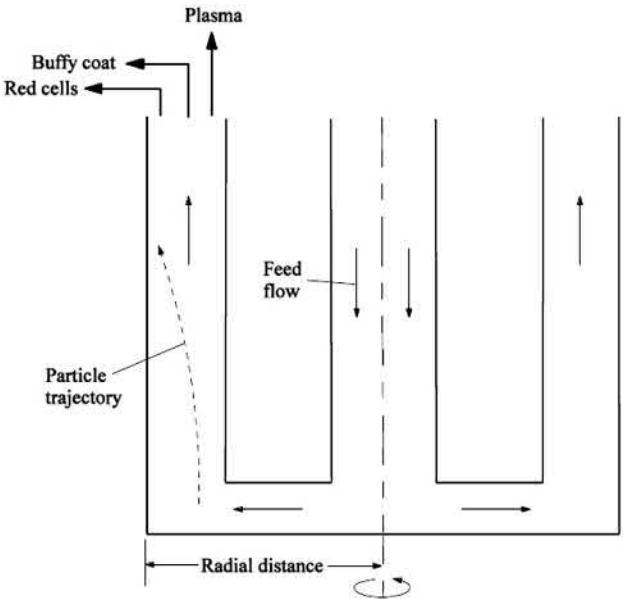
into the center of a rotating bowl and centrifugal forces (in the order of 100 × ***g***) cause separation into three distinct streams of red blood cells, buffy coat, and plasma (Malchesky, 2004). Table 2.5.3.2 gives the concentration, cell diameter, density and sedimentation coefficient for the constituents of whole blood. The most dense element of the blood is the red blood cells, and hence these will be most affected by the centrifugal forces, followed by the white blood cells, and then the platelets. One-stage separation can isolate the red blood cells, buffy coat, and the plasma, but two or more stages are required if concentration of specific white blood cell types is to be achieved. As the velocities used in the separation must not be too high, to prevent damage to the cells, it is usual for the plasma fraction to contain some cells—usually platelets.

Membrane plasma separation is dependent on the pore size of the membrane and it is usual to use pore sizes much smaller than the cells to prevent sieving. Fig. 2.5.3.22 shows the principle of membrane separation. If the pressure on the blood side is higher than the pressure on the plasma side, then there will be ultrafiltration of water and solutes with a molecular weight lower than the membrane cut off. Due to the nature of the process, the separated plasma will not contain any cells, and the concentration of macromolecular solutes in the filtrate will be almost identical to the concentration in the plasma.

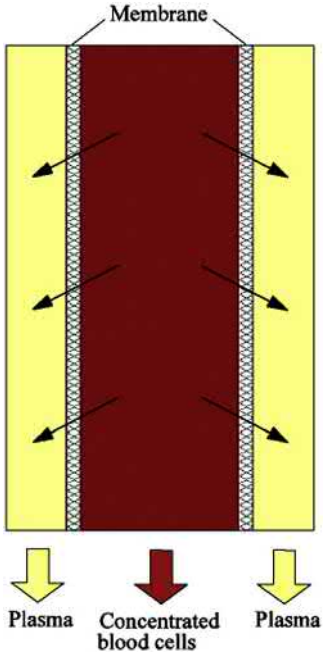
The production of particulate-free filtrate by membrane plasma separation is considered to be a key advantage of this process over centrifugal plasma separation. The absence of these particulates is particularly important if the plasma is to be treated, and then returned to the patient, as the particulates may interfere with the treatment process.

Plasma Exchange

Plasma exchange has already been introduced in the section on hemofiltration. It is the most used form of plasmapheresis, and



• **Figure 2.5.3.21** Centrifugal separation of blood into plasma, buffy coat, and red cells (adapted from Malchesky, 2004).



• **Figure 2.5.3.22** Membrane plasma separation (adapted from Malchesky, 2004).

is very effective in the removal of toxins from the bloodstream. However, it has the disadvantage that it is indiscriminate—in addition to the toxins and metabolites removed, large quantities of beneficial or physiological proteins including albumin, immunoglobulins, and clotting factors will be removed as well. This limits the volume of plasma that can be removed in a single session, and the infusion of substitution fluids carries the risk of allergic reactions or viral infections. Plasma exchange would usually be used when the specific pathogenic factors in the plasma are unknown, or where a specific technique to remove these factors is not available (Malchesky, 2004). It could also be used if a combination of factors is to be removed and plasma exchange is the simplest and most effective method to achieve this. The substitution fluid typically contains ionic solutes and albumin, but in some cases donated whole plasma or reconstituted plasma containing plasma fractions such as immunoglobulins can be used.

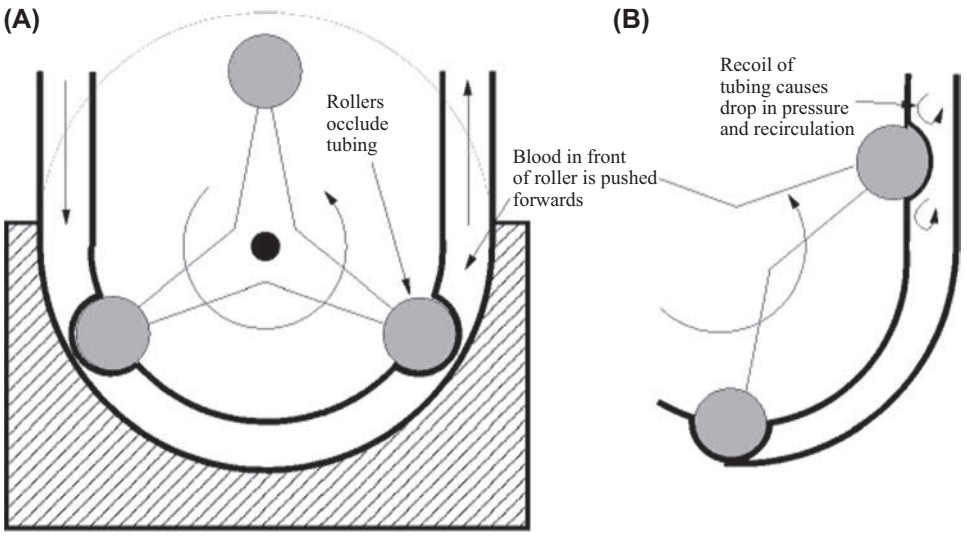
Plasma Treatment

Plasma may be treated by dialysis, membrane filtration, sorption, and processing by enzyme or biological reactions. Dialysis of fractionated plasma is similar to the dialysis of whole blood, and achieves the same result—removal of small solutes with a molecular weight below the membrane's cut-off. In membrane filtration, the plasma is filtered through one or more membranes following separation from the blood. The membrane cut-off of these membranes would be larger than a dialysis membrane, but smaller than the cut-off of the membrane plasma separator, so that larger molecules in the plasma would be filtered out. It is also possible to perform membrane filtration at temperatures below physiological levels (cryofiltration) and above physiological levels (thermofiltration). Cryofiltration is used to remove serum solutes which aggregate at lower temperatures, while thermofiltration is used to selectively remove low-density lipoproteins (LDL) in the treatment of hyperlipidemia.

The principle of plasma treatment by sorption is similar to hemoperfusion over a sorbent column. The plasma is perfused through a sorbent column to remove the targeted solutes, then recombined with the concentrated cell fraction and returned to the patient. Sorption has been used to treat poisoning, drug overdose, uremia, liver insufficiency, autoimmune disorders, and familial hypercholesterolemia.

Sorbent Dialysis

The main area of application for sorbent dialysis is the treatment of acute liver failure, a condition for which the medical prognosis is usually poor (Bosch, 2005; Galletti and Jauregui, 2006). Improvement in patient condition has been



• **Figure 2.5.3.23** Principle of operation of a roller pump.

shown as a result of treatment by albumin dialysis (molecular adsorbent recirculating system, or MARS) and by fractionated plasma separation and adsorption (Prometheus), a form of plasmapheresis, discussed above.

The MARS system passes the patient's blood through a high-flux dialyzer, and albumin-bound toxins in the patient's blood diffuse through the membrane to bind with albumin recirculating in the primary dialysate compartment. The dialysate coming out of the dialyzer is regenerated in a series of sorbent columns (typically activated charcoal and anion exchange resin) which will remove toxins from the albumin, and a low-flux dialyzer which removes water soluble toxins. Prospective randomized controlled trials of MARS treatment in acute-on-chronic hepatic failure have shown significantly improved patient survival compared to the control group (patients receiving conventional ICU care). A meta-analysis of MARS trials has shown that further studies are needed before a final judgment can be made regarding the superiority of the MARS treatment (Bosch, 2005).

Blood Pumps in Extracorporeal Circulation

The common factor in the extracorporeal circuits described in this chapter is the need for a pump to move the blood through the circuit. In apheresis and hemodialysis, roller pumps are used, as blood flow rates are relatively small and the flexible tubing required for pumping can be easily incorporated into a single-use tubing kit.

While a full discussion of the operating principles and efficiency of the pumps used in extracorporeal circulation lies beyond the scope of this chapter, mechanical pumping of the blood will have an effect on its condition, and may add to the complications of the procedure.

Roller Pumps

In a roller pump, a section of flexible tubing is mounted against a rigid outer support, as shown in Fig. 2.5.3.23. The rollers compress a section of tubing, preventing backflow, and pushing the blood forwards. The flow from a roller pump is pulsatile, which can have a beneficial effect on mass transfer, and if the rollers occlude the tubing completely, the flow rate is dependent on the speed of rotation of the roller head, and relatively independent of the back-pressure due to the flow resistance of the extracorporeal circuit.

The roller pump is very versatile, and flow can be reversed if this is desired. It has the disadvantage that it can damage the blood, due to high shear rates induced in the vicinity of the rollers during occlusion and particularly during the reopening of the tubing once the roller has passed. During reopening, there may be momentary backflows with very high velocities. High shear on the cell membranes can lead to premature aging of the red blood cells, which leads to aggregation and in extreme cases, to hemolysis of the red blood cells, releasing hemoglobin into the plasma.

Platelets and leukocytes are more susceptible to shear damage than red blood cells, and hence the mechanical trauma of pumping will add to the effects of blood–biomaterial contact, particularly platelet activation and leukopenia. The degree of trauma is considerably increased when high flow rates are needed—hence the roller pump is most often used in applications where flow rates are low, such as dialysis and apheresis.

Summary

Artificial lungs and kidneys save millions of lives each year via their treatment of acute and chronic organ failure. Their effectiveness is limited, however, by the negative interactions between blood and the artificial materials used to provide mass transfer within these devices. This results in clotting, inflammation, and increases in patient morbidity and mortality. These negative interactions have been significantly improved by new biomaterials that provide similar levels of mass transfer but a lesser degree of coagulation and inflammation. Despite this, a significant degree of innovation must occur before kidney dialysis has similar long-term outcomes as kidney transplantation and artificial lungs are capable of years of continuous support for patients with chronic lung diseases.

Chapter Exercises

1. What are the common disease states that might require the use of an artificial lung? What conditions require the most challenging requirements for respiratory support or blood–biomaterial interactions?
2. What is the dominant cause of coagulation in an ECMO circuit? Why is this the primary cause? What are some other causes?
3. Below is the schematic of the extracorporeal circuit used during cardiopulmonary bypass (CPB) when the heart is stopped to allow for surgical correction of cardiac defects (Fig. 2.5.3.24). This circuit is often described as a "heart–lung machine."
   a. What are the similarities and differences between CPB and ECMO surgeries and circuits?
   b. How will these differences increase or decrease activation of coagulation and inflammation?
   c. The vast majority of publications test commercial anticoagulant surface coatings during CPB or simulated CPB. Discuss the confounding factors present during CPB and how this might lead to misconceptions about the effectiveness of the coatings during ECMO?
4. In the study by Ladd et al., (2008) they evaluated hydrophilic and zwitterionic coatings on a gold surface using four types of biological media: (1) 10% serum, (2) 100% serum, (3) 10% plasma, and (4) 100% plasma (see Fig. 2.5.3.9).
   a. What is the fundamental difference between serum and plasma? How might this cause changes in the results?
   b. Is 10% plasma sufficient for evaluating these coatings? How might blood present additional challenges?
   c. Speculate on what these results say about surface coatings tested to examine the adsorption of single dilute proteins, such as albumin or fibrinogen?
5. What would be the total rate of nitric oxide delivery to the bloodstream in mL/min if it is delivered at a flux rate sufficient to significantly inhibit clot formation through a typical oxygenator?
6. Speculate on biocompatibility differences between peritoneal dialysis and hemodialysis. From your reading, what might be the differences in how these two treatment modes affect activation of coagulation and inflammation?
7. The typical hemodialysis blood flow rates were described as 200–400 mL/min through a dialyzer with a surface area of 0.8–2.5 m^2. Discuss how both the process of hemodialysis and the dialyzer design might be adjusted to reduce the duration of dialysis. What are the mitigating, negative consequences of these changes?
8. Discuss the similarities and differences between hemodialysis and ECMO and how these might affect the extent of coagulation and inflammation and their effects on the patients using these support modes.

2.5.4
Orthopedic Applications

NADIM JAMES HALLAB, JOSHUA J. JACOBS

Department of Orthopedic Surgery, Rush University Medical Center, Chicago, IL, United States

Orthopedic biomaterials are enormously successful in restoring mobility and quality of life to millions of individuals each year. Orthopedic implants include reconstructive implants, fracture management products, spinal products, rehabilitation products, arthroscopy products, electrical stimulation products, and casting products. These products are generally used for fracture fixation enhancement, joint replacement, or dynamic stabilization. More specific orthopedic applications within these categories are listed below.

(1) Fracture fixation devices
- Spinal fixation devices
- Fracture plates
- Wires, pins, and screws
- Intramedullary devices
- Artificial ligaments

(2) Joint replacement (Fig. 2.5.4.1)
- Hip arthroplasty
- Knee arthroplasty
- Spine arthroplasty
- Ankle arthroplasty
- Shoulder arthroplasty
- Elbow arthroplasty
- Wrist arthroplasty
- Finger arthroplasty

(3) Dynamic stabilization devices (new)
- Spine stabilization devices

Orthopedic Biomaterials Market: The overwhelming success of orthopedic biomaterials is exemplified by their worldwide market, dominating biomaterial sales at approximately $24 billion in 2007 with an expected growth rate of 7%–9% annually. Global sales of trauma fracture management products only totaled approximately $3.7 billion in 2007, whereas $10 billion was spent on knee and hip joint replacements (Fig. 2.5.4.1). Global sales of knee implant products equaled approximately $5.8 billion in 2007, representing approximately 1.5 million knee replacement surgeries which include first-time joint replacement procedures and revision procedures for replacement, repair, or enhancement of an implant product or component from a previous procedure. Revision procedures are growing at an accelerated rate of approximately 60% in the United States.

Orthopedic Biomaterials: Orthopedic biomaterials are generally limited to those materials that withstand cyclic load-bearing applications. While metals, polymers, and ceramics are used in orthopedics, it remains metals, which have over the years uniquely provided appropriate material properties such as high strength, ductility, fracture toughness, hardness, corrosion resistance, formability, and biocompatibility necessary for most load-bearing roles required in fracture fixation and total joint arthroplasty (TJA). The use of orthopedic biomaterials generally falls into one of three surgical specialty categories: upper extremity, spine, or lower extremity, and each specialty is typically divided into three general categories: pediatric, trauma, and reconstruction. Despite these numerous specialties and the hundreds of orthopedic applications there are only a few orthopedic metals, ceramics, and polymers which dominate all implants. Knowing the general properties, uses, and limitations of the "primary" orthopedic biomaterials is requisite to understanding what is required to improve the performance of current implant materials and why only a few dominate the industry. A summary of seven more prevalent orthopedic biomaterials and their primary use(s) are listed in Table 2.5.4.1.

Orthopedic Biomaterials Design: New biomaterials for orthopedic purposes face the same concerns present in current implants: (1) the material must not adversely affect its biological environment and (2) in return the material must not be adversely affected by the surrounding host tissues and fluids. (3) New materials must exceed the performance of present materials. Thus, understanding the interrelationship between the structure and properties of the natural tissues that are being replaced is important. An appreciation of the "form–function" relationship in calcified tissues will help provide insight into critical factors determining implant design as well as deciding which materials best meet a specific orthopedic need.

Structure and Properties of Calcified Tissues: There are several different calcified tissues in the human body and several different ways of categorizing them. All calcified

TABLE 2.5.4.1 Most Common Orthopedic Biomaterials

Material	Primary Use(s)
Metals	
Ti alloy (Ti–6%Al –4%V)	Plates, screws, TJA components (nonbearing surface)
Co–Cr–Mo alloy	TJA components
Stainless steel	TJA components, screws, plates, cabling
Polymers	
Polymethylmethacrylate (PMMA)	Bone cement
Ultra-high-molecular-weight-polyethylene (UHMWPE)	Low-friction inserts for bearing surfaces in TJA
Ceramics	
Alumina (Al_2O_3)	Bearing surface TJA components
Zirconia (ZrO_2)	Bearing surface TJA components

tissues have one thing in common: in addition to the principal protein component, collagen, and small amounts of other organic phases, they all have an inorganic component hydroxyapatite [abbreviated as OHAp, HA, or $Ca_{10}(PO4)_6(OH)_2$]. In the case of long bones such as the tibia or femur, an understanding of the organization of these two principal components is central to characterization. It has been convenient to treat the structure of compact cortical bone (e.g., the dense bone tissue found in the shafts of long bones) using four levels of organization.

The first level or molecular level of organization is the collagen triple helical structure (tropocollagen) and OHAp crystallography. It forms a hexagonal unit cell with space group symmetry P 6_3/m and lattice constants a = 9.880 Å and c = 6.418 Å, containing two molecular units, $Ca_5(PO4)_3OH$, per unit cell. How cells produce this mineral phase and whether it is the first calcium phosphate laid down are subjects of considerable research at present. Because of its small crystallite size in bone (approximately 2 nm × 20 nm × 40 nm), the X-ray diffraction pattern of bone exhibits considerable line broadening, compounding the difficulty of identifying additional phases. A Ca-bearing inorganic compound in one of the components of calcified tissues has led to the development of a whole class of ceramic and glass-ceramic materials that are osteophilic within the body (i.e., they present surfaces that bone chemically attaches to). As yet, we do not know fully how the two components, collagen and OHAp, are arranged and held together at this molecular level. Whatever the arrangement, when it is interfered with (as is apparently the case in certain bone pathologies in which the collagen structure is altered during formation), the result is a bone that is formed or remodeled with seriously compromised physical properties.

The second or ultrastructural level may be loosely defined as the structural level observed with transmission electron microscopy (TEM) or high-magnification scanning electron microscopy (SEM). Here too, we have not yet achieved a full understanding of the collagen–OHAp organization. It appears that the OHAp can be found both inter- and intrafibrillarly within the collagen. At this level, we can model the elastic properties of this essentially two-component system by resorting to some sort of linear superposition of the elastic moduli of each component, weighted by the percent volume concentration of each.

The third or microstructural level of organization is where these fibrillar composites form larger structures, fibers, and fiber bundles, which then pack into lamellar-type units that can be observed with both SEM and optical microscopy. The straight lamellar units forming the plexiform (lamellar) bone are found generally in young quadruped animals the size of cats and larger. This is the structural level that is described when the term "bone tissue" is used or when histology is generally being discussed. At this level, composite analysis can also be used to model the elastic properties of the tissue, thus providing an understanding of the macroscopic properties of bone. Unfortunately, this modeling is very complex and a complete description lies beyond the

scope of this chapter (and the authors). Interested readers are referred to some of the original sources (Katz, 1980a,b).

The fourth level is that of each of the macroscopic levels of each bone sample or large section of bone.

Since a significant portion of bone is composed of collagen, it is not surprising to find that in addition to being anisotropic and inhomogeneous, bone is also viscoelastic like all other biological tissues. Duplicating such properties with long-lasting synthetic biomaterials remains an unrealized goal of orthopedic biomaterials, where the history of implant development has been characterized by the elimination of available candidate materials based on their poor performance rather than production of biocompatible synthetic bone-mimetic materials.

Perhaps the best example of how orthopedic biomaterials have undergone implant design improvements over the past 100 years resulting in widespread success is total hip replacement (THR) or total hip arthroplasty (THA). While newer types of total joint arthroplasties such as those currently used for disc replacements (total disc arthroplasty, TDA) have benefitted from the arduous history of the total joint arthroplasty. Many if not all of the biomaterial-related issues (both mechanical and biological) that impact the performance of the THRs are applicable to other orthopedic implants. Therefore this chapter details the characteristics of where we come from using the total hip arthroplasty, and where we are using the example of current total disc arthroplasty designs, general current orthopedic materials technology, and future developments as a proxy of clinical concerns of orthopedic biomaterial development and current technology. The history of total hip arthroplasty is particularly pertinent to biomaterials science because it is one of the best illustrations of how an implant first used over a century ago has evolved to the highly successful status it has, primarily because of advances in biomaterials.

Biomaterials Development: A History of Total Hip Arthroplasty

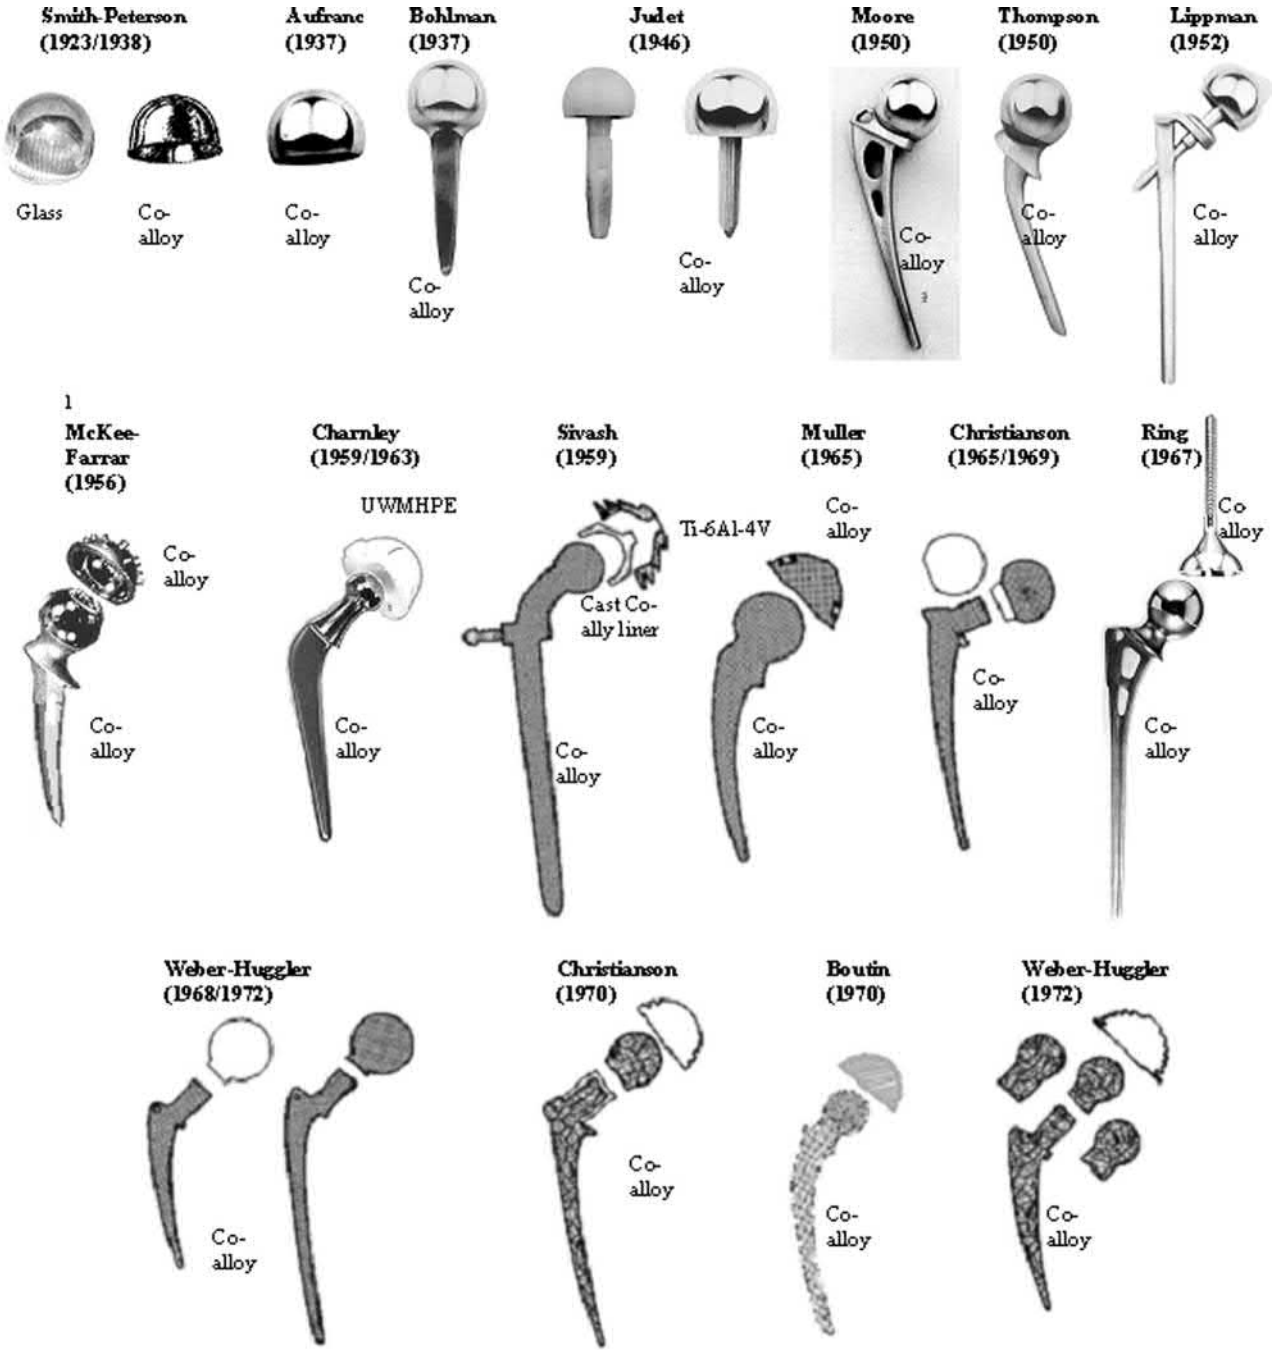
The earliest attempts to restore mobility to painful and deformed hip joints took place in the 1820s (Dr Charles White in 1822 and John Rhea Barton of Philadelphia in 1826 conducted the first osteotomy on patients with posttraumatic ankylosis) and centered on simply removing the affected femoral and actetabular bone involved. This evolved in the 1830–80s into ghastly attempts to restore mobility using interpositional membranes between the femoral head and acetabulum, where such materials as wooden blocks and animal (e.g., pig) soft tissue were tried. The first prosthetic hip replacement is dated to 1890, when Gluck published a description of a carved ivory femoral head replacement using bone-cement-like materials such as pumice and plaster of Paris to secure the implants in place (Walker, 1978; Stillwell, 1987).

The interpositional membrane strategy continued from the 19th into the 20th century where the use of new implant materials in the early 1900s (1900–20) included organic materials (e.g., pig bladders and periimplant soft tissues) and inorganic materials such as gold foil. The use of the individual's own soft tissues was the most popular method of interpositional membrane hip surgery. The limited success of this procedure prevented widespread use and thus the treatment of painful, disfigured, and "frozen" (ankylosed) hip joints remained commonplace into the 1920s.

Mold Arthroplasty: It was not until 1923 when Marius Smith-Peterson was credited with ushering in the modern era of total joint replacement with his development of the "mold" arthroplasty (Fig. 2.5.4.2), made of glass, inspired by a shard of glass found in a patient's back with a benign synovial-like membrane around it. This mold or cup arthroplasty was designed as a cup that fit in between the femoral head and the acetabular cup and articulated on both surfaces prompting a "tissue-engineered" synovial/cartilage-like layer. This was the first widespread attempt to develop a better interpositional membrane, a technique that had been in practice for the previous 100 years. The efforts of Smith-Peterson and his colleagues over the years from 1923 to 38 were spent improving the fracture resistance of the glass mold arthroplasty cup design using materials such as early polymers (e.g., celluloid or phenol-formeldehyde Bakelite or Formica) and improved glass, e.g., Pyrex. But it was not until 1939 when the first metal, a cobalt alloy termed Vitallium, was available and used by Venable, Stuck, and Beach that the corrosion resistance of the hip arthroplasty provided sufficient biocompatibility and performance (Fig. 2.5.4.2).

In 1937, Venable, Stuck, and Beach published a landmark article that was the first to analyze in a systematic fashion the electrolytic effects of various metals on bone and tissues (e.g., aluminum, copper, iron, nickel, lead, gold, magnesium, silver, stainless steel, and other alloys) and arrived at the conclusion that Vitallium (a cobalt–chromium alloy) was superior to the other metals in corrosion resistance and mechanical properties required for an implant (Charnley, 1979; Venable et al., 1937). By observing the effects of corrosion and proposing guidelines for performance Venable, Stuck, and Beach set the standard by which future metallic alloys were selected for use in hip and other types of implants.

The superior material properties of the Vitallium alloy facilitated further design modifications of the mold arthroplasty by Otto E. Aufranc (Fig. 2.5.4.2) where the rim of the Smith-Peterson mold was removed (which often was the cause of adhesions and cup "freezing," and subsequent pain and immobility) and matching curves on the inner and outer surface were machined to meet at the rounded outer edge. Despite the high short-term success rates (<4 years) reported by Aufranc (>82%), the overall failure rate remained high (>50%). Another design modification of the mold arthroplasty in the 1940s–50s was the fixation of the mold to the acetabulum rim with screws, by such physicians as Albee-Pearson and Gaenslen. Although used in only four cases, Gaeslen reported using a cobalt alloy mold fixed to the acetabulum and another fixed to the femoral head creating a metal-on-metal total hip replacement. The popularity of mold arthroplasties endured into the 1970s when they



• **Figure 2.5.4.2** The history of total hip arthroplasty is particularly pertinent to biomaterials science because it is one of the best illustrations of how an implant first used over a century ago has evolved to the highly successful status it has, primarily because of advances in biomaterials.

remained touted as the treatment of choice for traumatic arthritis of the hip by leading orthopedic surgeons (Harris, 1969). However back in the 1930s the natural progress in THA development was the progression from mold arthroplasty to short-stem prostheses.

Femoral Head Prostheses/Short-Stem Prostheses: Femoral head prosthetics were first made of such materials as ivory (Dr. Themistocles Gluck in 1890 Berlin) and rubber (French surgeon Dr. Pierre Delbet in 1919) and were cemented (using a plaster-like cement) for stability (Walker, 1978; Stillwell, 1987). At about the same time these replacement heads were first fitted with a short stem by Earnest Hey Groves who used an ivory nail to replace the articular surface of the femur. These types of implants were rare and remained unpopular compared to mold arthroplasties until 1937 when Harold Bohlman, using the work of Venable and Stuck, designed a corrosion resistant cobalt–chrome alloy femoral head replacement with a short stem. This design was popularized by the Judet brothers in Paris in 1946, who used polymethylmethacrylate (PMMA), which was presumed biologically inert in vivo, to manufacture short-stemmed prostheses (Fig. 2.5.4.2). Initial good results were soon replaced with

problems of implant fracture and excessive wear debris, and by the early 1950s these implants were losing favor and being removed by surgeons. Vitallium (cobalt–chrome alloy) eventually replaced acrylic in several other short-stem designs. However, there were sound short-stem designs as early as 1938 when Wiles introduced the cobalt alloy femoral shell attached to the femur with a central nail. This design was later popularized by Peterson in 1950, when he used a similar Vitallium shell design with a central nail and a plate attached to the nail for added stability. Others adopted and adapted the Judet brothers' design using Vitallium, such as J. Thompson (1951) and Rossignal (1950). Rossignal designed large threads onto the stem to aid in fixation. These short-stem designs were subject to what was deemed high shear stress and resulted in early loosening and failure in some patients. Short-stem designs were gradually replaced by longer stem designs that provided less stress concentration.

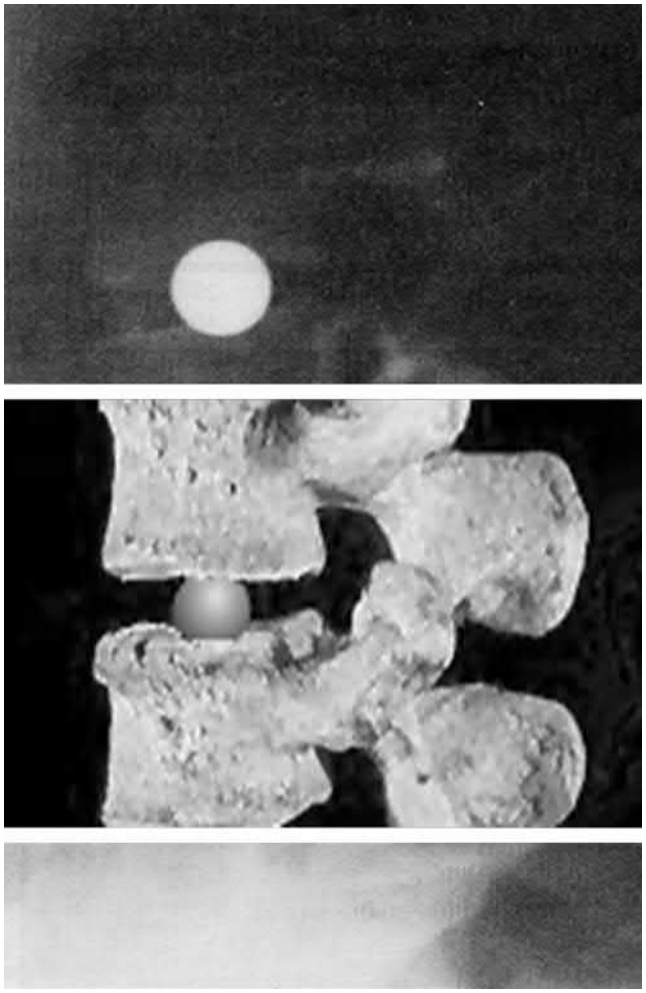
Long-Stem Prostheses: Long-stem prostheses continued the trend established by short-stemmed prostheses, that is, more and more weight-bearing forces were transferred to the femur though an intramedullary stem. The pattern for a long-stem prosthesis was established in 1940 by Bohlman in collaboration with Austin T. Moore in which they implanted a 12-inch Vitallium prosthesis that replaced the femoral head and had long supports that were screwed into the outside of the femoral shaft (Moore, 1943). And while there were innovations in long-stem design in the 1940s, such as the door knob design of Earl McBride, where a threaded stem was screwed into the intramedullary canal of the femur for fixation and load transferral, these designs were not popular. In was not until 1950 with the designs of Frederick R. Thompson and Austin T. Moore that long-stemmed prostheses became popular (Fig. 2.5.4.2). These designs were cast in Vitallium (cobalt–chrome alloy) and required the removal of the femoral head but only part of the neck. The design of Moore differed from that of Thompson in that it had fenestrations through the implant to allow bone growth and it had a rear vane to enhance rotational stability. Initially these implants were used without bone cement. Evidence for the successful designs of the Thompson and Moore prostheses is proved by their continued use with only slight variations from the original. Despite the excellent design of these early long-stemmed prostheses they were primarily successful when used in place of diseased femoral heads and did not work well when acetabular reaming was required. Therefore, this inadequacy prompted the development of the total hip replacement arthroplasty.

Total Hip Replacement Arthroplasty: Philip Wiles is credited with the first total hip arthroplasty in 1938 when he used a stainless steel ball secured to the femur with a bolt and a stainless acetabular liner secured with screws (Wiles, 1953). The results of this design were disappointing because of the poor corrosion resistance of early stainless steel in vivo, and the high stress concentrations of short-stemmed prostheses. An adaptation of this design that proved successful was developed by G.K. McKee and J. Watson-Farrar in 1951. They used a stainless steel cup and long-stemmed prosthesis (Thompson stem) which failed rapidly due to the poor corrosion resistance of the stainless steel, and was then changed to cobalt–chrome alloy with greater success. The McKee-Farrar prosthesis evolved quickly to incorporate a true spherical femoral head that was undercut at the neck to reduce the impingement of the head on the rim of the acetabular prosthesis and provide for a greater range of mobility (Fig. 2.5.4.2) (McKee and Watson-Farrar, 1943).

The next milestone in the evolution of modern total hip arthroplasty was the advent/popularization of acrylic dental bone cement, first used by Sven Kiar in 1950 to attach a plastic prosthesis to bone (Charnley, 1964). Later that year the Hospital for Joint Diseases in New York used polymethylmethacrylate (acrylic) bone cement as a means of fixation in total hip arthroplasties (Wilson and Scales, 1970; Charnley, 1960). The development of acrylic bone cement dramatically reduced the rates of loosening associated with metal–metal total hip arthroplasty. The Stanmore metal–metal design, which used a horseshoe-shaped cup, was popular but led to excessive wear and was replaced by a complete cup. McKee and Watson-Farrar adapted their design to facilitate bone cement with a land-mine-like studded acetabular cup intended to maximize mechanical fixation.

The 1950s marked the introduction and popularization of the total hip arthroplasty when it became simple and reliable enough to be practiced on a wide scale by the average orthopedic surgeon. However, the squeaking reported to occur in Judet and some later metal prostheses was identified by Charnley to be a result of the relatively high frictional forces in the joint. These high torque and frictional forces resulted in the generation of significant metallic debris which purportedly resulted in early loosening. In 1960, Charnley developed a "low-friction arthroplasty" device using shells of polytetraflourothylene (PTFE; commonly called Teflon in related publications) on the femoral and acetabular sides, which resulted in early/immediate failures because of the massive debonding and wear debris. This was quickly followed by a thick-walled Teflon acetabular component articulating on a small head designed to reduce the shearing forces and torque. However, this design also generated excessive wear debris, which produced immediate and severe inflammation and failure of the prosthesis. Charnley then replaced the Teflon with high-density polyethylene which was not as friction-free as Teflon but was 1000 times more wear resistant. This prototype of total hip arthroplasty developed in 1962 was the basis for future designs, which remain the most popular form of total hip arthroplasty performed today (Fig. 2.5.4.2).

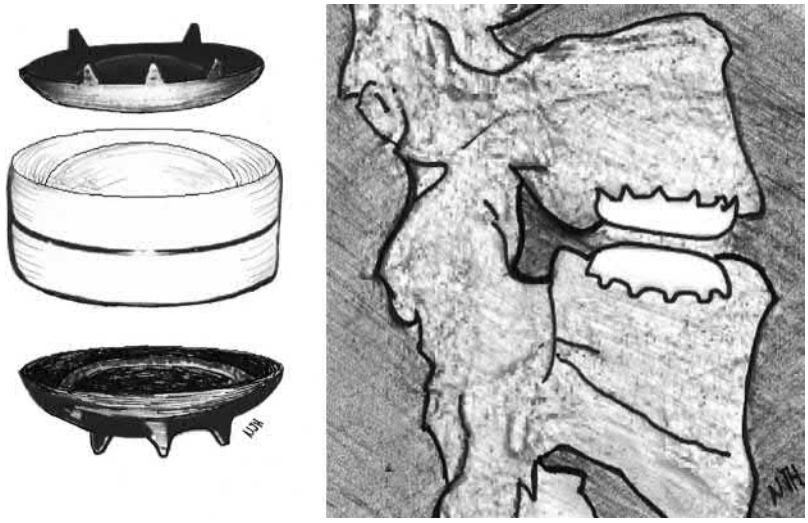
The basic design of Charnley was modified by Muller with variable neck sizes and larger heads. At the same period metal-on-metal designs by Smith, Ring, and others (Ring, 1968) were unsuccessful challengers to the basic Charnley metal-on-polymer design. Other currently adopted design modifications were developed by Ling, Aufranc, Turner, Amstutz, Harris, and Galante, which include such innovations as femoral prosthesis geometrical modification for increases in stability and mobility, modular components for increased customization, porous coatings, surface texturing/coating to



• **Figure 2.5.4.3** Fernström ball implants (stainless steel metal spheres) were the first disc arthroplasties. (Courtesy of BioEngineering Solutions Inc.)

increase fixation and bone ingrowth, etc. Charnley is often deified in orthopedic literature as the metaphorical spark that lit the flames of innovation in prosthetic design. This is a typical surgeon-centered overglorification. For one thing other implant designs which predate Charnley, such as the all-metal McKee-Farrar THA implant, have enjoyed similar success rates to those reported by Charnley. More importantly, total hip arthroplasty is, perhaps, the best example of how orthopedic biomaterials and implant success have evolved over the last century through the innovation and hard work of many scientists and physicians and advances in areas of materials technology, biomechanics, biochemistry, immunology, infectious diseases, thrombosis, and pharmacology to name a few.

In contrast to THA, total disc arthroplasty (TDA) is a relatively recent development and, despite clinical use over the past 10 years, it has yet to become a mainstream option for treating disc degeneration when compared with fusion. Spinal fixation device usage is steadily increasing, where the number of cervical and lumbar fusions increased 111% from 1993 to 2003 to roughly 105 fusions per 100,000 people in the United States, which is about 305,000 fusions per year (Cowan Jr. et al., 2006). The ultimate goal of intervertebral disc replacement technology is to replace spine fusion, eliminate pain, and restore structure and mobility. The first disc arthroplasties were cobalt-alloy spheres implanted as early as 1957 between vertebrae without any method of fixation (Harmon, 1963). A decade later stainless steel metal spheres termed Fernström balls (Fig. 2.5.4.3) were used in 103 patients starting in 1969 (McKenzie Alvin, 1995; Fernstrom, 1966). Others clinicians around the same time tried using polymer balls made of polymethyl methacrylate but the results were disastrous (Hamby and Glaser, 1959). The era of modern disc arthroplasty began in 1982, the first functional artificial intervertebral disc, the SB Charité, at the Charité hospital in Berlin (Fig. 2.5.4.4) (Büttner-Janz, 1992). This design was that using the low-friction

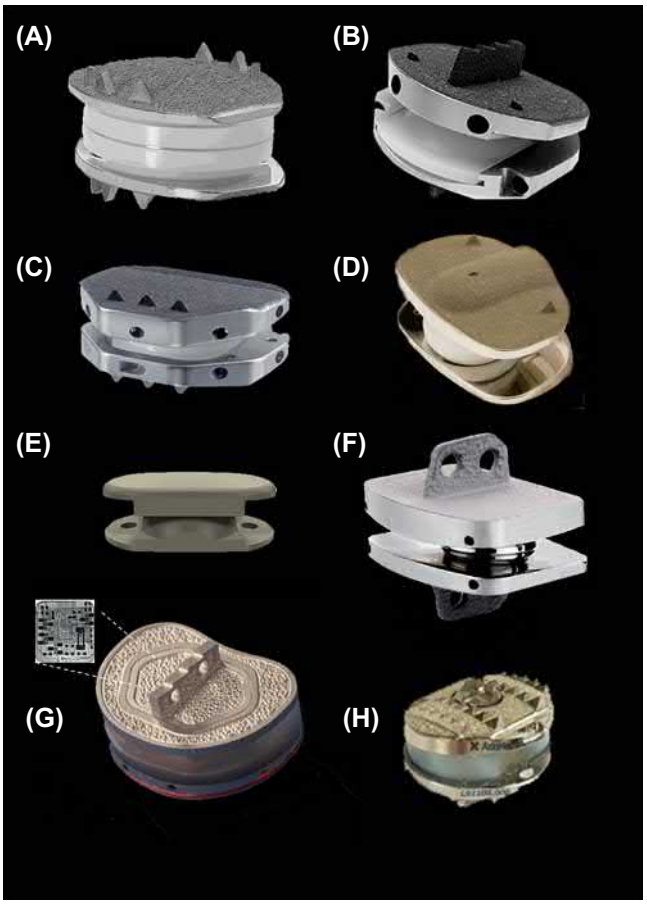


• **Figure 2.5.4.4** In 1982, Schellnack and Büttner-Janz developed the SB Charite artificial disc, which consisted of a UHMWPE sliding core articulating unconstrained between two highly polished stainless steel metal endplates. (Courtesy of Bioengineering Solutions Inc., Oak Park, IL.)

arthroplasty principle of John Charnley's, which by that time was successful used in total hip replacement for over 20 years. The Charitè TDA consisted of a UHMWPE sliding core, which articulates between two metal endplates with multiple teeth-like projections for fixation to the vertebral endplates (Fig. 2.5.4.4). In general, current TDA designs have a TKA-like primary articulation (or motion) using polymer-on-metal, polymer-on-polymer, metal-on-metal, or some form of an all-elastic core technology. The long-term clinical success of many current total disc arthroplasty designs with motion-preserving properties remains under close evaluation (Fig. 2.5.4.5).

Current Biomaterials in Total Arthroplasty

Today, the archetype of the total hip implant remains much as it was in the 1970s, albeit with more variety of implant materials and geometries. Current THA is typically constructed of a titanium or cobalt–chromium alloy femoral stem (cemented with polymethylmethacrylate, PMMA, or press fit into place, connected to a "modular" cobalt–chrome alloy or ceramic head that articulates on an ultrahigh-molecular-weight polyethylene (UHMWPE) or ceramic acetabular cup fitted into a titanium or cobalt–chromium cup liner which is cemented, screwed, or press-fit into place. Despite this simple archetype of the total hip replacement there exist hundreds of variations on this theme offered to today's orthopedic surgeons, with little in terms of absolute guidelines as to which type of implant is (or which of the over 10 major manufacturers has) the best for well-defined orthopedic disease states. However, there are some general guidelines. Typically, implants in older individuals (>80 years of age) are cemented into place with PMMA bone cement, because the chance for revision is minimal when compared to younger individuals (<60 years) and removing bone cement is both technically challenging and may compromise the availability of bone stock. Generally, there are choices of surface roughness, coatings, geometry, material composition, etc. and each manufacturer claims that its product is superior to the rest. This, in combination with little to no publicly available information tracking the performance of each type of implant in patients, precludes accurate scientific analysis of which implant materials and design perform best. Additionally, competition between manufacturers and the requisite attention to marketing required to compete in the marketplace has resulted in a dizzying array of new implants released each year claiming to be improved over the previous year's model. These claims are suspect, because the typical total hip replacement enjoys a success rate of over 90% at 7 years, therefore, in most cases a minimum of 7–10 years must transpire before such claims can be substantiated, and even then proof of superior performance is compromised by a myriad of external factors such as surgeon, region of the country, average activity of patient populations, etc. This conflict between science, marketing, and market share may (in the opinion of this author) represent the single biggest obstacle to the scientific



• **Figure 2.5.4.5** Lumbar total disc replacements include metal-on-polymer, metal-on-metal, polymer-on-polymer, and flexible core technologies. (A) Metal-on-polymer articulation: the *LINK SB Charité III* (DePuy Spine) cobalt chrome alloy endplates articulate on a mobile bearing ultrahigh-molecular-weight polyethylene core. The endplates are covered with an osteoconductive surface of titanium/calcium-phosphate double coating under the trade name "TiCaP" (B) Metal-on-polymer articulation: The Prodisc (Synthes) lumbar TDR is composed of cobalt–chrome–molybdenum alloy and covered with a porous titanium alloy and articulates on a central core of UHMWPE. (C) Metal-on-polymer articulation: ActivL (Aesculap) uses a polymeric center core intended to allow both translation and rotation and to more closely approximate physiological motion. (D) Metal-on-polymer articulation: Dynardi (Zimmer) is a disc replacement implant with two opposing Co-alloy (Co–Cr–Mo) endplates coated with porous pure titanium for bone ingrowth, that articulate on a semiconstrained UHMWPE core. (E) Polymer-on-polymer articulation: NUBAC (Pioneer Surgical) is a polymer-on-polymer disc arthroplasty device and the first polyetheretherketone (PEEK)-on-PEEK articulated disc arthroplasty device. (F) Metal-on-metal articulation: The Maverick Disc (Medtronic) uses metal-on-metal articulation where the end plates are constructed of Co-alloy. (G) Elastic core articulation: The Theken eDisc (Theken Disc) represents another step in the evolution of orthopedic implant devices, in that as well as containing an elastic polyurethane-based core it provides measured in vivo load information to the surgeon and patient via electronic sensors and transmitters. (H) Elastic core articulation: The Freedom Lumbar Disc (Axiomed) uses a viscoelastic polymer (like polyurethane) to replicate the native function of a natural disc. The elastic core in combination with the implant design provides a three-dimensional motion that functions within the natural biomechanics of the spine. (Courtesy of DePuy Spine Inc, Medtronic, Spine Solutions Inc., and BioEngineering Solutions Inc.)

determination of superior implant design and progress. The unenviable responsibility rests with the FDA to prevent the zeal of economic pressure from undermining implant design in a regressive fashion. Today optimal implant selection is moving toward which material couple may best suit the individual from a biocompatibility standpoint (as described later) (Fig. 2.5.4.6).

Polymers: Polymers are most commonly used in orthopedics as articulating bearing surfaces of joint replacements (Fig. 2.5.4.3) and as an interpositional cementing material between the implant surface and bone (Fig. 2.5.4.4). Polymers used as articulating surfaces must have low coefficients of friction and low wear rates when in articulating contact with the opposing surface, which is usually made of metal. Initially, John Charnley used Teflon (PTFE) for the acetabular component of his total hip arthroplasty (Fig. 2.5.4.2). However, its accelerated creep and poor stress corrosion (for the material he used) caused it to fail in vivo, requiring replacement with his ultimate choice, ultrahigh-molecular-weight polyethylene (UHMWPE).

Polymers used for fixation as a structural interface between the implant component and bone tissue require appropriate mechanical properties of a polymer, which can be molded into shape and cured in vivo. The first type to be used, polymethylmethacrylate (PMMA), was again popularized by Charnley's who borrowed from the field of dentistry. He adapted dental PMMA as a "grouting" material to fix both the stem of the femoral component and the acetabular component in place, and thus distribute the loads more uniformly from the implants to the bone. Since high interfacial stresses result from the accommodation of a high-modulus prosthesis within the much lower modulus bone, the use of a lower modulus interpositional material has been a goal of alternatives seeking to improve upon PMMA fixation. Thus, polymers such as polysulfone have been tried as porous coatings on the implant's metallic core to permit mechanical interlocking through bone and/or soft tissue ingrowth into the pores. However, to date, PMMA remains the method of choice for orthopedic surgeons. This requires that polymers have surfaces that resist creep under the stresses found in clinical situations and have high enough yield strengths to minimize plastic deformation. As indicated earlier, the important mechanical properties of orthopedic polymers are yield stress, creep resistance, and wear rate. These factors are controlled by such parameters as molecular chain structure, molecular weight, and degree of branching or (conversely) of chain linearity.

One of the more prevalent polymerics used in orthopedics today is a highly cross-linked UHMWPE, which is typically used in total joint arthroplasty as a load-bearing articulating surface, designed to provide low-friction load-bearing articulation. Polyethylene is available commercially in three different grades: low-density, high-density, and UHMWPE. The better packing of linear chains within UHMWPE results in increased crystallinity and provides improved mechanical properties required for orthopedic use even though there is a decrease in both ductility and fracture toughness. In total hip arthroplasty applications, an acetabular cup of UHMWPE typically articulates against a femoral ball of cobalt–chromium alloy. The predominant problem presented by these metal–polymer articulating surfaces is the production of wear particles, i.e., polymer debris. The resultant wear of the polyethylene bearing purportedly produces billions of submicron-sized wear particles annually, in the <1–10 micron range. Producing greater cross-linking of polyethylene, using chemical and radiation techniques, has only recently improved its wear resistance in orthopedic applications. Wear tests have shown that the wear resistance of UHMWPE is improved by cross-linking with gamma irradiation at 2.5–5.0 Mrad and below as evidenced by simulator studies, however this can negatively affect such physical properties as tensile strength (McKellop et al., 2000). Therefore, care must be taken to minimize any negative oxidative effects, while preserving high wear characteristics. Although newer more highly cross-linked polyethylene has generally been accepted as superior to previous implant UHMWPE, there remains incomplete data regarding its ultimate long-term performance. In order to maximize the performance characteristics of polyethylene it is cross-linked prior to fabrication into its final form, e.g., an

acetabular cup. Typically, an extruded bar of polyethylene is cross-linked using conventional gamma irradiation and then heat treated to reduce residual free radicals.

Ceramics: In recent years, ceramics and glass ceramics have played an increasingly important role in implants. Although used in Europe for over a quarter century, only relatively recently (February 3, 2003), has the FDA approved the first ceramic-on-ceramic bearing hip implant to be used in total hip replacement procedures (Fig. 2.5.4.5). The primary reason for the introduction of this alternative bearing surface is the superior wear resistance of ceramics when compared to metal–metal or metal–polymer bearing surfaces. This and other improved properties such as resistance to further oxidation (implying inertness within the body), high stiffness, and low friction require the use of full-density, controlled, small, uniform grain size (usually less than 5 μm) ceramic materials. The small grain size and full density are important since these are the two principal bulk parameters controlling the ceramic's mechanical properties. Any voids within the ceramic's body will increase stress, degrading the mechanical properties. Grain size controls the magnitude of the internal stresses produced by thermal contractions during cooling. In ceramics, such thermal contraction stresses are critical because they cannot be dissipated as they can in ductile materials via plastic deformation.

Alumina (Al_2O_3) and zirconia (ZrO_2) ceramics have been used in orthopedic THA for the past 30 years, The first ceramic couple (alumina/alumina) was implanted in 1970 by Pierre Boutin. Since the outset the theoretical advantage of hard-on-hard articulating surfaces was low wear. Ceramics, because of their ionic bonds and chemical stability, are also relatively biocompatible. Initial concerns about fracture toughness and wear have been addressed by lowering grain size, increasing purity, lowering porosity, and improving manufacturing techniques (e.g., hot isostatic pressing, HIP). Early failures of these couples were plagued with both material-related and surgical errors. The very low wear rates combined with steadily decreasing rates of fracture (now estimated to occur to one in 2000 over 10 years) have resulted in the growing popularity of all ceramic bearings.

Zirconia was introduced in 1985, as a material alternative to Al_2O_3 for ceramic femoral heads, and was gaining market share because of its demonstrable enhanced mechanical properties in the laboratory when compared to alumina. Femoral heads of zirconia can typically withstand 250 kN (or 25 tons), a value generally exceeding that possible with alumina or metal femoral heads. However, the mechanical integrity of all ceramic components is extremely dependent on manufacturing quality controls as evidenced in the recall of thousands of zirconia ceramic femoral heads, by their manufacturer St. Gobain Desmarquest in 2001. This was because of in vivo fracture of some components due to a slight unintended variation in the manufacturing sintering process caused when the company bought a newer high-throughput assembly line type oven. In general ceramic particulate debris is chemically stable and biocompatible and causes untoward biologic responses at high concentrations.

There have been recent attempts to take advantage of the osteophilic surface of certain ceramics and glass ceramics. These materials provide an interface of such biological compatibility with osteoblasts (bone-forming cells) that these cells lay down bone in direct apposition to the material in some form of direct chemicophysical bond. Special compositions of glass ceramics, termed bioglasses, have been used for implant applications in orthopedics. The model proposed for the "chemical" bond formed between glass and bone is that the former undergoes a controlled surface degradation, producing an SiO-rich layer and a Ca,P-rich layer at the interface. Originally amorphous, the Ca,P-rich layer eventually crystallizes as a mixed hydroxycarbonate apatite structurally integrated with collagen, which permits subsequent bonding by newly formed mineralized tissues. There is still an entirely different series of inorganic compounds that also have been shown to be osteophilic. These include OHAp, which is the form of the naturally occurring inorganic component of calcified tissues, and calcite, CaCO, and its Mg analog, dolomite, among others being studied. The most extensive applications in both orthopedics and dentistry have involved OHAp. This has been used as a cladding for metal prostheses for the former, and in dense, particulate form for the latter. The elastic properties of OHAp and related compounds are compared with those of bone, dentin, and enamel in Table 2.5.4.2. The use of both OHAp and the glass ceramics as claddings on the metallic stems of hip prostheses is yet another method of providing fixation instead of using PMMA. In these cases, the fixation is via the direct bonding of bone to the cladding surface.

Metals: Since the principal function of the long bones of the lower body is to act as load-bearing members, it was reasonable that the initial materials introduced to replace joints, such as artificial hips, were metals. Both stainless steel, such as 316L, and Co–Cr alloys became the early materials of choice, because of their relatively good corrosion resistance and reasonable fatigue life within the human body. Of course, their stiffness, rigidity, and strength, exceeded those of bone considerably. However, in certain applications, owing to size restrictions and design limitations (e.g., in rods used to straighten the spine in scoliosis), fatigue failures did occur. Metals remain the central material component of state-of-the-art total hip arthroplasties. Metals provide appropriate material properties such as high strength, ductility, fracture toughness, hardness, corrosion resistance, formability, and biocompatibility necessary for use in load-bearing roles required in fracture fixation and total joint arthroplasty (TJA). Implant alloys were originally developed for maritime and aviation uses where mechanical properties such as high strength and corrosion resistance are paramount. There are three principal metal alloys used in orthopedics and particularly in total joint replacement: (1) titanium-based alloys, (2) cobalt-based alloys, and (3) stainless steel alloys. Alloy-specific differences in strength, ductility, and hardness generally determine which of these three alloys is used for a particular application or implant component. However it is the high corrosion resistance of

all three alloys, more than anything, which has lead to their widespread use as load-bearing implant materials. These material properties of metals (Table 2.5.4.2) are due to the miraculous nature of the metallic bond, molecular microstructure, and elemental composition of metals.

Stainless Steel Alloys: Stainless steels were the first metals to be used in orthopedics in 1926. However, it was not until 1943 when ASTM 304 was recommended as a standard implant alloy material that steels were reliable as an implant alloy. All steels are comprised of iron and carbon and may typically contain chromium, nickel, and molybdenum. Trace elements such as manganese, phosphorous, sulfur, and silicon are also present. Carbon and the other alloy elements affect the mechanical properties of steel through alteration of its microstructure.

The form of stainless steel most commonly used in orthopedic practice is designated 316LV (American Society for Testing and Materials F138, ASTM F138 others include F139, F899, F1586, F621 etc). "316" classifies the material as austenitic, and the "L" denotes the low carbon content and "V" the vacuum under which it is formed. The carbon content must be kept at a low level to prevent carbide (chromium-carbon) accumulation at the grain boundaries.

Although the mechanical properties of stainless steels are generally less desirable than those of the other implant alloys (lower strength and corrosion resistance), stainless steels do possess greater ductility indicated quantitatively by a threefold greater "percentage of elongation at fracture" when compared to other implant metals (Table 2.5.4.2). This aspect of stainless steel has allowed it to remain popular as a material for cable fixation components in total knee arthroplasty, and a low-cost alternative to Ti and Co alloys.

Cobalt–Chromium Alloys: Of the many Co–Cr alloys available, there are currently only two predominantly used as implant alloys (Table 2.5.4.3). These two are (1) cobalt–chromium–molybdenum (CoCrMo), which is designated ASTM F-75 and F-76 and (2) cobalt–nickel–chromium–molybdenum (CoNiCrMo) designated as ASTM F-562. Other Co-alloys approved for implant use include one which incorporates tungsten (W) (CoCrNiW, ASTM F-90) and another with iron (CoNiCrMoWFe, ASTM F-563). Co–Ni–Cr–Mo alloys, which contain large percentages of Ni (25%–37%), promise increased corrosion resistance, yet raise concerns of possible toxicity and/or immunogenic reactivity (discussed later) from released Ni. The biologic reactivity of released Ni from Co–Ni–Cr alloys is cause for concern under static conditions, and due to their poor frictional (wear) properties Co–Ni–Cr alloys are also inappropriate for use in articulating components. Therefore, the dominant implant alloy used for total joint components is Co–Cr–Mo (ASTM F-75).

Cobalt alloys are generally cast into their final shape because they are susceptible to work-hardening at room temperatures. That is, the improvements in strength and hardness gained by cold working are not worth the loss in fracture toughness. Thus Co–Cr–Mo alloy hip implant components are predominantly manufactured using lost wax (investment) casting methods.

Although Co–Cr–Mo alloys are the strongest, hardest, and most fatigue resistant of the metals used for joint replacement components, care must be taken to maintain these properties because the use of finishing treatments can also function to reduce these same properties (Table 2.5.4.2). For example, sintering of porous coatings onto femoral or tibial TJA Co–Cr–Mo stems can decrease the fatigue strength of the alloy from 200–250 to 150 MPa after heating (annealing) the implant at 1225°C.

Titanium Alloys: Titanium alloys were developed in the mid 1940s for the aviation industry and were first used in orthopedics around the same time. Two post-World War II alloys, commercially pure titanium (CPTi) and Ti–6Al–4V, remain the two dominant titanium alloys used in implants. Commercially pure titanium (CPTi, ASTM F67) is 98%–99.6% pure titanium. While CPTi is most commonly used in dental applications, the stability of the oxide layer formed on CPTi (and consequently its high corrosion resistance; Table 2.5.4.4) and its relatively higher ductility (i.e., the ability to be cold worked) compared to Ti–6Al–4V, has led to the use of CPTi in porous coatings (e.g., fiber metal) of TJA components. Generally, joint replacement components (i.e., TJA stems) are made of Ti–6Al–4V (ASTM F-136) rather than CPTi, because of its superior mechanical properties (Table 2.5.4.2).

Titanium alloys are particularly good for THA components because of their high corrosion resistance compared with stainless steel and Co–Cr–Mo alloys. A passive oxide film (primarily of TiO_2) protects both Ti–6Al–4V and CPTi alloys. Generally Ti–6Al–4V has mechanical properties that exceed those of stainless steel, with a flexural rigidity less than stainless steel and Co–Cr–Mo alloys. The torsional and axial stiffness (moduli) of Ti alloys are closer to those of bone and theoretically provide less stress shielding than do Co alloys and stainless steel. However, titanium alloys are particularly sensitive to geometrical factors, in particular notch sensitivity. This reduces the effective strength of a component by increasing the material's susceptibility to crack propagation through the component. Therefore, care is taken both in the design geometry and in the fabrication of Ti alloy components. Perhaps the greatest drawback to Ti alloys is their relative softness compared to Co–Cr–Mo alloys (Table 2.5.4.2) and their relatively poor wear and frictional properties. Ti–6Al–4V is >15% softer than Co–Cr–Mo alloys and also results in significantly more wear than Co–Cr–Mo when used in applications requiring articulation, e.g., TKA or THA femoral heads. Thus Ti alloys are seldom used as materials where hardness or resistance to wear is the primary concern.

Zirconium and Tantalum Alloys: Zirconium (Zr) and tantalum (Ta) are characterized as refractory metals (others include molybdenum and tungsten) because of their relative chemical stability (passive oxide layer) and high melting points. Because of its high strength, chemical stability, and resistance to wear, alloys, such as Zr (e.g., Oxinium), are likely to gain popularity as orthopedic biomaterials. Because of their surface oxide layer's stability, Zr and Ta are highly corrosion resistant. Corrosion resistance generally correlates with biocompatibility (although not always)

**, No current ASTM standard; The corrosion potential represents the Open Circuit Potential (OCP) between the metal and a calomel electrode. The more negative the OCP, the more chemically reactive and thus the less corrosion resistance. Generally low current density indicates greater corrosion resistance. The higher the breakdown potential the better (i.e., the more elevated the breakdown potential, the more stable the protective layer).

• **Figure 2.5.4.7** Examples of new THA and TKA oxidized zirconium components currently gaining popularity because of enhanced mechanical and biocompatibility properties (Oxinium, Smith and Nephew Inc., Memphis, TN). (Courtesy of Smith and Nephew Inc.)

because more stable metal oxides tend to be less chemically active and/or biologically available and are thus less participatory in biologic processes. This enhanced biocompatibility is produced by the relatively thick surface oxide layer (approximately 5 μm) and the ability to extend ceramic-like material properties (i.e., hardness) into the material through techniques such as oxygen enrichment has resulted in the production of new implant components using these alloys (Fig. 2.5.4.7; e.g., Oxidized Zirconium TKA femoral components, Smith and Nephew Inc.). Although Zr alloys such

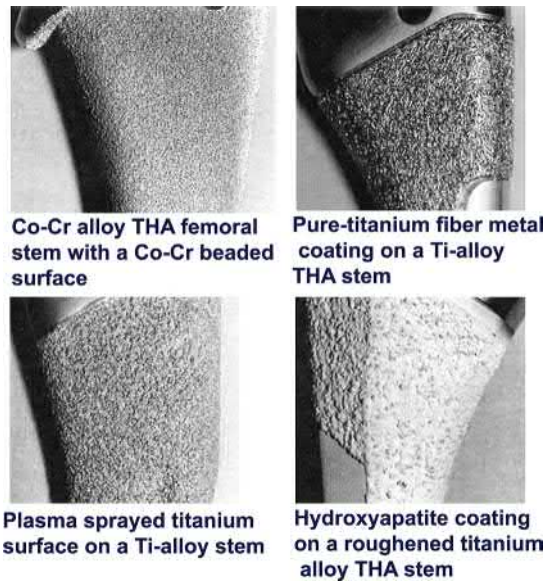
as Oxinium generally possess high levels of hardness (12 Gpa) and wear resistance (approximately 10-fold that of Co and Ti alloys, using abrasion testing), which makes them well suited for bearing surface applications, they are costly to manufacture and currently are sought after in special circumstances where issues such as a metal-allergy (or more accurately metal-hypersensitivity) require particular attention to biocompatibility. As difficulties associated with the cost of forming and machining these metals are overcome the use of these materials is expected to grow (Black, 1992).

Surfaces and Coatings: A variety of surface coatings are currently used to enhance the short- and long-term performance of implants by encouraging bone ingrowth and providing enhanced fixation. These different surfaces include roughened titanium, porous coatings made of cobalt chromium or titanium beads, titanium wire mesh (fiber mesh), plasma-sprayed titanium, and bioactive nonmetallic materials such as hydroxyapatite or other calcium phosphate compositions (Fig. 2.5.4.8). Currently, osteoconductive and osteoinductive growth factors such as transforming growth factor beta (TGF-beta) are being developed for use as osteogenic surface coating treatments to enhance orthopedic implant fixation.

Orthopedic Biomaterials: Clinical Concerns

Implant biocompatibility/performance is dependent on the type and amount of degradation produced by wear and electrochemical corrosion. The host response to orthopedic implants debris is central to clinical performance (Willert and Semlitsch, 1977). Implant loosening due to aseptic osteolysis accounts for over 75% of TJA implant failure and is the predominant factor limiting the longevity of current total joint arthroplasties; other reasons include infection (7%), recurrent dislocation (6%), periprosthetic fracture (5%), and surgical error (3%) (Holt et al., 2007). Properly positioned implants tend to wear at predictable rates. However, there are variable amounts of debris-induced bone loss around implants in patients with similar rates of implant wear (i.e., debris generation). It is commonly noted that some individuals with severely worn components can demonstrate little periprosthetic bone loss, while others with modest amounts of wear can demonstrate extensive osteolysis and implant loosening (Harris, 1995; Jacobs et al., 1992; Jasty et al., 1994; Huk et al., 1994; Schmalzried et al., 1994; Granchi et al., 1998b; Thompson and Puleo, 1995; Jones et al., 1999; Yao et al., 1995; Goodman et al., 1998; Huo et al., 1992; von Knoch et al., 2000; Willert et al., 1990). Debris-induced immune reactivity, aseptic inflammation, and subsequent early failure can be as high as 4%–5% at 6–7 years post op in current-generation metal-on-metal total hip arthroplasties (Jacobs and Hallab, 2006; Koroveseis et al., 2006; Milosev et al., 2006). The benefits provided to patients by orthopedic implants in terms of pain, mobility, and quality of life are immeasurable. Therefore, the following sections which focus on the problems associated with implants seeks to provide the student of biomaterials a foundation for understanding the relevant issues for orthopedic research and is not intended to serve as an indictment of orthopedic materials.

Despite their overwhelming success over the long term (>7 years), orthopedic biomaterials have been associated with adverse local and remote tissue responses. It is generally the degradation products of orthopedic biomaterials (generated by wear and electrochemical corrosion) which mediate these adverse effects. This debris may be present as particulate wear, colloidal nanometer size complexes (specifically or nonspecifically bound by protein), free metallic ions, inorganic metal salts/oxides, or in an organic storage form such as hemosiderin. Clinical aspects of biocompatibility regarding polymer and metal release from orthopedic prosthetic devices have taken on an increasing sense of urgency due to the escalating rates of people receiving implants and the recognition of extensive implant debris within local and remote tissues. Particulate debris has enormous specific surface areas available for interaction with the surroundings and chronic elevations in serum metal content. Clinical issues associated with biomaterial degradation can be broken down into four basic questions: (1) How much material is released from the implant? (2) Where is the material transported and in what quantity? (3) What is the chemical form of the released degradation products (e.g., inorganic precipitate vs. soluble organometallic complex)? and (4) What are the pathophysiological interactions and consequences of such degradation? The answers to these questions, over the long term, remain largely unknown. There is a growing body of literature addressing the issues associated with the first two questions. However, little is currently known with regard to the latter two questions. The remainder of this chapter will focus on that which is known (and of orthopedic clinical concern) regarding biomaterial degradation (through wear and electrochemical corrosion), dissemination of debris, and consequent local/systemic effects.



• **Figure 2.5.4.8** Examples of currently used surface coatings on stems of THA to enhance both short- and long-term fixation.

Orthopedic Biomaterial Wear

The generation of wear debris, and the subsequent tissue reaction to such debris, is central to the longevity of total joint replacements. In fact, particulate debris is currently extolled as the primary factor affecting the long-term performance of joint replacement prostheses, and the primary source of orthopedic biomaterial degradation (based on overall implant mass or volume lost). Particulate debris generated by wear, fretting, or fragmentation induces the formation of an inflammatory reaction, which at a certain point promotes a foreign-body granulation tissue response that has the ability to invade the bone–implant interface. This commonly results in progressive, local bone loss that threatens the fixation of both cemented and cementless devices alike (Jacobs, 1995; Jacobs et al., 2001a, 1994a).

Mechanisms of Wear Debris Generation: Wear involves the loss of material in particulate form as a consequence of relative motion between two surfaces. Two materials placed together under load will only contact over a small area of the higher peaks or asperities. Electro-repulsive and atomic binding interactions occur at the individual contacts and, when the two surfaces slide relative to one another, these interactions are disrupted. This results in the release of material in the form of particles (wear debris). The particles may be lost from the system, transferred to the counterface, or remain between the sliding surfaces. There are primarily three processes which can cause wear: (1) abrasion—by which a harder surface "plows" grooves in the softer material; (2) adhesion—by which a softer material is smeared onto a harder countersurface forming a transfer film; and (3) fatigue—by which alternating episodes of loading and unloading result in the formation of subsurface cracks which propagate to form particles that are shed from the surface.

Wear Rates: During an initial "wearing in" period, the relative motion of surfaces causes a large number of asperities to break, resulting in a high wear rate. After this initial period, the actual contact area increases and the two surfaces can be said to have adapted to one other. Over time, the wear rates decrease and eventually become linearly dependent on the contact force and sliding distance represented by the steady-state wear equation:

$$V = KFx \qquad \textbf{(2.5.4.10)}$$

where V is volumetric wear (mm^3/year), K is a material constant of the material couple, F is the contact force (N), and x is the distance of relative travel (mm).

Different types of orthopedic materials and couples produce different amounts and kinds of wear debris. Hard-on-hard material couples such as metal-on-metal articulations generally produce less wear (weight loss) than metal-on-polymer (see Fig. 2.5.4.9). There is a great deal of variability associated with in vivo wear rates of orthopedic biomaterials, which are generally measured by radiographic follow-up studies. Radiographic wear measurements are expressed as linear wear rates, whereas in vitro studies generally report volumetric wear. Volumetric wear can be directly related to the number of wear particles released into periprosthetic fluids (typically on the order of 1×10^9 of particles per year). The most common wear couple for hip and knee arthroplasty currently in use in the United States is a cobalt–base alloy head (most commonly a Co–Cr–Mo alloy ASTM F-75) bearing on a UHMWPE cup or liner. The wear rates of this couple are generally on the order of 0.1 mm/year, with particulate generation as high as 1×10^6 particles per step or per cycle. Clinically, implant wear rates have been found to increase with the following: (1) physical activity, (2) weight of the patient, (3) size of the femoral head (32 vs. 28 mm), (4) roughness of the metallic counterface, and (5) oxidation of the polyethylene (Jacobs, 1995; Jacobs et al., 1994a, 2001).

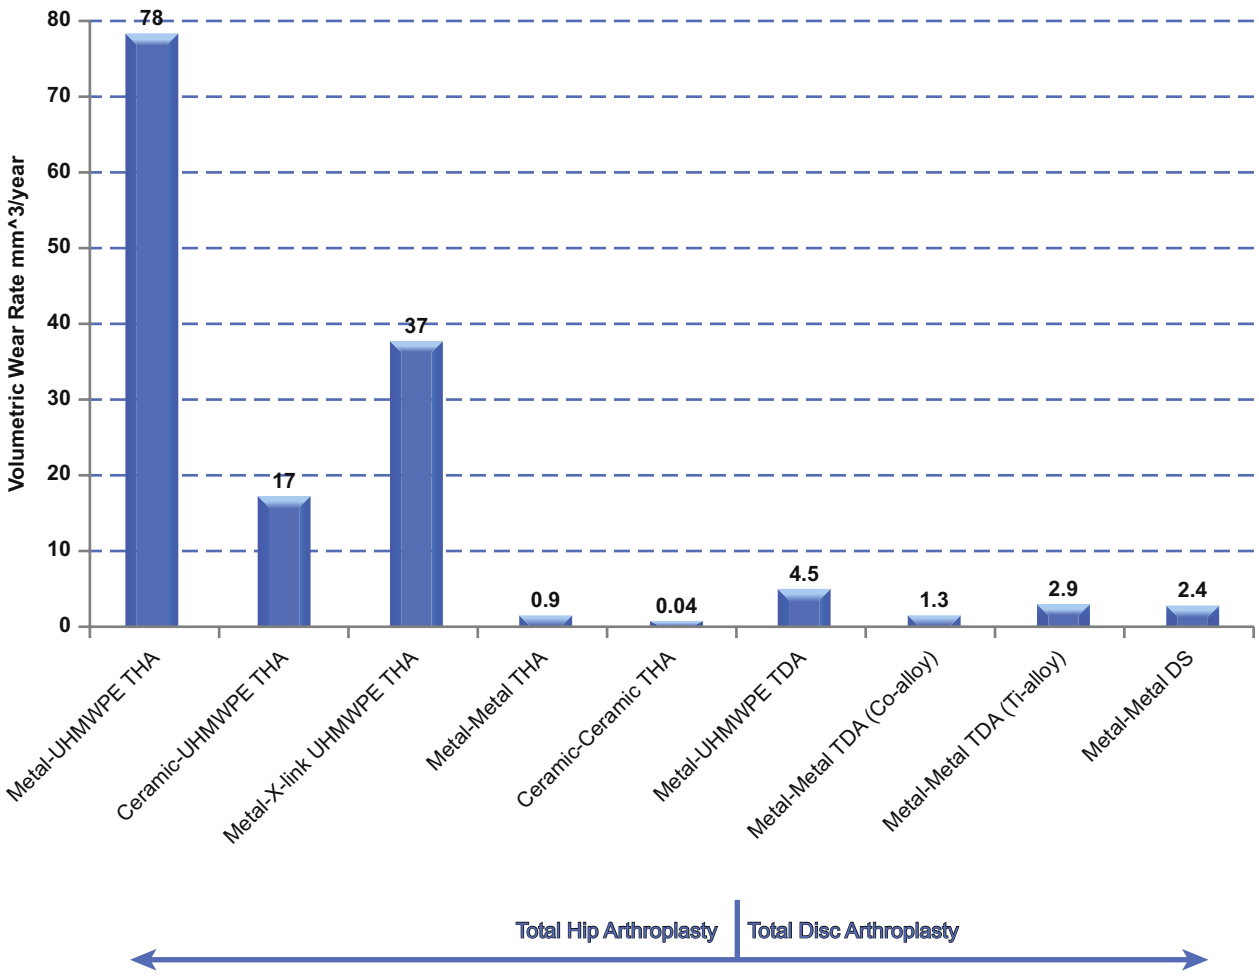
Although well established in the hip and knee, newer spinal implants are now undergoing the same types of analysis to try to assess which types of implant work best. These two basic types of articulating bearing designs are available in spine, knee, and hip arthroplasties.

Metal-on-polymer Spine Arthroplasty Wear: In vitro analysis of wear has demonstrated wear rates of metal-on-polymer bearing lumbar total disc arthroplasty devices range from 2 to 20.8 mm^3 per million cycles (Popoola et al., 2007; Pare et al., 2007), where the size of the wear debris generally ranges from 0.1 to 100 microns in diameter UHMWPE (Popoola et al., 2007; van et al., 2007; Anderson et al., 2003; Hallab et al., 2008). This amount of debris is 10-fold less wear than THAs and TKAs that are composed of metal on highly cross-linked polyethylene (x-UHMWPE)-bearing surfaces (Kurtz et al., 2005; Greenwald and Garino, 2001).

Metal-on-metal Spinal Arthroplasty Wear: In general the wear of metal-on-metal TJA is well below that of metal-on-polymer (Fig. 2.5.4.9) (Kurtz et al., 2005; Callaghan et al., 2007; Minoda et al., 2005; Heisel et al., 2004; Wroblewski et al., 1996; Saikko et al., 2002; Catelas et al., 2004; Tipper et al., 2002). The few published reports on the wear rates of metal-on-metal disc arthroplasty prostheses indicate a wear rate of 0.93–1.26 mm^3 per million cycles (cobalt-alloy) (Pare et al., 2007; Firkins et al., 2001). Another study of an all titanium–6%Al–4%V alloy disc arthroplasty found wear rates to be as high as 3 mm^3 per million cycles (Hellier et al., 1992). These values are similar to those reported for metal-on-metal hip replacements, which have been shown to range from approximately 0.05–6 mm^3 per million cycles (cobalt-alloy) (Catelas et al., 2004; Clarke et al., 2000; McKellop et al., 1996). Long-term follow-up of patients undergoing total disc arthroplasty is required to assess how intimately wear will correlate with inflammation and poor implant performance.

Orthopedic Biomaterial Corrosion

Electrochemical corrosion occurs to some extent on all metallic surfaces including implants. This is undesirable for two primary reasons: (1) the degradative process may reduce the structural integrity of the implant, and (2) the

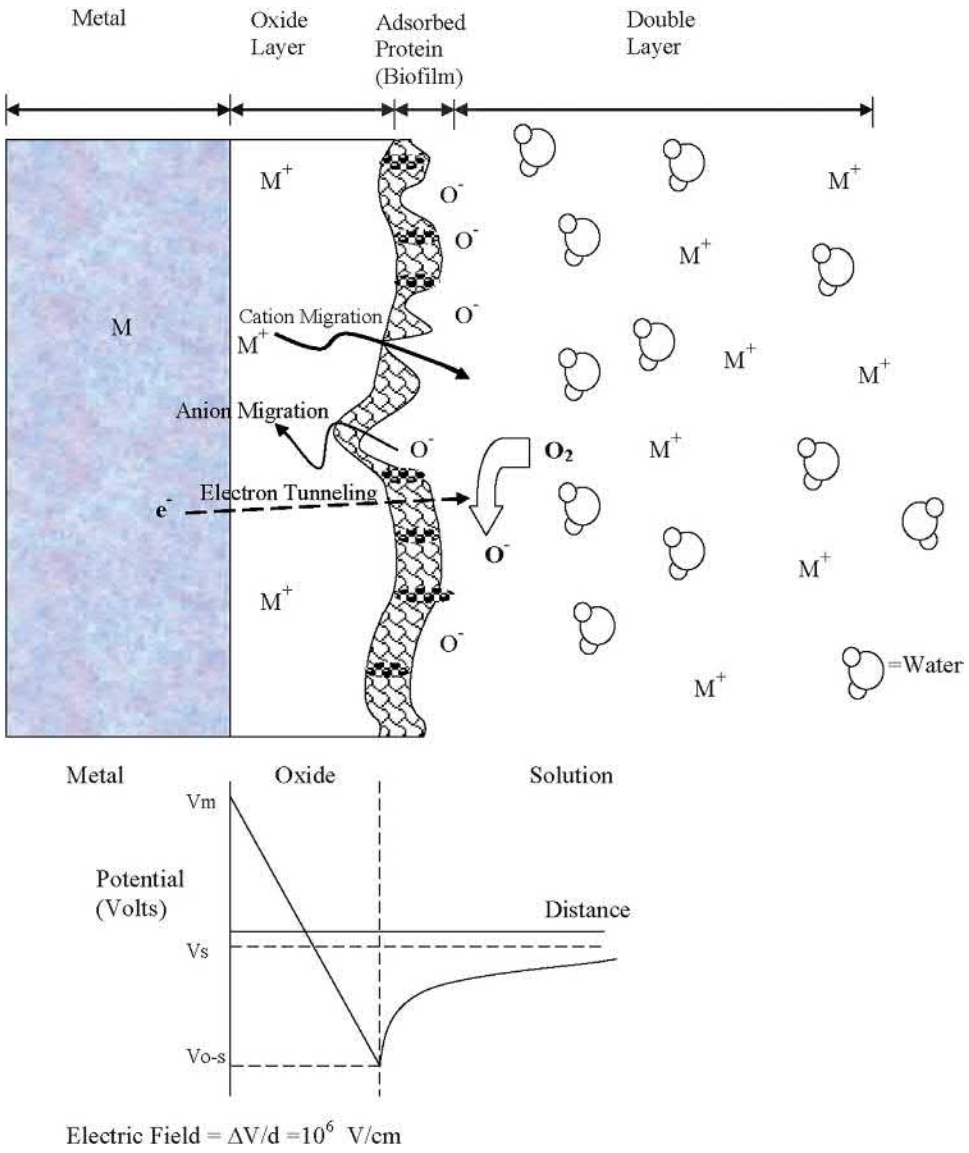


• **Figure 2.5.4.9** A comparison of the amount of wear debris generated from different types of total joint arthroplasties. There is relatively less (10×) polymeric debris generated by a total disc arthroplasty with a metal-on-polymer articulation. Note: Figure references: Metal–Poly (Callaghan et al., 2007):Ceramic–Poly (Minoda et al., 2005), Metal–X-linked Poly (Kurtz et al., 2005): Metal–X-linked Poly (Heisel et al., 2004), Metal–X-linked Poly (Wroblewski et al., 1996), Metal–X-linked Poly (Saikko et al., 2002), Metal–Metal (Catelas et al., 2004), Ceramic–Ceramic (Tipper et al., 2002), Metal–UHMWPE TDA (Popoola et al., 2007), Metal-Metal TDA (Pare et al., 2007).

release of products of degradation is potentially toxic to the host. Metallic biomaterial degradation may result from electrochemical dissolution phenomena or wear, but most commonly occurs through a synergistic combination of the two. Electrochemical processes include generalized corrosion uniformly affecting an entire surface, and localized corrosion affecting either areas of a device relatively shielded from the environment (crevice corrosion), or seemingly random sites on the surface (pitting corrosion). Additionally, these electrochemical and other mechanical processes interact, potentially causing premature structural failure and/or accelerated metal release (e.g., stress corrosion cracking, corrosion fatigue, and fretting corrosion) (Brown et al., 1992; Brown and Merritt, 1981; Bundy et al., 1991; Collier et al., 1992b; Cook et al., 1983; Gilbert and Jacobs, 1997).

Metallic corrosion happens through a series of reduction–oxidation reactions, similar to those of a battery. Note: The terms oxidation and reduction are complex and will be used as sparingly as possible in the following discussions. A "high-energy" material, metal oxidizes to a lower energy state when corroded and acts as the anode, i.e., the metal is oxidized, forming metal ions and free electrons. The free electrons "reduce" the oxygen which often forms hydroxides, phosphates, etc., and provides a complimentary cathodic reaction. Thus, the dissolution (oxidizing) metal at the anode has basically two possible outcomes; the metal ions can go into solution, becoming hydrated, or the metal ions can form a compound which can form as solids collecting on the surface. When metal ions are forming, further oxidation of the metal ions can occur and an open pit can form. When the solid compounds collect on the surface, a protective barrier typically forms where the accumulation of solid material inhibits further corrosion. The basic underlying reaction which occurs during corrosion is increasing of the valence state (i.e., loss of electrons) of the metal atom to form an ion.

Again this metal corrosion (oxidation) event (loss of electrons and increased valence) may result in free ions in



• **Figure 2.5.4.10** Schematic of the interface of a passivating alloy surface in contact with a biological environment.

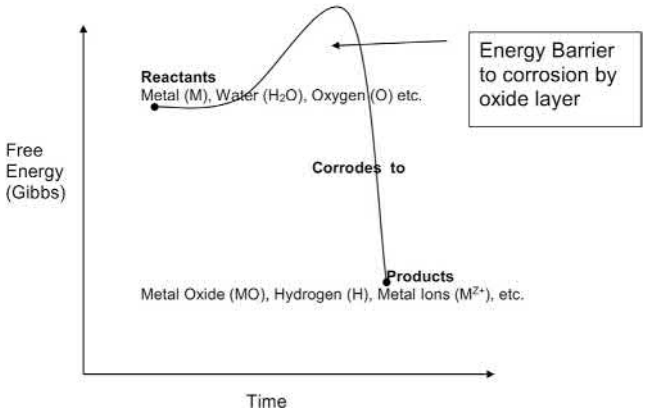
solution which can migrate away from the metal surface, or may result in other reactions such as the formation of metal-oxides, metal chlorides, organo-metallic compounds, or other species that typically precipitate out to form solid phases. The solid phases or oxidation products may be subdivided into (1) those which form adherent compact oxide films and (2) those which form nonadherent oxide (or other) particles which can migrate away from the metal surface.

Corrosion Mechanisms: Corrosion of orthopedic biomaterials is a multifactorial phenomenon and is dependent on five primary factors: (1) geometric variables (e.g., taper crevices in modular component hip prostheses), (2) metallurgical variables (e.g., surface microstructure, oxide structure, and composition), (3) mechanical variables (e.g., stress and/or relative motion), (4) solution variables (e.g., pH, solution proteins, enzymes), and (5) the mechanical loading environment (e.g., degree of movement, contact forces, etc.). Current investigational efforts to minimize the corrosion of orthopedic biomaterials deal directly with the complex interactions of these factors.

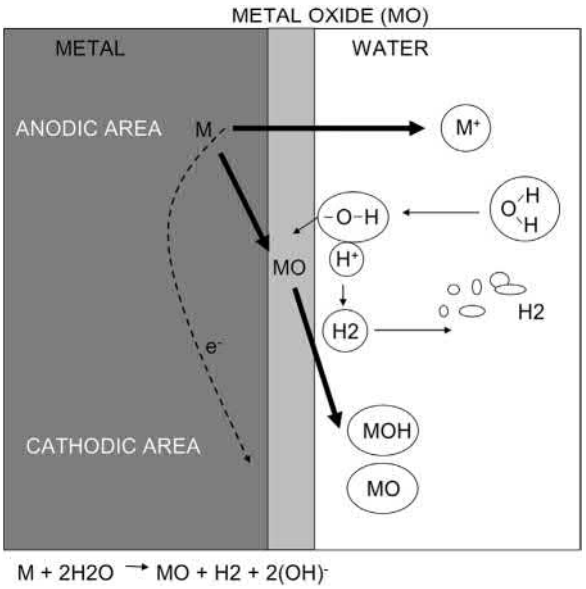
There are two essential features associated with how and why a metal corrodes. The first has to do with thermodynamic driving forces, which cause corrosion (oxidation/reduction) reactions. In general, whether or not corrosion will take place under the conditions of interest depends on the chemical driving force (ΔG), and the charge separation. This separation contributes to what is known as the electrical double layer (Fig. 2.5.4.10) which creates an electrical potential across the metal–solution interface (much like a capacitor):

$$\Delta G = -nF\Delta E \qquad (2.5.4.11)$$

where n is the valence of the ion, F is the Faraday constant (95,000 coulombs/mole electrons), and E is the voltage across the metal–solution interface. This potential is a



• **Figure 2.5.4.11** Metal-oxide passive films on metal surfaces are the typical example of a kinetic limitation to corrosion. In general, kinetic barriers to corrosion prevent either the migration of metallic ions from the metal to the solution, the migration of anions from solution to metal, or the migration of electrons across the metal–solution interface. Passive oxide films are the most common form of kinetic barrier in orthopedic implant corrosion, but other kinetic barriers exist including polymeric coatings.



• **Figure 2.5.4.12** All orthopedic alloys rely on the formation of passive films to prevent significant oxidation (corrosion) from taking place. These spontaneously formed films consist of metal oxides (ceramic films) that have an atomic structure which limits the migration of ions and/or electrons across the metal–oxide-solution interface; and are able to remain intact on the surface of these alloys, or reform rapidly during mechanical stressing or abrasion, expected with orthopedic devices.

measure of the reactivity of the metals or the driving force for metal oxidation. Therefore, the more negative the potential of a metal in solution, the more reactive it will tend to be (i.e., the greater is ΔG for reduction) (Fig. 2.5.4.11).

The second factor governing the corrosion process of metallic biomaterials is the kinetic barrier to corrosion (e.g., surface oxide layer). Kinetic barriers prevent corrosion not by energetic considerations but by physically limiting the rate at which oxidation or reduction processes can take place. The well-known process of passivation or the formation of a metal-oxide passive film on a metal surface is one example of a kinetic limitation to corrosion. In general, kinetic barriers to corrosion prevent either the migration of metallic ions from the metal to the solution, the migration of anions from solution to metal, or the migration of electrons across the metal–solution interface. Passive oxide films are the most well-known forms of kinetic barriers in corrosion, but other kinetic barriers exist, including polymeric coatings (Fig. 2.5.4.12) (Gilbert and Jacobs, 1997; Jacobs et al., 1998b).

Passivating Oxide Films: Most alloys used in orthopedic appliances rely on the formation of passive films to prevent significant oxidation from taking place. These films consist of metal oxides, which form spontaneously on the surface of the metal in such a way that they prevent further transport of metallic ions and/or electrons across the film. Passive films must have certain characteristics to be able to limit further oxidation. The films must be compact and fully cover the metal surface, they must have an atomic structure which limits the migration of ions and/or electrons across the metal–oxide–solution interface, and they must be able to remain on the surface of these alloys even with the mechanical stressing and abrasion which can be expected with orthopedic devices.

Passivating oxide films, which spontaneously grow on the surface of metals, have five primary structural and physical characteristics, which are particularly relevant to implant degradation processes:

1. First, these oxide films are very thin, typically on the order of 5–70 Å, which depends on the potential across the interface as well as solution variables (e.g., pH). Furthermore, the oxide structure may be amorphous or crystalline. Since the potential across the metal solution interface for these reactive metals is typically 1–2 V, the electric field across the oxide is very high, on the order of 10^6–10^7 V/cm. One of the more widely accepted models is based on the theory of Mott and Cabrera, which states that oxide film growth depends on the electric field across the oxide. If the potential across the metal–oxide–solution interface is decreased (i.e., made closer to the electrochemical series potential), then the film thickness will decrease by reductive dissolution processes at the oxide. If the interfacial potential is made sufficiently negative or the pH of the solution is made low enough, then these oxide films will no longer be thermodynamically stable and will undergo reductive dissolution, without which corrosion will increase (Gilbert and Jacobs, 1997; Jacobs et al., 1998a).
2. Second, oxide films have the characteristics of semiconductors with an atomic defect structure, which determines the ability for ionic and electronic transport across films. Metal cations and oxygen anions require the presence of cationic or anionic vacancies (respectively) in the oxide for transport of these species across the film. If there is a deficit of metal ions in the oxide film (i.e., there are cationic vacancies), for example, then metal ion transport

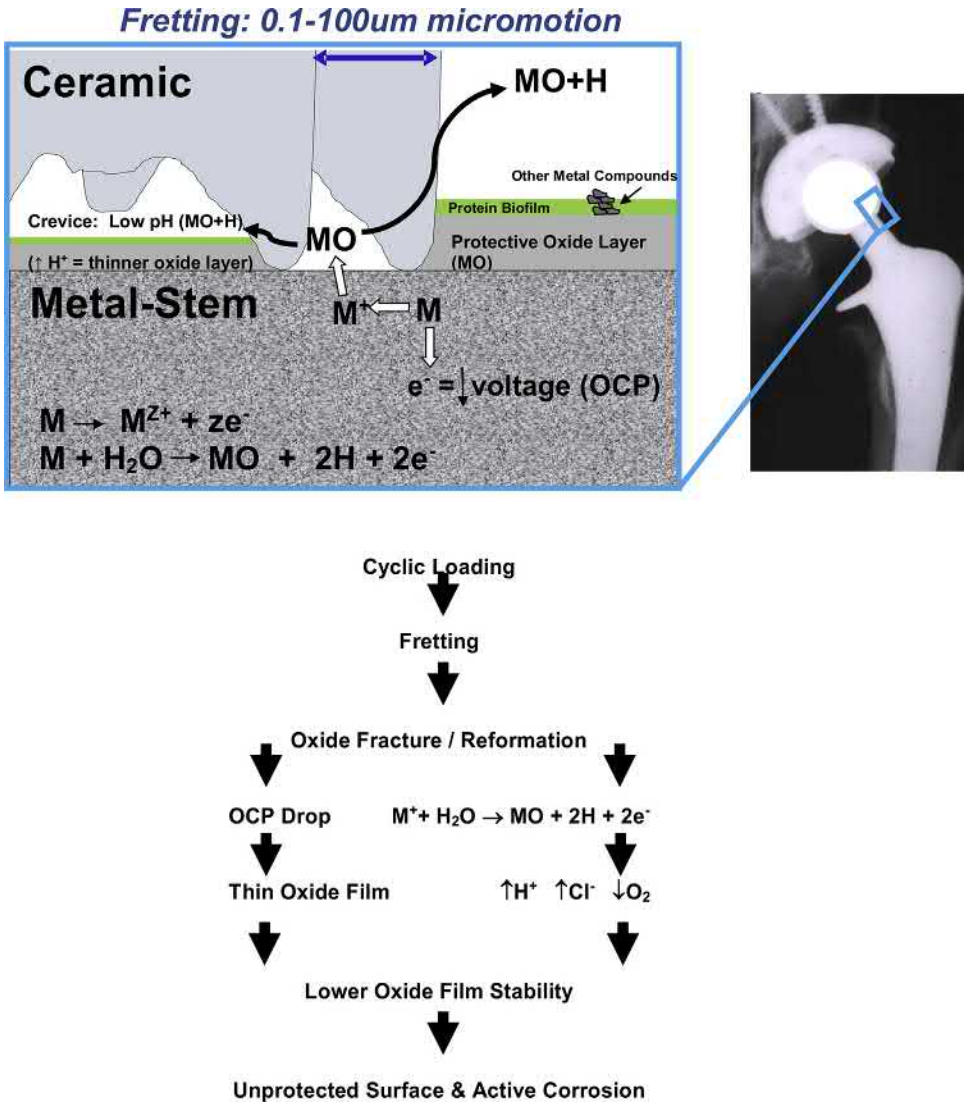
is possible, and these oxides are known as p-type semiconductors. Chromium oxide (Cr_2O_3) is such a metal-deficit oxide. On the other hand, if there is an excess of metal ions in the oxide (or a deficit of anions) then cation transport is limited but anion transport can occur. These oxides will also have excess electrons and are known as n-type semiconductors. TiO_2 spontaneously formed on titanium alloy implant (Ti–6Al–4V) surfaces is one such n-type semiconductor. The greater the number of defects (vacancies or other valence species) the less able is the oxide film to prevent migration of ionic species and the lower is the kinetic barrier to corrosion. TiO_2 is very close to being stoichiometric (chemically homogeneous) and hence does not have many ionic defects resulting in an increased resistance to ionic transport. Other defects may be present in these passive oxide films which may alter their ability to limit corrosion. For instance, the addition of other metal ions with valence states, which are different from the native metal ions, can alter both the electronic and ionic transport of charge across the interface. These additions may enhance or degrade the ability of the oxide to prevent corrosion depending on the nature of the oxide. One example of improved corrosion resistance from mixed oxides comes from what is known as a spinel. Spinels are typically mixed oxides of the form $(A_2O_3)BO$, where A and B are +3 and +2 valence metal ions. In Co–Cr alloys, for instance, a spinel of $(Cr_2O_3)CoO$ can form on the surface. Spinels are typically known to have higher strengths and better resistance to diffusion of ions compared to single metal ion oxides. Therefore, a high concentration of spinels in the oxide layer will act to resist dissolution of a metal implant (Gilbert and Jacobs, 1997; Jacobs et al., 1998a).

3. Third, the ratio of the "oxide specific volume" to metal alloy specific volume (i.e., Pilling Bedworth ratio) will determine if the oxide will adhere to the metal or not. If there is too great a mismatch between the metal and oxide lattice parameters then consequential stresses will be generated between the two. The magnitude of the internal stress will vary with the thickness of the oxide. Too great an oxide thickness will thus result in spontaneous fracture or spalling of the oxide, lowering the kinetic barrier effect of the oxide to corrosion (Gilbert and Jacobs, 1997; Jacobs et al., 1998a).
4. Fourth, the morphology of these oxide films is not one of a smooth, flat, continuous sheet of adherent oxide covering the metal. Transmission electron microscopy (TEM) and atomic force microscopy (AFM) techniques have shown that oxides of titanium, for instance, consist of needle or dome shapes. The size and shape of these oxide domes change with applied potential when immersed in oxalic and other acids (Gilbert and Jacobs, 1997; Jacobs et al., 1998a).
5. Finally, mechanical factors such as fretting, micromotion, or applied stresses may abrade or fracture oxide films. When an oxide film is ruptured from the metal substrate, fresh unoxidized metal is exposed to solution. When these films reform or repassivate, the magnitude of the repassivation currents, which are subsequently generated, may be large. This is because large driving forces exist for oxidation and when the kinetic barrier is removed these large driving forces can operate to cause oxidation. However, the extent and duration of the oxidation currents will depend on the repassivation kinetics for oxide film formation. Hence, the mechanical stability of the oxide films as well as the nature of their repassivation process are central to the performance of oxide films in orthopedic applications (Gilbert and Jacobs, 1997; Jacobs et al., 1998a).

Corrosion at Modular Interfaces of Joint Replacements: One issue associated with orthopedic alloys is the corrosion observed in the taper connections of retrieved modular joint replacement components. With the growing number of total joint designs which use metal-on-metal conical tapers as modular connectors between components, the effects of crevices, stress, and motion take on increasing importance. Severe corrosion attack can take place in the crevices formed by these tapers in vivo.

Fretting Corrosion or Mechanically Assisted Crevice Corrosion (MACC)

Fretting corrosion or MACC, occurs at junctions or connections of implant components. It is caused by small-scale (1–100 μm) relative motion between implant components from cyclic loading (normal use). This type of corrosion occurs in all types of alloys regardless of material couple (e.g., stainless steel (SS)/stainless steel, Co-alloy/Co-alloy, Co-alloy/titanium, titanium/titanium, etc.). These corrosion products are bioreactive and cause local inflammation that results in local bone loss (osteolysis), pain, and ultimately implant loosening. Inflammation from corrosion debris is proportional to the amount of debris and thus can occur slowly over time (decades) with little debris or can occur within months. Stainless steel intermedullary rods used for femur fracture demonstrated aggressive corrosion in the modular taper resulting in rapid bone loss and ultimately recall of the implants (Jones et al., 2001). Fretting corrosion is dependent on the amount of micromotion, the designs of modular connections, the alloy combination, and other factors that affect the mechanical or chemical environment of the implant, including surgical factors. Fretting corrosion is typically mechanically assisted corrosion within a crevice where the mechanical abrasion of the oxide layer radically alters the chemistry within the crevice solution in a negative way further enhancing corrosion (it has also been termed MACC, mechanically assisted crevice corrosion). This process is driven by the reduction in free energy associated with metal-oxide formation that results in the sequestration of O_2 from any available source (primarily H_2O). Repassivation of a metal surface within the crevice environment results in a buildup of H^+ and Cl^-, and lowers the pH. This MACC (Gilbert and Jacobs, 1997; Gilbert et al., 2009) model of modular junction fretting corrosion is schematically represented in Fig. 2.5.4.13. The ultimate result of this



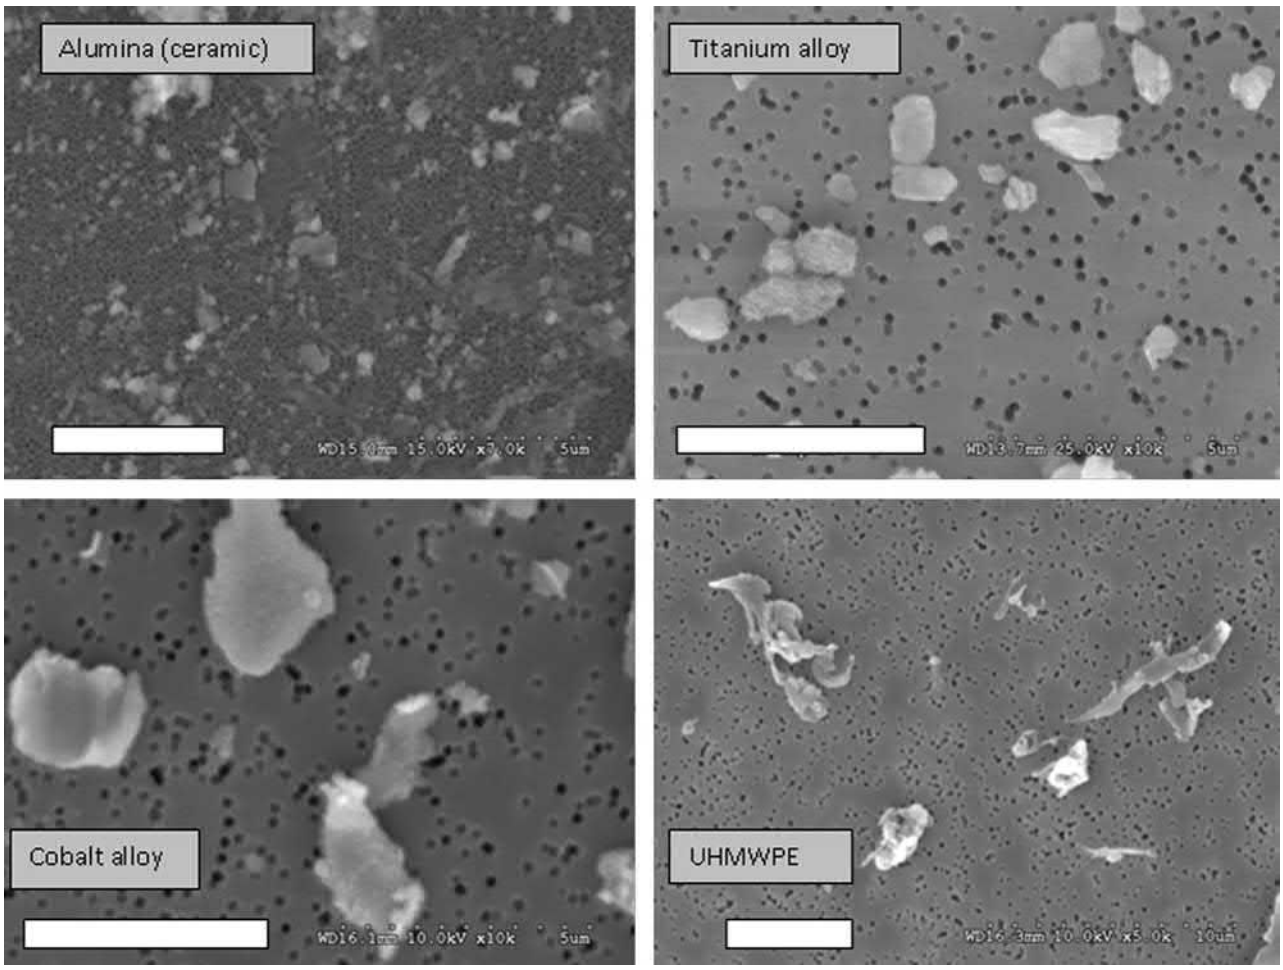
• **Figure 2.5.4.13** Fretting corrosion or mechanically assisted crevice corrosion (MACC). Fretting corrosion or MACC occurs at modular junctions or connections of implant components and is produced by small-scale (1–100 μm) relative motion between implant components induced by cyclic loading (normal use). This type of corrosion occurs in all types alloys regardless of material couple (e.g., stainless steel (SS)/stainless steel, Co-alloy/Co-alloy, Co-alloy/titanium, titanium/titanium, etc.).

process is a loss of the oxide film and its kinetic barrier effect and an increase in the rate of corrosive attack in the taper region. The corrosion processes in the Co–Cr alloys have been observed to consist of intergranular corrosion, etching, selective dissolution of cobalt, and the formation of Cr-rich particles. In isolated cases, this occurs to such an extent that intergranular corrosion caused fatigue failure in the neck of a Co–Cr stem. Corrosion attack of titanium alloy stems has also been observed in some cases.

Very little is known about the mechanical stability of passive oxide films and the electrochemical reactions (e.g., ion and particle release) which occur when the oxide film is fractured. What is known is that when the oxide films of these orthopedic alloys are abraded or removed from the surface by rubbing, the open circuit potential can decrease to as low as −500 mV (vs. standard calomel electrode). These voltage potentials may be significant and prolonged enough to cause changes in the oxide structure and stability by bringing the interface potential into the active corrosion range of the alloy, thereby dramatically accelerating the corrosion rate and decreasing implant performance (Brown et al., 1992, 1995; Bobyn et al., 1994; Collier et al., 1992a; Gilbert et al., 1993).

Implant Debris Types: Particles and Ions

The degradation products of all orthopedic implants are one of two basic types: particles or soluble debris (metal ions). While there is a large distinction between the two (ions vs. particles) the difference between them blurs as the size of particles decreases into the nanometer range and become essentially "in solution." Typically, particulate wear debris (metal, ceramic, or polymer) exists from the submicron size up to thousands of microns (mm), while so-called "soluble



• **Figure 2.5.4.14** Implant debris from four types of materials are shown where the metal (cobalt alloy and titanium) and ceramic (alumina) debris are more rounded versus the polymeric (UHMWPE) debris which is more elongated in shape. Note: scale bars = 5 μm.

debris" is limited to metal ions (or nanoparticles that are too small to be distinguished from ions) that are bound to plasma proteins.

Particulate Debris

Different types of joint arthroplasty designs not only produce different amounts and kinds of wear debris, but also different sizes and shapes of debris that are specific to the type of implant materials used for the bearing interfaces. For instance, hard-on-hard material couples such as metal-on-metal articulations generally produce smaller sized (submicron), fairly round debris, whereas traditional metal-on-polymer bearings produce larger (micron-sized) debris that is more elongated in shape (see Fig. 2.5.4.14).

As is evident in Fig. 2.5.4.14, hard-on-hard material couples (e.g., metal-on-metal) produce smaller debris than do hard-on-soft material couples (e.g., metal on polyethylene). The particles produced from the articulating bearing in any metal-on-poly bearing implants are dominated by polymer particles, with little metallic debris unless there are other sources of metal release such as corrosion at metal–metal connections. Polymeric particles produced from implants generally fall into the range of 0.23–1 μm (Fig. 2.5.4.14). Past investigations, primarily of UHMWPE wear debris in periimplant tissues, have shown that 70%–90% of recovered particulates were submicron, with the mean size being approximately 0.5 μm (Jacobs et al., 1994a; Campbell et al., 1995; Maloney et al., 1993). Metal and ceramic particles have generally been characterized as an order of magnitude smaller than polymer particles (at approximately 0.05 μm in diameter).

Histological Identification of Particles in vivo: The tissues surrounding modern implants may include areas of osseointegration, fibrous encapsulation, and a variable presence of the foreign-body response to polyethylene and cement debris in joint replacement devices. Absent is any specific histologic evidence of the slow release of metallic species that is known to occur with all metallic implants. However, accelerated corrosion and a tissue response that can be directly related to identifiable corrosion products can be demonstrated in the tissues surrounding multipart devices (Urban et al., 2000).

(1) *Stainless Steels:* Histological sections of the tissues surrounding stainless steel internal-fixation devices generally show encapsulation by a fibrous membrane with

little or no inflammation over most of the device. At screw–plate junctions, however, the membranes often contain macrophages, foreign-body giant cells, and a variable number of lymphocytes in association with two types of corrosion products. The first consists of iron-containing granules. The second, termed microplates, consists of relatively larger particles of a chromium compound. Microplates are found within the tissues as closely packed, plate-like particle aggregates ranging in size from 0.5 to 5.0 mm.

Hemosiderin-like granules often surround the collections of microplates, but the granules are found alone as well. The granules are yellow-brown, mainly spherical, and 0.1–3 or more micrometers in diameter. They are predominantly intracellular, most often in macrophages, but may also be found in other periprosthetic cells (e.g., fibroblasts). X-ray diffraction has indicated that the granules consist of a mixture of two or more of the iron oxides, αFe_2O_3 and σFe_2O_3, and the hydrated iron oxides, $\alpha Fe_2O_3 \cdot H_2O$ and $\sigma Fe_2O_3 \cdot H_2O$.

(2) *Cobalt-Base Alloys:* The nature of corrosion at modular connections is similar whether modular heads are mated with cobalt–chromium alloy or Ti–6Al–4V alloy femoral stems. The principal corrosion product identified by electron microprobe energy-dispersive X-ray analysis and Fourier-transform infrared microprobe spectroscopy is a chromium–phosphate ($Cr(PO_4)4H_2O$) hydrate-rich material termed "orthophosphate" This corrosion product can be found at the modular head–neck junction and as particles within the joint capsules, at the bone–implant interfacial membranes and at sites of femoral osteolytic lesions. Particles of the orthophosphate material have been found at the bearing surface of the UHMWPE acetabular liners suggesting their participation in three-body wear and an increased production of polyethylene debris. Particles of the chromium orthophosphate hydrate-rich corrosion product found in the tissues ranged in size from submicron to aggregates of particles up to 500 µm.

(3) *Titanium-Base Alloys:* The degradation products observed in histologic sections of tissues adjacent to titanium base alloys are of a different nature than the precipitates associated with stainless steel and cobalt base alloys. Despite the remarkable corrosion resistance of titanium base alloys, there have been persistent reports of tissue discoloration due to metallic debris in the periprosthetic tissues. These particulates observed in local tissues surrounding titanium alloy implants have the same elemental composition as the parent alloy as opposed to precipitated corrosion products which occur with stainless steel and cobalt–chromium alloys (Fig. 2.5.4.15). However, wear debris presents an enormous surface area for electrochemical dissolution, which, in all likelihood, is a major factor contributing to observed systemic elevations in titanium of patients with titanium implants (Urban et al., 1996b, 1997).

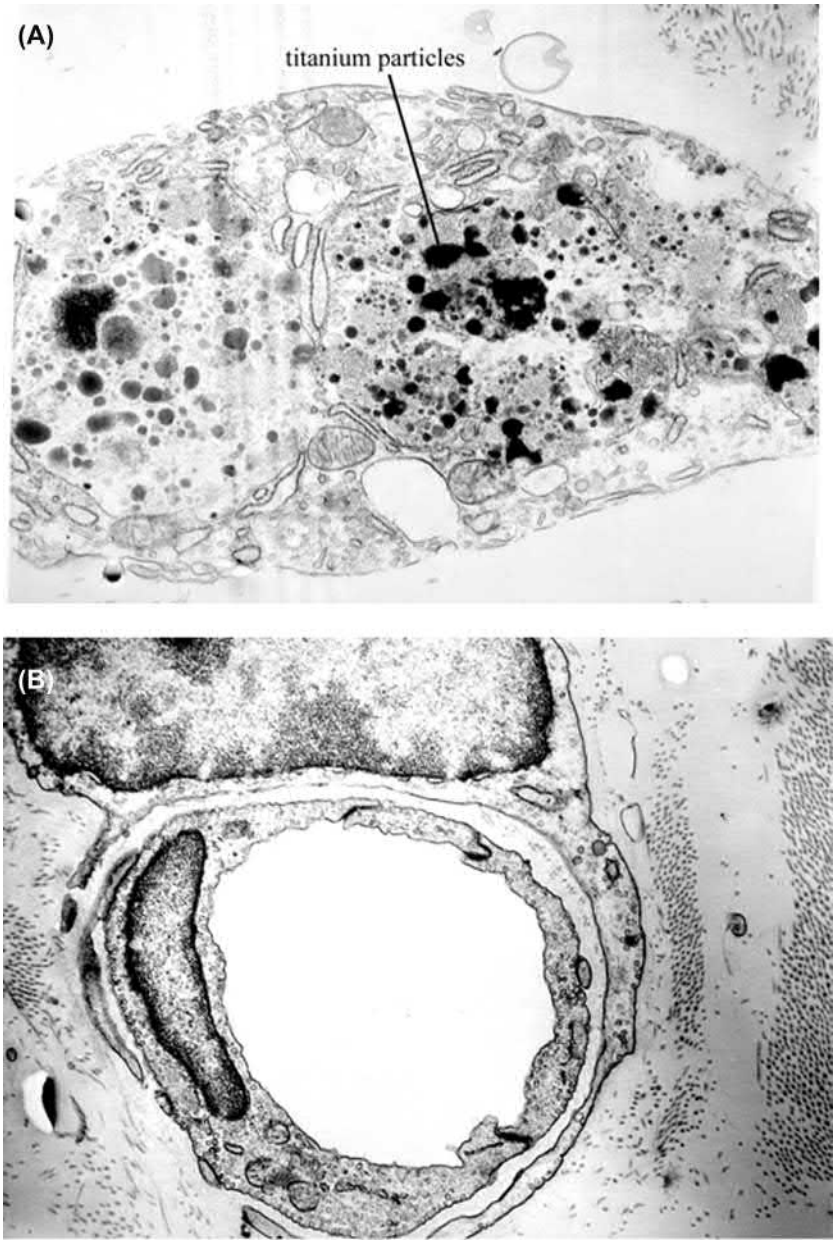
Particle Characterization: Traditionally, particle characterization uses methods such as scanning electron microscopy (SEM) or transmission electron microscopy (TEM), both of which are number-based counting methods. These methods have indicated that the majority of the wear (mass loss) from an implant is comprised of particles in the nanometer to submicron range. This understanding stems from the relatively low numbers of particles (e.g., 100s to 1000s) that are counted using image-based analysis techniques such as SEM. Newer analytical techniques, such as low-angle laser diffraction (LALLS) have the capability of sampling millions to billions of particles, counted as they pass in front of and scatter a laser light beam proportionally to their size. Thus, as millions of particles flow by LALLS analysis can detect the one-in-a-million large particle that comprises a significant portion of the total mass loss (i.e., total debris). This brings up the confusing concept that particle size of any given distribution depends on the method of evaluation. There is no one particle size. For example, the average size of 500 marbles and five basketballs is approximately the size of the marbles on a number basis and approximately the size of the basketball on a volume basis. Thus, when asking "what is the average size of particles that comprises approximately 50% of the total volume of particles?" is another way of asking what the mean size is (or average size) on a volume basis. Asking "what is the average size of the particles that comprises 50% of the total number of particles?" is the average size based on number basis. The stark differences between a volume- and number-based analysis of implant debris are shown in Fig. 2.5.4.16. When comparing the volume and number distributions in this figure the dominant contribution of larger particles to the total debris mass (volume) is evident and yet is insignificant to the total number of particles (Fig. 2.5.4.16).

The ability to comprehensively characterize implant debris is important to the new designs and bearing surfaces used in new spinal implants. This multianalysis approach is necessary because a given amount of wear debris (weight loss from the implant) after a year of use could be attributed to the loss of a relatively few large particles, or hundreds of millions of small particles (e.g., approximately 0.2 mm^3 volume loss after a million cycles of use could be from approximately 400 particles of 100 microns diameter or 400 million particles only 1 micron in diameter). The bias of techniques limited to number analysis is that very similar number-based distributions can look very different from a volume perspective. This phenomenon is illustrated in Fig. 2.5.4.16 when comparing samples, A and B, where different samples of particles look like very different volume-based distributions, however they look like very similar number-based distributions. This shows how important it is to have both number- and volume-based distributions of the same particles to fully characterize the types of particles in the mix, if there is enough particulate mass (>0.05 mg of particles) for an LALLS type analysis. Unfortunately, in implant debris analysis there is usually less than 0.05 mg of debris

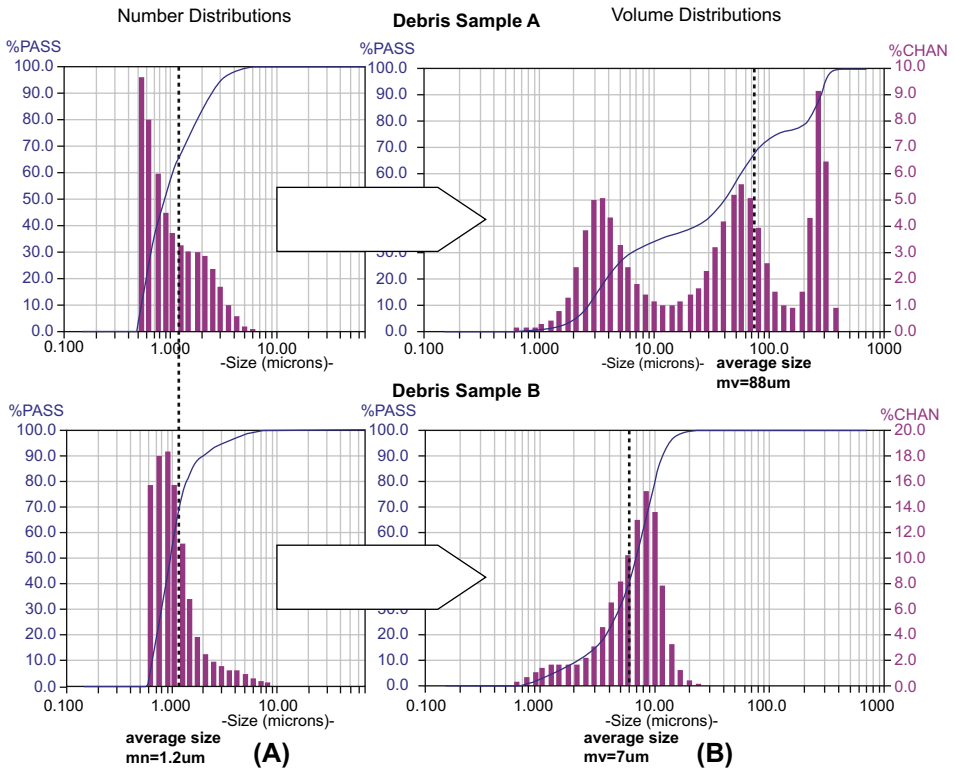
required for obtaining an accurate volume distribution and thus historically SEM and TEM analyses have been used to characterize debris.

Particulate Debris Reactivity Characterization: Macrophages are immune cells that are involved in the phagocytosis of implant debris and the resulting inflammatory responses. Once debris is ingested by macrophages a host of biologic reactions can occur such as activation of T cells through antigen presentation (Hallab et al., 2001), release of proinflammatory mediators (Glant and Jacobs, 1994; Shanbhag et al., 1994; Matthews et al., 2000; Ingham et al., 2000; Cunningham et al., 2002), cytotoxicity (Hallab et al., 2005a), DNA damage (Hallab et al., 2005a; Savarino et al., 2000; Nagaya et al., 1989), and oxidative stress (Soloviev et al., 2005). Macrophage reactions to debris are responsible for mediating debris-induced inflammation that is the leading cause of implant loosening over time.

Despite the large number of studies on metal, polymer, and ceramic particles effects on periimplant cells (e.g., macrophages, fibroblasts, osteoblasts, and osteoclasts), there are surprisingly few guidelines on what type of debris is most deleterious or bioreactive. However, there are a few general particle characteristics on which local inflammation has been shown to depend: (1) particle load (which depends on both particle size and total volume), (2) aspect ratio (the shape of the particles), and (3) chemical reactivity (the



• **Figure 2.5.4.15** Transmission electron photomicrographs. (A) Macrophage containing phagocytized titanium particles. (B) Endothelial cell lining with embedded titanium debris. These specimens were obtained from a tissue sample overlying the posterolateral fusion mass (16-week autograft + titanium) (TEM magnification = 20,000×).



• **Figure 2.5.4.16** These graphs demonstrate that the analysis of two sets of particles (debris) show very similar (A) "number" distributions (left panels), but very different (B) "volume" distributions (right panels) because the large particles that take up a dominant share of the total volume of debris are very few in number. Note: The x-axis is particle diameter and the y-axis is (i) percentage of total number of particles in each size range and (ii) the percentage of total mass in each size range. (Courtesy of BioEngineering Solutions Inc.)

chemical composition). Thus, theoretically a bioreactivity index of particulate would take the mathematical form:

$$\text{Particle Pro} - \text{inflammatory Index} \times K_{\text{Load}}\,(\text{particle load}) \times K_{\text{Shape}}\,(\text{aspect ratio}) \times K_{\text{Material}}\,(\text{material type}) \quad (2.5.4.1)$$

where: Ks are constants that depend on the testing environment, particle load is a function of both particle size and total debris volume.

(1) **Greater particle load: (size and volume) increases inflammation.** An inflammatory response in vivo is proportional to the particle load (the concentration of phagocytosable particles per tissue volume, which is characterized by both the size and total volume) (Matthews et al., 2000; González et al., 1996). While this seems obvious, the ramifications and the conditions under which this remains true are important and not so obvious. If a given amount of debris (mass loss from an implant) is comprised of small-diameter particles there will far greater numbers than if that same mass of debris was composed of larger diameter particles (Matthews et al., 2000). The degree to which equal numbers (doses) of large particles (e.g., 10 micron diameter) and smaller particle (1 micron diameter) induce a proinflammatory response has not been thoroughly investigated and remains unknown.

(2) **Aspect ratio: elongated (fibers) particles are more proinflammatory than round particles** (Laquerriere et al., 2003; Sieving et al., 2003). That fibers are more reactive than round debris has been well established over 30 years ago, with studies of asbestos fibers (Bruch, 1974). However, it remains unknown at what aspect ratio (aspect ratio: length/width) in the transition from round particles to fibers that elevated inflammation is generally initiated, and thus to date there is no "guideline" aspect ratio for implant debris particles to remain below.

(3) **More chemically reactive particles are more proinflammatory:** There is a growing consensus that metal particles are more proinflammatory when compared to other materials such as polymers (Ramachandran et al., 2006). However, this is not a unanimous opinion, others have concluded that polymers are more proinflammatory than metals (von Knoch et al., 2000). And other reports have shown no differences between similar metal and polymer particles (Baumann et al., 2004, 2005, 2006). Despite these reports to the contrary, there is a growing consensus that metallic particles are more proinflammatory because they are capable of corroding and releasing ions that have been associated with hypersensitivity responses, cytotoxicity, and DNA damage (Hallab et al., 2001, 2005; Caicedo et al., 2007b).

Controversial Particle Characteristics: Does particle size matter? Absolutely. In vitro inflammatory responses generally require particles <10 microns diameter to be phagocytosed. Thus, to produce an in vitro inflammatory response particles need to be less than 10 μm, that is, within a phagocytosable range. Purportedly, particles with a mean size of 0.2–10 μm are the most proinflammatory. Within this range there is no consensus as to which specific size(s) and/or dose of particles (particles/cell or particles/tissue volume) are maximally inflammatory (Matthews et al., 2000; Ingram et al., 2002; Rader et al., 1999; Shanbhag et al., 1995).

The effects of bacteria products (or endotoxin) on implant debris particles are presumably important because it has been found in periprosthetic tissue of failed implants, even in the absence of clinical signs of infection (Nalepka et al., 2006). Furthermore, even bacteria that is present at below clinically detectable levels have been shown to affect implant performance because antibiotic-eluting bone cement and systemically administered antibiotics reportedly reduce the frequency of long-term failure, i.e., aseptic loosening (Espehaug et al., 1997).

Metal Ions (Soluble Debris)

There is continuing concern regarding the release of chemically active metal ions, which bind to proteins and remain in solution from which they can then disseminate into the surrounding tissues, bloodstream, and remote organs. Particulate metallic wear debris presents an enormous surface area for electrochemical dissolution, which, in all likelihood, is a major factor contributing to observed systemic elevations in metals of patients with titanium implants (Jacobs et al., 1998a; Urban et al., 1996a, 1997, 1998, 2000). Normal human serum levels of prominent implant metals are approximately: 1–10 ng/mL Al, 0.15 ng/mL Cr, <0.01 ng/mL V, 0.1–0.2 ng/mL Co, and <4.1 ng/mL Ti. Following total joint arthroplasty, levels of circulating metal have been shown to increase (Jacobs et al., 1998a; Urban et al., 1996, 1997, 1998, 2000).

Metal Ion Release: In the long clinical experience of permanent and temporary metallic implants there has always been concern with local tissue reactions. Multiple studies have demonstrated chronic elevations in serum and urine Co and Cr following successful primary total joint replacement. In addition, transient elevations of urine and serum Ni have been noted immediately following surgery. This hypernickelemia/hypernickeluria may be unrelated to the implant itself since there is such a small percentage of Ni within these implant alloys. Rather, this may be related to the use of stainless-steel surgical instruments or the metabolic changes associated with the surgery itself.

Chronic elevations in serum Ti and Cr concentrations are found in subjects with well-functioning Ti- and/or Cr-containing THR components without measurable differences in urine and serum Al concentrations. Vanadium concentrations have not been found to be greatly elevated in patients with TJA (Jacobs et al., 1994b, 1998a; Dorr et al., 1990; Michel et al., 1984; Stulberg et al., 1994).

Metal ion levels within serum and urine of TJA patients can be affected by a variety of factors. For example, patients with total knee replacement components containing Ti-base alloy and carbon fiber-reinforced polyethylene wear couples demonstrated 10-fold elevations in serum Ti concentrations at an average of 4 years after implantation. Up to 100 times higher than normal control values of serum Ti elevations have also been reported in patients with failed metal-backed patellar components where unintended metal/metal articulation was possible. However, even among these TJA patients, there was no elevation in serum or urine Al, serum or urine V levels, or urine Ti levels. Mechanically assisted crevice corrosion in patients with modular femoral stems from total hip arthroplasty has been associated with elevations in serum Co and urine Cr. It has been previously assumed that extensively porous coated cementless stems would give rise to higher serum and urine chromium concentrations due to the larger surface area available for passive dissolution. Recent studies suggest that disseminated Cr can predominantly come from fretting corrosion of the modular head/neck junction. However, wear of the articulating surface remains the purported predominant source of metallic implant debris (Jacobs et al., 1998a,b; Jacobs et al., 1999).

Metal-on-Metal Bearings: Metal-on-metal (MoM) bearing hip replacements (with a metal head and metal cup) are known to release metal ions through mechanical wear of their metallic bearings. For cobalt-alloy MOM bearings, wear results in the release of primarily Co and Cr ions and, to a lesser degree, Mo and Ni ions, which then results in ion elevations and ultimately excretion. A systemic level of metal ions reached steady state where excretion matches production and for MoM implants it is in the range of one–three parts per billion for both Co and Cr (ppb or μg/L) (Jacobs et al., 2001a,b; Campbell et al., 2014; Levine et al., 2013; Hallab et al., 2013). The acceptable level of serum Co and Cr ions is hotly debated. The current consensus statement by the American Association of Hip and Knee Surgeons, suggests that levels below 3 ppb (<3 μg/L) are considered low risk (and are associated with well performing implants over the long term), levels between 3 and 10 ppb are considered intermediate risk, and levels greater than 10 ppb are considered high risk and have been associated with implant performance issues such as THA cup–neck impingement and subsequent ALTR (Kwon et al., 2014a).

Corrosion at Modular Junctions: Corrosion at modular junctions in all orthopedic implants (e.g., modular necks, spinal scoliosis screw–rod connections, etc.) occurs through the process of MACC (Fig. 2.5.4.17). Head–neck corrosion causes a differential elevation of Co:Cr as most of the released Cr ions are presumed to precipitate locally on the taper in the form of chromium orthophosphate, resulting in a systemic ratio of Co:Cr > 5–10:1. This is in contrast to the ratio of Co:Cr in the bulk metal of the implant, which is approximately 3:1. Reference values have not yet been established for assessing the risk of head–neck corrosion, however past studies have suggested that the serum Co level in a well-functioning MoP THA should be <1 ppb (Levine et al., 2013).

• **Figure 2.5.4.17** Modular junction taper connection of a total hip arthroplasty showing corrosion of the taper connections. Macrograph of deposits of $CrPO_4$ corrosion particles products on the rim a modular cobalt–chrome femoral head.

When corrosion occurs at the modular junctions of implant component, there is typically a two- to fivefold differential elevation of serum Co:Cr ratio. Cr is sequestered into a more chemically stable oxide form (e.g., orthophosphate) on the implant surface and builds up locally as a precipitate. Cobalt, however, does not form a precipitate as easily and is transported away. Thus, although cobalt is three times more prominent in the parent alloy it is not typically released at higher concentrations than Cr when there are mild corrosion conditions. When there are aggressive corrosion conditions, Co begins to be released more substantially and thus aggressive corrosion can be detected diagnostically by a higher serum Co:Cr ratio. The current consensus statement by the American Association of Hip and Knee Surgeons suggests that levels below 1 ppb and a Co:Cr ratio <1 can be considered low risk, levels of 1–5 ppb with a ratio of one to five are considered moderate risk, and levels >5 ppb with a Co:Cr ratio >5 are considered high risk (Kwon et al., 2014a) and a sign of aggressive corrosion likely to lead to early device failure or local excessive inflammation.

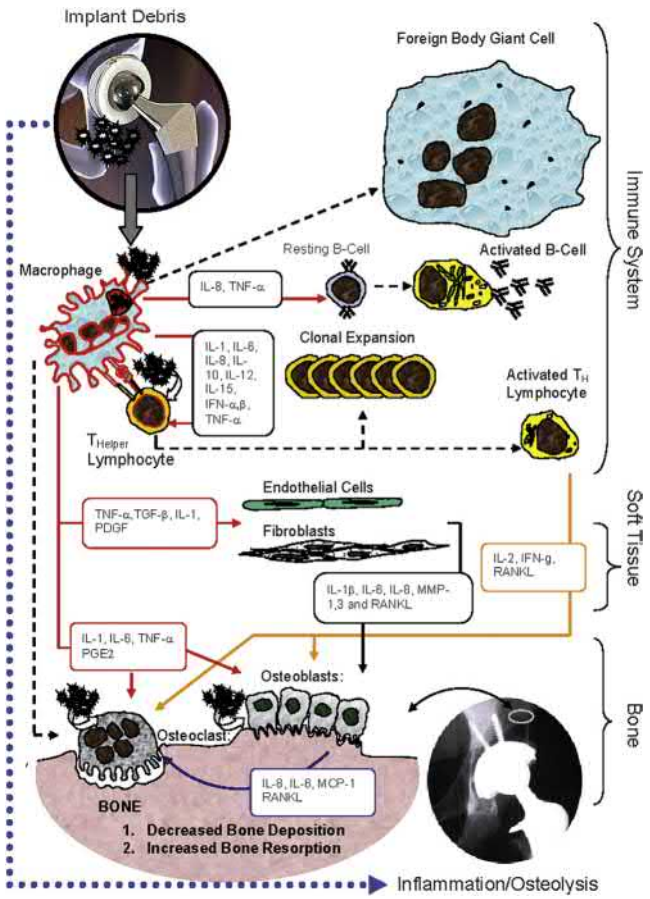
When is High too High: A "safe" threshold level has not been established, due to the complexity of patient-, implant-, and environment-dependent situations. Levels of 5–10 ppb (parts per billion, μg/L or ng/mL) have been generally accepted as guidelines for metal ion level limits that are indications for further analysis, surveillance, and/or action in the United States for orthopedic clinicians (Campbell et al., 2014; Kwon et al., 2014b). A lower threshold of 7 ppb for cobalt or chromium for all types of MoM hip implants was put forward by the British Medicines and Healthcare Products Regulatory Agency as an indication for cross-sectional imaging (http://www.mhra.gov.uk/home/groups/dtsbs/documents/medicaldevicealert/con079162.pdf). There have been some reports of metal ion referable systemic toxicity at levels of >100 ppb (Zywiel et al., 2016). Established systemic effects have been limited to delayed-type hypersensitivity immune responses to metals (Amini et al., 2014; Kwon et al., 2010; Ricciardi et al., 2016). In the past very high levels of environmental cobalt exposure and toxicity have been reported connected with forms of blindness, hearing loss, tinnitus, cognitive decline, peripheral neuropathy, hypothyroidism, and cardiac dysfunction (Zywiel et al., 2016; Jacobs et al., 2009). Implant-referable toxicity has not been definitively established in any orthopedic populations (Ricciardi et al., 2016; Jacobs et al., 2009).

Metal Ion Summary: The recognition that metal ion release from orthopedic implants can be pathogenic is well established. The measurement of systemic (whole blood or serum) Co and Cr levels is a minimally invasive tool in the armamentarium of doctors and is growing in popularity and reliability to implant performance and assess patients that have a painful implant. The clinical ramifications of metal ion release are discussed further in the next few sections.

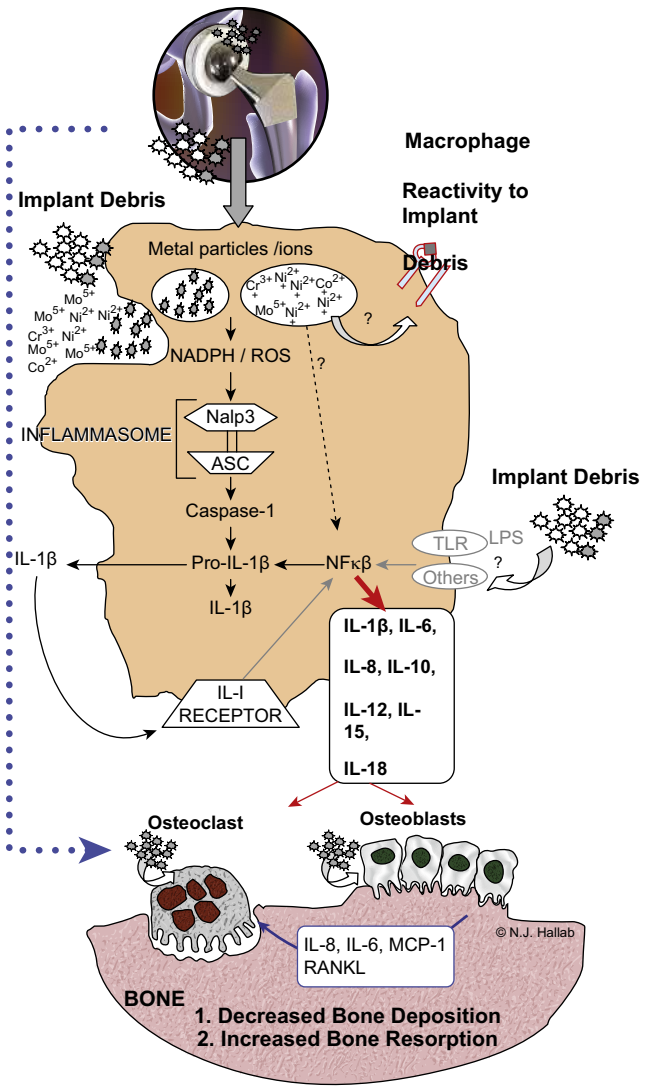
Local Tissue Effects of Wear and Corrosion

Implant debris limits the long-term performance of total joint replacement by causing a local inflammatory response that leads to bone erosion and implant loosening. Normal bone maintenance relies on the balance of bone formation and bone resorption, which mainly involves the coordinated function of osteoblasts and osteoclasts. Thus, either a decrease in osteoblastic bone formation or an increase in osteoclastic bone resorption can result in net bone loss and osteolysis. Bone loss (i.e., osteolysis) around an implant is the primary concern associated with the local effects of orthopedic implant degradation. This osteolysis-causing implant debris occurs through both wear and corrosion mechanisms. Osteolysis is observed either as diffuse cortical thinning or as a focal cyst-like lesion. It was initially thought that reaction to particulate polymethylmethacrylate (PMMA) bone cement produced osteolytic lesions based on histological studies demonstrating cement debris associated with macrophages, giant cells, and a vascular granulation tissue. Recently, however, osteolysis has been recognized in association with loose and well-fixed uncemented implants, demonstrating that the absence of acrylic cement does not preclude the occurrence of osteolysis (Jacobs et al., 2001a; Vermes et al., 2001b).

Implant debris causes low-grade inflammation that ultimately leads to implant failure. Exactly how this happens remains unclear. Over the past 40 years implant debris-induced inflammation has been characterized ad nauseam, where debris-induced localized inflammation is caused in large part by macrophages which upregulate NFκβ and secrete inflammatory cytokines like IL-1β, TNFα, IL-6, and IL-8 (Jacobs et al., 2001a) (Fig. 2.5.4.18). Other anti-inflammatory cytokines such as IL-10 modulate the inflammatory process. Other factors involved with bone resorption include the enzymes responsible for catabolism of the



• **Figure 2.5.4.18** This schematic shows the numerous proinflammatory mediators produced by periimplant tissue and immune cells reacting to implant debris, which can negatively affect bone turnover. The proinflammatory cytokines IL-1, IL-6, and TNF-alpha are thought to be some of the most potent cytokines in this cascade of signaling. These cytokines produced by cells reacting to implant debris act through a variety of pathways to negatively affect bone turnover.



• **Figure 2.5.4.19** The inflammasome pathway within cells such as macrophages has recently been reported to be central to implant debris-mediated proinflammatory reactivity. (Courtesy of BioEngineering Solutions Inc.)

organic component of bone. These include matrix metalloproteinases, collagenase, and stromelysin. Prostaglandins, in particular PGE_2, also are known to be important intercellular messengers in the osteolytic cascade produced by implant debris. More recently, several mediators known to be involved in stimulation or inhibition of osteoclast differentiation and maturation, such as RANKL (also referred to as osteoclast differentiation factor) and osteoprotegerin, respectively, have been suggested as key factors in the development and progression of bone loss (osteolytic lesions) produced from implant debris. Over the past 30 years we understand these mediators act to promote inflammation that decreases bone remodeling and are associated with the pathogenesis of osteolysis. However, we are only beginning to understand how implant debris could actually induce this immune system response at the cellular level.

Implant debris is typically sterile, relatively inert, and does not "look" like a pathogen in any molecularly recognizable way. How then can implant debris provoke an inflammatory response? That is, how do intracellular mechanisms sense and respond to sterile nonbiological challenge agents such as implant debris? This question has remained unanswered for the past 40 years. But recently progress has implicated the "inflammasome," a danger-signaling pathway (Fig. 2.5.4.19) (Caicedo et al., 2010).

In 1996, the discovery of specific pattern recognition receptors (PRRs) in the membrane and cytosol of human immune cells, such as macrophages, identified toll-like receptors(Taguchi et al., 1996) and their role in recognizing specific bacterial glycoproteins, now called "pathogen-associated molecular patterns" or PAMPs. We now understand that these receptors to highly conserved pathogen-associated molecular patterns (Mariathasan and Monack, 2007) now include toll-like receptors (TLRs), mannose receptors (MRs), and NOD-like receptors (NLRs) (Mariathasan and Monack, 2007). Upon pathogen/cell contact these PRRs initiate a downstream cascade of events that activate the cell and induce the secretion of proinflammatory cytokines leading to a broader inflammatory response.

In 2005, danger signal pathways were discovered where nonpathogenic derived stimuli were found to activate immune cells, similarly to PAMPs. Key components in this pathway were named the "inflammasome" and the activating stimuli were termed "danger-associated molecular patterns", or DAMPs (Martinon et al., 2006). The paradigm for immune system activation, now includes reliance on specific receptors that recognize both PAMPs and DAMPs (Medzhitov, 2008; Ting et al., 2008). The inflammasome complex of proteins was the first pathway to explain how cells transduce sterile, nonpathogen-derived stimuli (e.g., cell stress and cell necrosis), into an inflammatory response (Mariathasan and Monack, 2007; Mariathasan et al., 2004). Nonpathogen-derived dangers include such nonbiological stimuli as UV light, particulate adjuvants present in modern vaccines (Dostert et al., 2008; Hornung et al., 2008) and, as it turns out, implant debris (Caicedo et al., 2009).

When the inflammasome pathway is activated it causes the release of IL-1β, IL-18, IL-33, and other cytokines. This happens is as follows:

Debris → phagocytosis → lysosome damage → ROS (reactive oxygen species) → inflammasome (NALP3/ASC) → caspase 1 → IL-1β (and other IL-1-family) cytokines (Fig. 2.5.4.18).

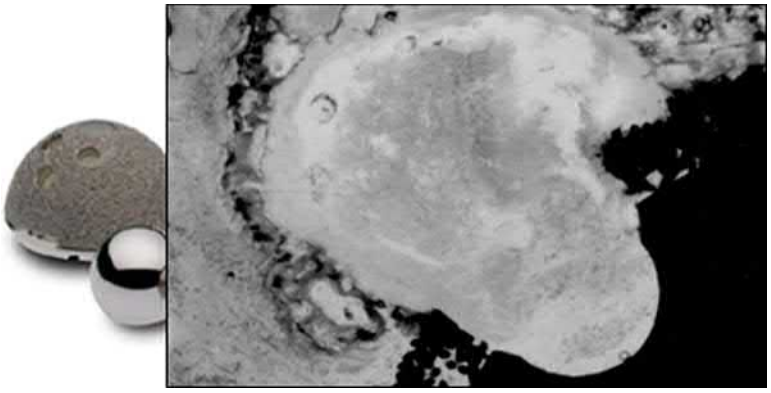
Once ingested by immune cells, DAMPs, such as asbestos and implant debris, etc. (i.e., macrophages) induce some degree of lysosomal destabilization. This causes an increase in NADPH (nicotinamide adenine dinucleotide phosphate-oxidase), and an increase in reactive oxygen species (ROS). This is not surprising given the protease- and acid-rich extreme environment inside lysosomes, used to digest and breakdown ingested particles/bacteria, etc. The release of these intracellular contents is sensed by the intracellular multiprotein inflammasome complex which is composed of NALP3 (NACHT-, LRR-, and pyrin domain-containing protein 3). NALP3 protein, in association with ASC (apoptosis-associated speck-like protein containing a CARD domain) is termed the inflammasome (Mariathasan and Monack, 2007; Petrilli et al., 2007). Activation of the inflammasome (NALPs–ASC complex) leads to the cleavage of procaspase-1 into active caspase-1. Active caspase-1 is required for the processing and subsequent release of active proinflammatory cytokines such as IL-1β and IL-18 (and others) by cleaving intracellular pro-IL-1β, pro-IL-18, etc. into their mature forms, IL-1β and IL-18 etc.

How different implant debris can cause different immune responses through specific mechanisms, such as the inflammasome, remains unknown and is currently under study. These new understandings facilitate both direct targeting for drugs and can enhance diagnostic measurement for improving, measuring, and predicting when implant debris will result in loose total joint arthroplasties.

Goldring et al. (1983) were among the first to describe the synovial-like character of the bone–implant interface in patients with loose total hip replacements and determine that the cells within the membrane have the capacity to produce large amounts of bone-resorbing factors PGE_2 and collagenase. However, since studies typically can only document the end stage of the loosening process, rather than those initiating processes, pharmacologic interventions have been limited.

Osteolysis associated with total knee arthroplasty has been reported less frequently than that associated with total hip arthroplasty. It is unclear why. However, in addition to obvious factors such as implant/bone mechanical loading environments, other more subtle differential mechanisms of hip and knee wear, and differences in interfacial barriers to migration of debris have been postulated to account for this apparent disparity.

Although polyethylene particles are generally recognized as the most prevalent particles in the periprosthetic milieu, metallic and ceramic particulate species are also present in variable amounts and may have important repercussions. The bulk of this debris originates from the articular surface and has easy access to local bone. When present in sufficient amounts, particulates generated by wear, corrosion, or a combination of these processes can induce the formation of an inflammatory, foreign-body granulation tissue with the ability to invade the bone–implant interface (Fig. 2.5.4.20). Localized osteolytic lesions in these areas are common, but their clinical significance is limited unless large granulomatous lesions develop.



• **Figure 2.5.4.20** Photomicrograph (5×) of a section through an acetabular section of a femoral stem retrieved at autopsy, 89 months after implantation. Note the periprosthetic cavity surrounding development of a granuloma emanating from an unfilled screw hole.

The common observance of particle-induced osteolysis remote from the articulation surfaces has shown there is substantial particle migration between the joint space and the distal regions of the THA implant space. Autopsy specimens of retrieved implants have demonstrated the presence of connective tissue macrophages (histiocytes) in cavities surrounding regions of the femoral component. While the overall incidence of femoral osteolysis associated with THA tends to be proximal in the initial stages, over time it tends to progress distally. The volume of debris generated from THA polyethylene is related to a number of variables, including the smoothness of the concave metallic surface of the acetabular component, the tolerance between polyethylene and metal shell, and the relative stability of the insert (LaBerge, 1998; Shanbhag et al., 1998; Wimmer et al., 1998).

Sex Differences in Reactivity: Recent studies indicate that CoCrMo implant debris induces significantly increased osteolysis in females over that of males using a murine model of particle-induced osteolysis (Landgraeber et al., 2018). However, not all implant debris types have demonstrated sex-based differences in animal models of osteolysis in that UHMWPE particles did not induce sex-based differences in either particle-induced soft-tissue inflammation or osteolysis. Clinical observations have reported that women can suffer higher failure rates of some metal-on-metal THA designs under conditions of elevated metal release (Bornert et al., 2015). There are many possible mechanisms that account for this phenomenon. Metals such as CoCrMo and polyethylene particles can elicit different types of immune responses in vitro (Zhang et al., 2015; Endres et al., 2008; Masui et al., 2005), due to the pleotropic effects of cobalt-alloy implant debris such as induced hypoxia or hypoxia-like effects (Samelko et al., 2013), as well as innate (Caicedo et al., 2009, 2010, 2013) and adaptive immune reactivity (Hallab et al., 2001, 2005b, 2013). UHMWPE implant particles do not induce similar toxicity and immune responses, yet they do elicit innate immune reactivity inflammatory responses through inflammasome danger signaling (Zhang et al., 2015; Endres et al., 2008; Chen et al., 2015; Cunningham et al., 2013; Hallab et al., 2012). Thus the data at present support a complex picture where toxicity (e.g., hypoxia, pyroptosis, necrosis, DNA damage, etc.) and/or adaptive immune reactivity (such as lymphocyte-mediated metal hypersensitivity) (Hallab et al., 2001, 2005, 2013; Samelko et al., 2013) may alone, or in concert, produce greater downstream particle-induced osteolysis responses in women than in men. For central mechanisms of innate reactivity alone there does not appear, as yet, to be sex-based differences in innate immune reactivity alone (such as NLRP3 inflammasome, TLR signaling, costimulatory molecule expression, cytokine expression, etc.).

Remote and Systemic Effects of Wear and Corrosion

Implant surfaces and wear debris generated from the implant may release chemically active metal ions into the surrounding tissues. While these ions may stay bound to local tissues, there is an increasing recognition that released metal products bind to specific protein moieties and are transported in the bloodstream and/or lymphatics to remote organs. The concern about the release and distribution of metallic degradation products is justified by the known potential toxicities of the elements used in modern orthopedic implant alloys: titanium, aluminum, vanadium, cobalt, chromium, and nickel. In general terms, metal toxicity may occur through (1) metabolic alterations, (2) alterations in host–parasite interactions, (3) immunologic interactions of metal moieties by virtue of their ability to act as haptens (specific immunological activation) or antichemotactic agents (nonspecific immunological suppression), and (4) by chemical carcinogenesis (Hartwig, 1998; Britton, 1996; Goering and Klaasen, 1995; Beyersmann, 1994; Luckey and Venugopal, 1979).

Cobalt, chromium, and possibly nickel and vanadium are essential trace metals in that they are required for certain enzymatic reactions. In excessive amounts, however, these elements may be toxic. Excessive cobalt may lead to polycythemia, hypothyroidism, cardiomyopathy, and carcinogenesis. Excessive chromium can lead to nephropathy, hypersensitivity, and carcinogenesis. Nickel can lead to eczematous dermatitis, hypersensitivity, and carcinogenesis. Vanadium can lead to cardiac and renal dysfunction, and has been associated with hypertension and depressive psychosis.

Biologically nonessential metallic elements also possess specific toxicities. Titanium, although generally regarded as inert, has been associated with pulmonary disease in patients with occupational exposure and with platelet suppression in animal models. Aluminum toxicity is well documented in renal failure and has been associated with anemia, osteomalacia, and neurological dysfunction, possibly including Alzheimer's disease. However, when considering the variety of documented toxicities of these elements, it is important to keep in mind that the toxicities generally apply to soluble forms of these elements and may not apply to the chemical species that result from prosthetic implant degradation.

At this time, the association of metal release from orthopedic implants with any metabolic, bacteriologic, immunologic, or carcinogenic toxicity is conjectural since cause and effect have not been well established in human subjects. However, this is due in large part to the difficulty of observation in that most symptoms attributable to systemic and remote toxicity can be expected to occur in any population of orthopedic patients (Jacobs et al., 1999).

Homogenates of remote organs and tissue obtained postmortem from subjects with Co base alloy total joint replacement components have indicated that significant increases in Co and Cr concentrations occur in the heart, liver, kidney, spleen, and lymphatic tissue (Table 2.5.4.5). Similarly, patients with Ti-base alloy implants demonstrated elevated Ti, Al, and V levels in joint pseudocapsules

TABLE 2.5.4.5 Concentrations of Metal in Body Tissue of Humans With and Without Total Joint Replacements (μg/G)

		Cr	Co	Ti	Al	V
Skeletal muscle	Normal	<12	<12	*	*	*
	TJA	570	160	*	*	*

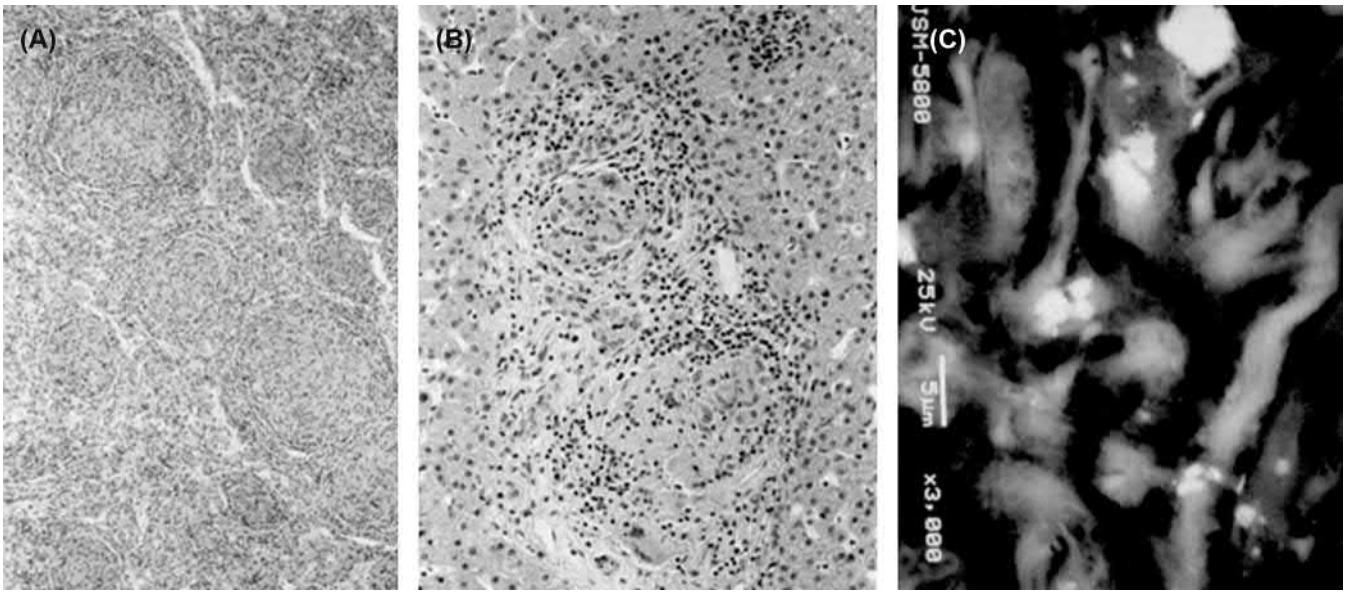
(with up to 200 ppm of Ti six orders of magnitude greater than that of controls, 880 ppb of Al, and 250 ppb of V). Spleen Al levels and liver Ti concentrations can also be markedly elevated in patients with failed titanium-alloy implants (Jacobs et al., 1994c).

Systemic Particle Distribution: Variables influencing accumulation of wear debris in remote organs are not clearly identified. When the magnitude of particulate debris generated by a prosthetic device is increased, it seems likely that a corresponding elevation in both the local and systemic burdens of particles may be expected. Thus, component loosening, duration of implantation, and the modular designs of contemporary hip and knee replacement prostheses provide the potential for increased generation of metallic and polymeric debris. Wear particles found disseminated beyond the periprosthetic tissue are primarily in the submicron size range. Numerous case reports document the presence of metallic, ceramic, or polymeric wear debris from hip and knee prostheses in regional and pelvic lymph nodes (Fig. 2.5.4.21) along with the findings of lymphadenopathy, gross pigmentation due to metallic debris, fibrosis (buildup of fibrous tissue), lymph node necrosis, and histiocytosis (abnormal function of tissue macrophages), including complete effacement of nodal architecture. The inflammatory response to metallic and polymeric debris in lymph nodes has been demonstrated to include immune activation of macrophages and associated production of cytokines. Metallic wear particles have been detected in the para-aortic lymph nodes in up to 70% of patients with total joint replacement components.

Lymphatic transport is thought to be a major route for dissemination of wear debris. Wear particles may migrate via perivascular lymph channels as free or phagocytosed particles within macrophages. Within the abdominal para-aortic lymph nodes the majority of disseminated particles are submicron in size, however metallic particles as large as 50 μm and polyethylene particles as large as 30 μm have also been identified. These particles may further disseminate to the liver or spleen where they are found within macrophages or, in some cases, as epithelioid granulomas throughout the organs. Within liver and spleen, the maximum size of metallic wear particles is nearly an order of magnitude less than that in lymph nodes, indicating there may be additional stages of filtration proceeding the lymphatic system or alternate routes of particle migration. In the liver and spleen, as in the lymph nodes, cells of the mononuclear–phagocyte system may accumulate small amounts of a variety of foreign materials without apparent clinical significance. However, accumulation of exogenous particles can induce granulomas or granulomatoid lesions in the liver and spleen (Fig. 2.5.4.21). It is likely that the inflammatory reaction to particles in the liver, spleen, and lymph nodes is modulated, as it is in other tissues by (1) material composition, (2) the number of particles, (3) their rate of accumulation, (4) the duration that they are present, and (5) the biologic reactivity of cells to these particles. Metallic particles in the



• **Figure 2.5.4.21** Epithelioid granulomas (A) within the portal tract of the liver (40×) and, (B) within the splenic parenchyma (15×) in a patient with a failed titanium-alloy total hip replacement and symptomatic hepatitis. (C) Backscattered SEM of a granuloma in the spleen (3000×) demonstrating titanium alloy particles.

liver or spleen have been more prevalent in subjects with previously failed arthroplasties when compared with cases of well-functioning primary joint replacements. Metal particles, unlike polyethylene debris, can be characterized using an electron microprobe, which allows identification of individual, submicron metallic wear particles against a background of particulates from environmental or sources other than the prosthetic components. Overall, the smallest identifiable disseminated particles using the microprobe are approximately 0.1 μm in diameter. However, metallic wear debris may extend into the nanometer range, suggesting that additional methods of specimen preparation and analytic instrumentation may be required to more fully define the high burden of metallic wear particles in remote tissues (Urban et al., 1995, 2000).

Polyethylene particles comprise a substantial fraction of the disseminated wear particles both in subjects with revision and primary TJAs. While the presence of these polyethylene particles in lymph nodes can be confirmed by Fourier transform infrared spectroscopy microanalyses, polyethylene particulates in liver and spleen have so far precluded unequivocal identification. In these sites, the size of wear particles may be much smaller than 0.1 μm, making differentiation impossible by polarized light microscopy or infrared spectroscopy.

Diseases which cause obstruction of lymph flow through lymph nodes, such as metastatic tumor, or which cause generalized disturbances of circulation, such as chronic heart disease or diabetes, may be expected to decrease particle migration to remote organs. Other diseases, such as acute or chronic active inflammation in the periprosthetic tissues may increase particle migration (Jacobs et al., 1999, 2001; Vermes et al., 2001a).

Hypersensitivity

Some adverse responses to orthopedic biomaterials are subtle and continue to foster debate and investigation. One of these responses is "metal allergy" or hypersensitivity to metallic biomaterials. Released ions, while not sensitizers on their own, can activate the immune system by forming complexes with native proteins. These metal–protein complexes are considered to be candidate antigens (or allergens) in human clinical applications. Polymeric wear debris is not easily chemically degraded in vivo and has not been implicated as a source of allergic-type immune responses. This is presumably due to the relatively large degradation products associated with the mechanical wear of polymers in vivo, which may be large enough to prevent the formation of polymer–protein haptenic complexes with human antibodies (Hallab et al., 2000a,b, 2001a,b).

Metal hypersensitivity is a well-established phenomenon. Moreover, dermal hypersensitivity to metal is common, affecting about 10%–15% of the population. Dermal contact and ingestion of metals have been reported to cause immune reactions which most typically manifest as skin hives, eczema, redness, and itching. Although little is known about the short- and long-term pharmacodynamics and bioavailability of circulating metal degradation products in vivo, there have been many reports of immunologic-type responses temporally associated with implantation of metal components. Individual case reports link hypersensitivity immune reactions with adverse performance of metallic clinical cardiovascular, orthopedic, and plastic surgical and dental implants.

Metals accepted as sensitizers (haptenic moieties in antigens) include beryllium, nickel, cobalt, and chromium,

while occasional responses have been reported to tantalum, titanium, and vanadium. Nickel is the most common metal sensitizer in humans followed by cobalt and chromium. Cross-sensitivity reactions between metals are common. Nickel and cobalt are, reportedly, the most frequently cross-reactive. The amounts of these metals found in medical-grade alloys are shown in Table 2.5.4.5.

Type IV delayed type hypersensitivity (DTH) is a cell-mediated type of response with which orthopedic implant-associated hypersensitivity reactions (metal sensitivity or metal allergy) are generally associated. Metal–antigen-sensitized T-DTH lymphocytes release various cytokines which result in the accumulation and activation of macrophages. The majority of DTH-participating cells are macrophages. Only 5% of the participating cells are antigen-specific T lymphocytes (T-DTH cells), within a fully developed DTH response. The effector phase of a DTH response is initiated by contact of sensitized T cells with antigen. In this phase T cells, which are antigen-activated, are termed T-DTH cells and secrete a variety of cytokines that recruit and activate macrophages, monocytes, neutrophils, and other inflammatory cells. These released cytokines include: IL-3 and GM-CF, which promote hematopoiesis of granulocytes; monocyte chemotactic activating factor (MCAF), which promotes chemotaxis of monocytes toward areas of DTH activation; INF-γ and TNF-β, which produce a number of effects on local endothelial cells facilitating infiltration; and migration inhibitory factor (MIF), which inhibits the migration of macrophages away from the site of a DTH reaction. Activation, infiltration, and eventual migration inhibition of macrophages is the final phase of the DTH response. Activated macrophages, because of their increased ability to present class II MHC and IL-2, can trigger the activation of more T-DTH cells, which in turn activates more macrophages, which activates more T-DTH cells, and so on. This DTH self-perpetuating response can create extensive tissue damage.

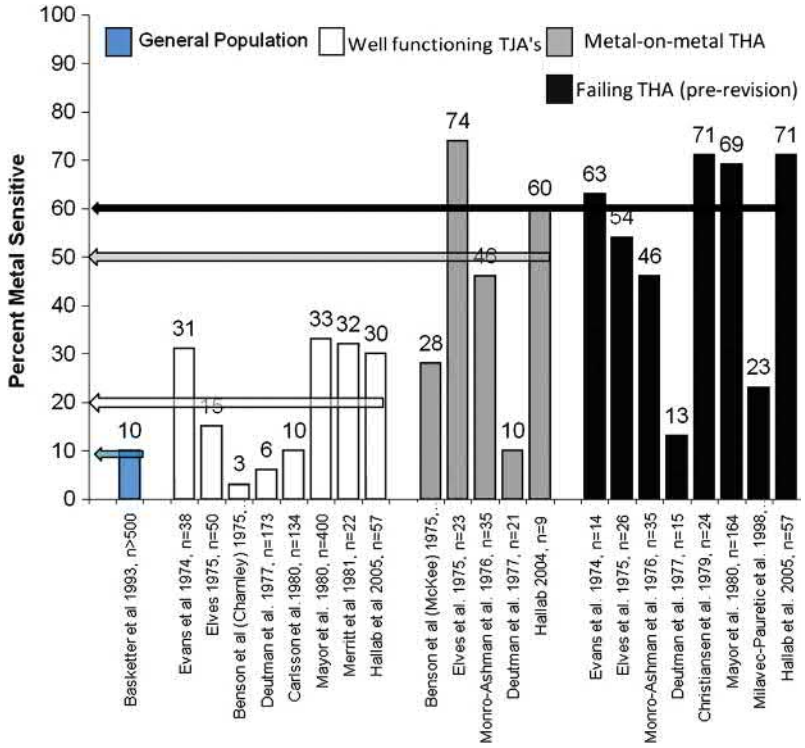
The first apparent correlation of eczematous dermatitis to metallic orthopedic implants was reported in 1966 by Foussereau and Laugier (Foussereau and Laugier, 1966), where nickel was associated with hypersensitivity responses. Over the past 20 years growing numbers of case reports link immunogenic reactions with adverse performance of metallic cardiovascular orthopedic and plastic surgical and dental implants. In some instances, clinical immunological symptoms have led directly to device removal. In these cases reactions of severe dermatitis (inflammation of the skin), urticaria (intensely sensitive and itching red round wheals on the skin), and/or vasculitis (patch inflammation of the walls of small blood vessels) have been linked with the relatively more general phenomena of metallosis (metallic staining of the surrounding tissue), excessive periprosthetic fibrosis, and muscular necrosis. The temporal and physical evidence leaves little doubt that the phenomenon of hypersensitivity to metal released from orthopedic implants does occur in some patients. These cases of severe metal sensitivity raise great concern.

Incidence of Hypersensitivity Responses Among Patients with Metal Implants: The incidence of metal sensitivity among patients with both well and poorly functioning implants is roughly twice as high as that of the general population, at approximately 25% (Fig. 2.5.4.22). Furthermore, the average incidence of metal sensitivity among patients with a "failed" implant (in need of revision surgery) is approximately 50%–60% (Fig. 2.5.4.22). This is greater than five times the incidence of metal sensitivity found in the general population and two to three times that of patients with metal implants. This increased prevalence of metal sensitivity among patients with a loose prosthesis has prompted the speculation that immunological processes may be a factor in implant loosening.

Specific types of implants with greater propensity to release metal in vivo may be more prone to induce metal sensitivity. Failures of total hip prostheses with metal-on-metal bearing surfaces were associated with greater incidence of metal allergy than similar designs with metal-on-ultrahigh molecular weight polyethylene bearing surfaces. Alternatively, several published reports have indicated that after total joint replacement with metallic components some patients show an induction of metal tolerance; that is, previously diagnosed metal sensitivity abated after implantation of a metallic prosthetic.

Confounding to any clear connection between metal sensitivity and implant failure is the lack of any reported correlation between incidence of metal sensitivity and implant residence time, infection, reason for removal, or pain. This lack of causal evidence implicating cell-mediated immune responses has prompted some to conclude that implantation of cemented metal-to-plastic joint prosthesis is safe, even in the case of a preexisting metal allergy. However, this is not a consensus opinion. At this time, however, it is unclear whether metal sensitivity causes implant loosening or whether implant loosening results in the development of metal sensitivity.

The majority of investigations conclude that metal sensitivity can be a contributing factor to implant failure. Such cases include instances in which clinical immunological symptoms lead directly to the need for device removal. In these or similar cases there have been reported reactions of severe dermatitis, urticaria, and/or vasculitis, all presumably linked to what has been reported as metallosis, excessive periprosthetic fibrosis, and muscular necrosis. The clinical observation of apparent immune sensitivity to metallic implants is not limited to orthopedic surgery. Some case reports suggest metal sensitivity to pacemakers, heart valves, reconstructive, dental, and general surgical devices. The temporal and physical evidence associated with such cases leaves little doubt that the phenomenon of metal-induced hypersensitivity does occur in some cases, currently accepted within the orthopedic community to be <1% of patients. However, it is currently unclear whether metal sensitivity exists only as an unusual complication in a few susceptible patients, or is a more subtle and common phenomenon, which over time plays a significant role in implant failure.



• **Figure 2.5.4.22** A compilation of investigations showing the averaged percentages of metal sensitivity among the general population for nickel, cobalt, and chromium, among patients after receiving a metal-containing implant, and among patient populations with failed implants. All subjects were tested by means of a patch or metal-LTT (lymphocyte transformation test).

It is likely that cases involving implant-related metal sensitivity have been underreported because alternate causes were attributed to failure of the implant. Mechanisms by which in vivo metal sensitivity occurs have not been well characterized. Thus, the degree to which a precondition of metal hypersensitivity may elicit an overaggressive immune response in a patient receiving an implant remains unpredictable. Continuing improvements in immunologic testing methods will likely enhance future assessment of patients susceptible to hypersensitivity responses (Hallab et al., 2000a,b, 2001a,b).

Testing for Metal Sensitivity. Implant debris-related DTH responses are bad enough to require revision arthroplasty in approximately 1%–2% of all orthopedic patients. There are only two accepted testing methods for diagnosing metal allergy, including skin testing (i.e., so-called patch testing) and cell culture blood testing called metal lymphocyte transformation testing (metal-LTT). Patch testing commercial kits exist for some metals (Hensten-Pettersen, 1993; Rooker and Wilkinson, 1980), however there is continuing concern about sensitizing patients using this type of patch testing (by placing high-concentration metal salt solutions in petroleum jelly on the skin for 48 h) (Merritt and Brown, 1980). Other problems associated with patch testing include disagreement as to how representative the skin is (with unique dermal antigen-presenting cells, i.e., Langerhans cells) as a proxy of periimplant antigen-presenting cells (Kuby, 1991; Korenblat, 1992). In vitro metal allergy testing, called lymphocyte proliferation testing (also known as LTT), involves measuring the proliferative response of lymphocytes after they are activated by an antigen. A radioactive marker is used to precisely measure the amount of cell division over a set time period by measuring the amount of radioactive [H^3] -thymidine that is incorporated into the cellular DNA upon cell division after 4–6 days of exposure to antigen. [^{3}H]-thymidine uptake is measured using liquid scintillation, and the amount of immune response (proliferation factor or stimulation index) is calculated using measured radiation counts per minute (cpm):

$$\text{Proliferation Factor} = \frac{(\text{cpm with treatment})}{(\text{cpm without treatment})}.$$

The use of proliferation testing to measure metal allergy was developed from similar methods to assess general drug sensitivity and has been well established as a method of testing DTH responses in a variety of clinical settings (Veien and Svejgaard, 1978; Veien et al., 1979; Svejgaard et al., 1978; Secher et al., 1977; Everness et al., 1990). The use of LTT for implant-related metal sensitivity is increasing given that it has been shown to have diagnostic efficacy, particularly in the area of metal-on-metal implants, which have led to higher rates of metal sensitivity responses (Granchi et al., 1998, 1999; Carando et al., 1985). Several investigations indicate that metal allergy can be more readily detected by LTT than by dermal patch testing (Carando et al., 1985; Granchi et al., 1996, 1998a). Thus, given the growing number of studies using the highly quantitative nature of LTT testing in orthopedics, it is likely better

suited for the testing of implant-related sensitivity than dermal patch testing (Veien and Svejgaard, 1978; Veien et al., 1979; Svejgaard et al., 1978; Secher et al., 1977; Everness et al., 1990; Carando et al., 1985; Granchi et al., 1995, 2003).

As we learn more about the subtleties of immune response to implant debris, the adaptive immune system may be involved to a much larger degree in debris-induced inflammation than what has been previously attributed to the innate immune system via macrophages reactivity.

Carcinogenesis

The carcinogenic potential of implant debris remains an area of concern. Animal studies have documented that implant metals can act as carcinogens. Small increases in rat sarcomas were found to correlate with high levels of serum cobalt, chromium, or nickel content produced by metal implants. Additionally, lymphomas with some form of bone involvement were also more commonly found in rat animal models with metallic implants. Although not common, implant site tumors in dogs and cats—primarily osteosarcoma and fibrosarcoma—have been associated with stainless steel internal fixation devices.

Some epidemiological studies implicate orthopedic implants in causing cancer 10–20 years after total hip replacement. However, more recently larger studies have found no significant increase in cancers such as leukemia or lymphoma, although these studies did not include people with high amounts of metal, such as those with a metal-on-metal prosthesis. The many differences in the populations with and without implants that do not depend on the implant itself confounds the interpretation of any epidemiological investigations.

It remains unknown if metal release from orthopedic implants is carcinogenic because causality has not been established in human subjects, and in fact, testing by the authors found that periimplant cells became toxic prior to any DNA strand breaks when tested with increasing concentrations of metal ions found in implants (Caicedo et al., 2007a; Hallab et al., 2002). The actual number of cases of tumors associated with orthopedic implants is likely underreported due to the frequency of tumors in the population demographic receiving metal implants. However, compared to the number of devices implanted on a yearly basis (over one million) the incidence of cancer at the site of implantation is relatively rare. Continued monitoring and large long epidemiological studies are required to fully understand this risk (Nyren et al., 1995; Matheisen et al., 1995; Visuri and Koskenvuo, 1991; Gillespie et al., 1988).

Preventive Strategies and Future Directions

Current strategies designed to address the problem of biomaterial-related implant failure are primarily aimed at decreasing the amount of periprosthetic particulate burden and any subsequent effects. Recently there has been a great deal of innovation regarding stronger, more wear-resistant polyethylene. These more highly cross-linked UHMWPE polymers are currently in various phases of clinical trial. However, initial results show a demonstrable decrease in polyethylene wear with potential for less particulate-induced bioreactivity/osteolysis and therefore greater implant performance. In the same vein, femoral heads with diameters of 32 mm have been associated with increased volumetric polyethylene wear; to combat this, smaller 28 mm heads are currently extolled as more biocompatible. Manufacturing flaws such as fusion defects and foreign body inclusions have also been suggested to contribute to adverse polyethylene wear properties. The elimination of polyethylene is another approach being investigated clinically in various centers. With the realization that early problems may have been related to the design and not the articulation, there has been renewed interest in the application of metal–metal and ceramic–ceramic bearings. Future designs which attempt to reduce wear include improved tolerances between polyethylene inserts and their metal backing, improved surface finish on the metallic concave surfaces, secure locking mechanisms, and the avoidance of holes on the convex portion of the acetabular prosthesis.

Metallic wear is also being addressed through techniques such as nitriding and nitrogen ion implantation to decrease the potential for abrasive wear and fretting in titanium alloy and cobalt alloy stems. Fabrication of metallic bearing surfaces with extremely low roughness can be expected to decrease articular wear rates. A polished metal head can be made as smooth as a ceramic head. Polishing of the stem will remove surface asperities and decrease particle generation from stem/bone fretting. In addition, polishing will minimize silicate contamination.

New metallic biomaterials are being proposed which attempt to improve load transfer to the bone and reduce the incidence of loosening and thigh pain. Currently used alloys (Co–Cr–Mo alloy, $E = 227$ GPa and Ti–6Al–4V alloy, $E = 115$ GPa) have relatively high elastic moduli, which limit smooth transfer of load to the surrounding bone in THA. Designs to improve load transfer can use a reduced cross-sectional area to increase flexibility, but at the expense of adequate stability of the implant within the bone. Additionally, the stresses may exceed the relatively low fatigue strength of Co–Cr–Mo implant alloy. Lower-modulus, more corrosion-resistant implant alloys are being developed. A Ti–13Nb–13Zr ($E = 79$ GPa) alloy is one such alloy which contains fewer elements of questionable cell response (i.e., Co, Cr, Mo, Ni, Fe, Al, V), and which possesses comparable strength and toughness to existing Ti–6Al–4V implant alloy. The Nb and Zr constituents seek to improve bone biocompatibility and corrosion resistance. Additionally, novel surface treatments on implant alloys such as the diffusion hardening (DH) treatment can produce a hardened surface with wear resistance superior to that of Co–Cr–Mo alloy, currently the industry leader for TKAs. These enhanced surface properties may lead to an improvement in the resistance to microfretting occurring within femoral head–neck taper regions and modular interfaces of current implant designs.

Electrochemical corrosion of orthopedic implants remains a significant clinical concern. Although the freely corroding implants used in the past have been replaced with modern corrosion-resistant "superalloys" deleterious corrosion processes have been observed in certain clinical settings. Attention to metallurgical processing variables, tolerances of modular connections, surface processing modalities, and appropriate material selection can diminish corrosion rates and minimize the potential for adverse clinical outcomes. For example, nitriding can reportedly significantly reduce the magnitude of fretting corrosion of Ti–6Al–4V devices. A need to further investigate the mechanical–electrochemical interactions of metal oxide surfaces in implants persists. Characterization of the stresses and motion needed to fracture passivating oxide films as well as the effects of repeated oxide abrasion on the electrochemical behavior of the interface and ultimately the implant remain avenues of active investigation.

The clinical significance of elevated metal content in body fluids and remote organs of patients with metallic implants needs to be further elucidated. Considerably more work will be required to discern the specific chemical forms and distribution of metal degradation products associated with the various forms of implant degradation. Continued efforts to better understand the constituents of orthopedic implant degradation and their biological effects is necessary to ultimately determine threshold levels of debris and circulating metal ions and measures of biologic reactivity (e.g., metal-LTT testing) that can be used to clinically determine when intervention is required to fix a downward spiral before too much bone loss and inflammation occur. The importance of this evaluation of orthopedic biomaterial performance is growing as the use of orthopedic biomaterials is increasing, as new orthopedic implants are being developed and as expectations of implant durability and performance increase (Jacobs et al., 1996; Black, 1996).

Chapter Study Questions

(1) What are the general mechanical property qualifications for orthopedic biomaterials and what are the major categories of orthopedic implants?

Answer: Generally orthopedic implants must be capable of high strength, fracture toughness, and most importantly corrosion resistance. The two major kinds of orthopedic implants are bone fixation or total joint arthroplasty (to a less extent new kinds of dynamic stabilization devices with articulating components are slowly making their way into the market.

(2) (A) What is the primary problem associated with the longevity of current total joint replacement implants and why? (B) How could this be solved by improved biomaterials?

Answer: (A) Particle and wear debris generation at the articulating surfaces of total joint replacements causes aseptic loosening of the implants through the induction of inflammation around the implant (macrophage-particle overload) which causes a decreased production of new bone and increased bone resorption. (B) More wear-resistant materials at the articulating surface while maintaining current available levels of other mechanical properties.

(3) What are the primary cytokines associated with particle-induced osteolysis and what is the primary cell type involved in this process.

Answer: The primary cytokines associated with osteolysis are TNF-alpha, IL-6, IL-1beta, prostaglandin E_2, etc. produced by macrophage interaction with particulate debris from implants.

(4) Name six of the primary orthopedic implant biomaterials?

Answer: (A) Co–base alloys, Ti–base alloys, stainless steel, PMMA, UHMWPE, and alumina.

(5) Name one new orthopedic biomaterial and why it was introduced (i.e., what specific problem/deficit is it attempting to solve?).

Answer: Zirconium alloy was introduced to decrease the amount of metallic wear debris being generated at the bearing surface and as an alternative metal less likely to induce hypersensitivity reactions because of its corrosion resistance and less common presence environmentally.

(6) What is one way in which current designs of orthopedic implants are creating more challenging conditions for biomaterials to overcome and why?

Answer: Orthopedic implant component modularity (more components that fit together in vivo) is creating more interfacial surfaces from which implant debris can be generated through fretting corrosion (micromotion) that interact both locally and systemically.

2.5.5 Dental Applications

Overview

The mouth is the gateway to the body. Links between oral and systemic health are widely accepted and compromises in general health are correlated with loss of oral dentition. Almost 20% of the US population older than 65 years is totally edentulous. A substantial number of other patients are partially edentulous, having an average of 10 missing teeth, and 50% of adults ages 20–64 has at least one missing tooth (Dye et al., 2015). In addition, 15% of the US population has periodontal disease severe enough to warrant surgery, 15 million people experience temporomandibular joint (TMJ) disorders, 30,000 patients a year undergo craniofacial resection surgery, and 4 million suffer from salivary gland disorders (Scheller et al., 2009). Collectively, more than 85% of the world's population requires repair or replacement of a dental, oral, or craniofacial (DOC) tissue.

Defects in DOC tissues resulting from disease, trauma, congenital abnormalities, or tumor resection present a challenge to clinicians, and replacement or restoration of these tissues is a subject of clinical, basic science and engineering concern. In addition to leaving patients with aesthetic deformities, defects in DOC tissues may be uncomfortable to the patient and affect function. Therefore structure, function, aesthetics, and pain must be managed and present challenges to biomaterial design that can be more complex than in other parts of the body.

Biomaterials scientists and engineers working in the DOC space have developed a wide range of solutions to manage loss of DOC tissue structure and function. In this chapter, we will start with a discussion of some of the unique needs in managing DOC problems and designing materials for DOC use. We will then provide an overview of restorative materials, followed by more in-depth discussions of dental implants and tissue-engineered medical products used in dentistry, two areas most relevant to biomedical engineers working in dentistry. Lastly, we will discuss how biomaterials in dentistry have informed other areas of biomaterials and have played a central role in their discipline.

Unique Needs in Developing Biomaterials for DOC Procedures

Replacement, reconstruction, and regeneration of DOC tissues require the synthesis of engineering, biology, and clinical sciences. The tissues of the DOC region are complex and developing biomaterials for functional replacement of these tissues presents many unique design challenges. In the DOC region, maintaining or restoring aesthetics, in addition to restoring structure and function, presents a more complex design problem than in other regions of the body. In designing biomaterials for use in the oral microenvironment, it is also necessary to consider the microbial environment and the potentially altered host immune response. It is rare that a single DOC tissue needs to be replaced; rather, multiple tissues are usually in need of replacement. The tooth, for example, consists of multiple mineralized tissues (enamel and dentin) surrounding a pulpal cavity that contains vasculature and innervation. Within the mineralized tissue compartment of the tooth, there is an elegant functionally graded transition from enamel to dentin (the dentin–enamel junction). There are also important developmental differences between the craniofacial and axial skeleton; the craniofacial bones are formed by intramembranous ossification, whereas bones of the axial skeleton are formed via endochondral ossification. Thus tissue-engineering strategies that seek to mimic aspects of developmental biology may need to be optimized specifically for DOC applications.

Restorative Materials

Restorative dental materials, or materials used to reconstruct all or part of teeth, have played a prominent role in health

care for several thousand years and the development of dental materials has progressed more rapidly than other areas of biomaterials. The oral environment is one of the harshest environments in the body and is subjected to high and varying forces, fluctuating pH and temperature, and bacteria. Knowledge of biomaterials science and engineering is therefore critical for the selection, processing, and function of restorative materials.

Restorative materials may be direct (restoration is inserted directly into the tooth) or indirect (restoration is fabricated outside of the mouth). A wide range of materials falls under the umbrella of restorative dental materials, including amalgams, composites, cements, crowns, bridges, inlays, liners, varnishes, orthodontic materials, dentures, impressions, and investment materials. Specific classes of materials used for these applications include metals (silver–mercury amalgam alloys, noble metal inlays and crowns, base metal alloy partial dentures and crowns), ceramics (porcelain denture teeth, gypsum investments), polymers (acrylics for dentures, alginates for impressions), and composites (methacrylates reinforced with silica). About 75% of a general dentist's practice involves the use of restorative materials and there are many textbooks dedicated solely to restorative materials (Sakaguchi et al., 2018).

Composite materials, consisting of inorganic particulate fillers dispersed in a cross-linked polymeric continuous phase, have displaced amalgams as primary restorative materials because of their improved aesthetic properties and mercury-centered toxicity concerns associated with amalgams. Composite restoratives are typically processed in situ by photopolymerization whereby a filled resin (typically a methacrylate) is placed in the patient's mouth and irradiated with visible light, generating reactive species that initiate polymerization and harden the material. Filler particles are manufactured from silica (quartz, glass, fumed or colloidal silica) and range in size from 20 nm to 10 μm. The volume fraction of particles ranges from 50% to 85% and influences mechanical properties (stiffness, strength, fracture toughness, and wear), polymerization shrinkage, and the handling characteristics of the composite, an important factor in a composite's acceptance by clinicians.

Polymerization is accompanied by a significant amount of volumetric shrinkage and associated shrinkage stress, leading to localized debonding from the tooth, marginal gap formation, tooth deflection, and tooth cracking. Mitigation of polymerization-induced shrinkage and/or the concomitant stress is a primary area of research in dental biomaterials, and has been explored using an array of approaches, including low shrinkage ring-opening polymerization chemistries, modification of the in situ processing, polymerization-induced phase separation, thiol–ene-based polymerization, and allyl sulfide-based addition–fragmentation chain transfer (Cramer et al., 2011).

In addition to reducing shrinkage, other key research needs are reducing wear and increasing the longevity of the bond between the hydrophobic biomaterial and hydrophilic tooth structure. As the population ages, restorations for exposed root surfaces are on the rise. With an aging population, chronic diseases are increasing and medically compromised patients present additional challenges. Nanotechnology and biofabrication may help overcome these challenges.

Dental Implants

Although removable dentures and fixed partial dentures offer effective treatments for many edentulous patients, those who have lost substantial tooth-bearing portions of bone and cannot manage prostheses or chew properly can improve their oral function through the use of dental implants. There are now 5 million dental implants inserted each year. Dental implants provide long-term (15 years) support for restorations. To design clinically effective dental implants, an understanding of the parameters governing the long-term success of the biomaterial/tissue composite system is needed. A requirement for dental implants to be successful is adequate bone (width, height, length, contour, and density) to support the implant.

Dental implants are classified into three categories:

1. Endosseous implants are embedded in mandibular or maxillary bone and project through the oral mucosa covering the edentulous ridge.
2. Subperiosteal implants rest on the surface of the bone beneath the periosteum.
3. Transosseous implants penetrate the inferior mandibular border and also project through the oral mucosa covering the edentulous ridge.

Root-form endosseous implants are the most common implants in clinical practice (Figs. 2.5.5.1 and 2.5.5.2). Early dental implants were primarily uniblock (single piece) systems combined with removable, fixed, or fixed–removable intraoral prosthetics. Many implant biomaterials and designs have been studied; however, the larger numbers of applications have now become root-form designs placed, restored, and maintained for function through osseointegrated interfaces with

• **Figure 2.5.5.1** Root-form type designs.

bone. The most common root-form implant is the two-stage endosteal screw-type implant. The implant is inserted first and the abutment and prosthetic components are assembled after a controlled period of postsurgical healing of bone and soft tissues. Access to the oral regions and the number of teeth per individual result in larger numbers of dental implants in use compared to other types of implant-based treatments for musculoskeletal disorders, such as hip and knee replacements. The biomaterials are now mostly titanium and alloys with a wide range of surface modifications for influencing interfacial tissue regions. Surface modifications include compositional (primarily oxides, calcium phosphates, and fluoride) and microtopographical features (degrees of roughness). These concepts also extend to the gingival and mucosal soft tissue to implant interfacial systems. Success rates for implants placed in the mandible are approximately 95% at 5 years and greater than 85% at 15 years. For maxillary implants, success rates are approximately 85%–90% at 5 years and 80% at 15 years (Kohn, 2008).

• **Figure 2.5.5.2** Radiograph of root-form implants supporting intraoral bridge reconstructions.

Criteria for Successful Implant Function

A clinically successful implant is guided by: (1) the implant material(s), (2) healing and remodeling of the adjacent tissues, and (3) the interfacial zone between the implant and tissue. In a well-functioning, stable implant, the interfacial zone is composed of a thin (<100 μm) layer of metal oxide, proteins, and connective tissue. The thickness of the interfacial zone affects interfacial integrity. Mechanical stability and integrity of the implant–tissue interface depend on material, mechanical, chemical, surface, biologic, and local environmental factors, all of which change as functions of time in vivo (Fig. 2.5.5.3). Implant success also depends on the patient's overall medical and dental status, surgical techniques, and the extent and kinetics of healing.

Osseointegration and Accelerating Healing and Attachment to Tissue

Unlike many biomaterials, which replace as much of a tissue's natural structure and function as possible, dental

• **Figure 2.5.5.4** Schematic of natural tooth versus implant attachment to bone. (Reprinted with permission from Taylor, T.D., 1990. Dental Implants: Are They for Me? Quintessence.)

implants do not restore function by mimicking the function of the periodontal ligament (PDL), which attaches the tooth to bone and absorbs forces of mastication (Fig. 2.5.5.4). Instead, osseointegration, or the direct structural and functional connection between ordered, living bone and the surface of a load-carrying implant, is what occurs with a well-functioning implant. This definition was originally based on retrospective radiographic and light microscopic observations of retrieved implants, and has since been modified based on scanning and transmission electron microscopic analyses and observations across multiple length scales (Palmquist, 2018).

Examination of implant/tissue interfaces from a wide range of implant materials, including steel, gold, platinum, and cobalt alloys, showed fibrous soft tissue (scar-like) at the interfaces where higher magnitude loads were transferred (Lemons, 1999). These zones were relatively dense collagenous structures that contained limited numbers of cells and blood vessels. In contrast, implants fabricated from higher purity aluminum oxides (alumina and sapphire forms), carbons, calcium phosphate compounds, and reactive group metals and alloys (primarily titanium) demonstrated a mixture of direct bone-to-implant contact and soft tissues when evaluated histologically by optical microscopy methods. These interfacial conditions were described as osseointegrated, and material and fabrication methods to routinely achieve osseointegration were developed.

The current definition of osseointegration is fundamentally the same: host bone responds in a safe, predictable, and versatile manner to surgical placement of an implant in a sterile wound, with healing sequelae leading to interfacial osteogenesis and mechanical stability of the implant. In a well-functioning implant, following these short-term (4–6 months) events, a stable marginal bone level is maintained. In comparison, poorly differentiated connective tissue adjacent to an implant leads to mobility and implant failure.

To function appropriately, a dental implant must carry occlusal stresses, transfer the stresses across the implant–tissue interface, and transmit them to the adjacent bone. Stresses should be of a "correct" orientation and magnitude so that they mimic physiologic stresses and allow tissue viability to be maintained. The ability to transmit stress from implant to bone depends on achieving interfacial fixation. Thus two design goals are to stabilize the interface in as short a time postoperatively as possible and have the interface remain stable for as long a time as possible. "Stability" is defined as the maximum allowable displacement at an implant–tissue interface that will still result in osseointegration and bone maintenance, and motion of an implant less than 100–200 μm is considered most conducive to creating and maintaining osseointegration. Because a stable interface must be developed before loading, it is desirable to accelerate tissue apposition to implant surfaces. Material developments that have been implemented in clinical practice include the use of surface-roughened implants, nanostructured surfaces, bioactive ceramic coatings, bone grafting, recombinant growth factors, platelet-rich plasma, antimicrobial coatings, and bisphosphonate- and other drug-eluting coatings (Kohn, 2018; Rasouli et al., 2018; Qin et al., 2018; Alenezi et al., 2018; Kellesarian et al., 2017).

Analysis of the interface zone at nano-, micro-, and macro-levels of resolution demonstrates the importance of controlling implant bulk and surface properties, surgical methods, site dimensions, times and conditions of intraoral abutment and restoration placement, and maintenance (cleaning) of the percutaneous transition zone. As an example of the importance of biomaterial properties, if unit area of implant, bone, and force are modeled, the interfacial strain magnitude will depend on the magnitude and direction of applied forces, the roughness of the contact zone, attachment (bonding), and the elastic moduli of the implant and bone. Most ceramics, such as alumina, zirconia, and titania, and most surface-oxidized metals have contact with bone, but minimal or no chemical bonding. Roughening the implant surface, which leads to an increase in surface area, provides conditions for accelerating early healing (blood clotting, fibrin deposition, integrin binding) and microscopic interdigitation with bone, leading to increased force transfer and resistance to microscopic shear at the interface. If the interface is noninterdigitated and nonchemically bonded, stress magnitudes of each constituent in the contact zone will be proportional to the elastic modulus of the constituent. Relative to compact bone, alumina and zirconia have moduli more than 10×, metals 5–10×, with unalloyed titanium having the lower magnitude and calcium phosphates about 0.5–2×.

Surface Topology and Chemistry

A variety of implant surface configurations can improve the cohesiveness of the implant–tissue interface. Alterations in surface topology can decrease relative motion and fibrous integration in the short term, increasing transfer of occlusal loads to tissue, which can help minimize loosening in the long term. Implant surfaces may be smooth, textured, screw threaded, or coated. Textured surfaces can be created by adding (plasma spraying) or subtracting surface layers (acid etching, grit blasting). Osseointegration around screw-threaded implants occurs through tissue ongrowth, or apposition of tissue to the implant surface. Tissue ingrowth into roughened or 3D surface layers yields higher bone–implant shear strength than other types of fixation. Increased interfacial shear strength results in a better stress transfer from the implant to the surrounding bone, a more uniform stress distribution between the implant and bone, and lower stresses in the implant.

Understanding implant surface chemistry is important to ensure that the biomaterials do not adversely affect local and systemic tissues and organs, and that the in vivo environment does not degrade the biomaterial and compromise its function. The success of any implant depends on its bulk and surface properties. The surface of a biomaterial is frequently different in chemical composition and morphology than the bulk material. These differences arise from the molecular arrangement, surface reactions, and contamination at the surface. For metal implants, interface chemistry is determined by the properties of the metal oxide, not by the metal itself. Metallic oxides dictate interactions between cells and proteins and the implant surface, and are continually altered by the diffusion of oxygen and metal ions. The surface potential of the implant also affects osseointegration; metal oxides with low dielectric constants promote the migration of cells to an implant surface.

Metals are more susceptible to electrochemical degradation than ceramics. Therefore a fundamental criterion for choosing a metallic implant material is that it elicits a minimal biologic response. Titanium-based materials are well tolerated by the body because of their passive oxide layers, and alloying elements can be tolerated by the body in trace amounts. Larger concentrations of many metal ions usually cannot be tolerated. Therefore minimizing mechanical and chemical breakdown of implant biomaterials is a primary design criterion, and is achieved by material selection and design. Anodization is an electrochemical process in which current is applied to the implant while immersed in an electrolyte, resulting in a thickened oxide layer. Laser treatment of implant surfaces serves as a secondary means of sterilization and altering surface energy.

Mechanical Parameters and Implant Design

Mechanical properties important in designing implant materials include stiffness, yield, ultimate and fatigue strengths, and fracture toughness. Stiffness (modulus) dictates the ability of the implant to transmit stresses to the adjacent tissue. Selecting materials with high static and fatigue strength is important to avoid material failure. Fracture toughness is a measure of the energy needed to cause fracture in the presence of a defect and is a critical parameter in designing biomaterials with surface topologies that could serve as sites of stress concentration.

Material failure of implants, generally by fatigue, does occur. Fatigue of implants is clinically important and fatigue properties of implant materials should be included in implant design. The stress distribution in an implant and surrounding tissue depends on the section size of the implant and the elastic moduli of the implant material and tissue. Use of larger, stiffer implants can reduce the probability of mechanical failure, but may compromise stress transfer to the tissue.

The design of dental implants is based on several factors, including the geometry of the implant (length, diameter, macroscopic and microscopic shapes), how the geometry affects mechanical properties, stress distribution, and the initial and long-term stability of the implant–tissue interface. Implants can be designed to: (1) maximize strength, (2) maximize interfacial stability, or (3) maximize load transfer, with each of these criteria a function of material and interfacial properties. Two goals of any implant design are to maximize initial stability to achieve osseointegration in as short a time as possible following implant placement, and minimize loosening (maintain osseointegration for as long a time as possible following achievement of stability).

Dental implants are subjected to axial, shear, bending, and torsional forces in service. In addition to the magnitude of the force, the direction must also be considered in the design process. Given the complex loading patterns a dental implant is subjected to and range of displacements that are considered "stable," the time at which an implant can begin to undergo loading is implant and location specific. Quantifying stresses and strains in implants, tissues, and implant–tissue interfaces is therefore important for implant design and understanding adaptation of tissue around an implant. Implant geometry, elastic properties, loading, boundary conditions, interface conditions, and local stresses and strains are all important in this regard.

Materials Used in Dental Implants

Two classes of materials—metals and ceramics—are used to manufacture dental implants, either alone or in hybrid fashion. Metallic implant materials are largely titanium based, either commercially pure titanium (CPTi) or Ti-6Al-4V alloy. The synergistic relationship among processing, composition, structure, and properties of both the bulk materials and their surfaces provides clinicians with implants having an array of properties. Processing conditions, such as casting, forging, and machining of metal implants, densification of ceramics, deposition of ceramic and metal coatings onto metal implants, as well as cleaning and sterilization procedures, can all alter the microstructure, surface chemistry, and properties. Biomaterials used for the construction of dental implant systems are summarized in Tables 2.5.5.1–2.5.5.3. This summary includes the nominal bulk compositions, mechanical properties, and surface conditions as described in national and international standards.

TABLE 2.5.5.1 Engineering Properties of Metals and Alloys Used for Surgical Implants[a]

Material	Nominal Composition (w/o)	Modulus of Elasticity GPa	Ultimate Tensile MPa	Elongation to Fracture (%)	Surface
Titanium	99^{+}Ti	100	240–550	>15	Ti oxide
Titanium–aluminum–vanadium	90Ti–6Al–4V	120	860–930	>8	Ti oxide
Cobalt–chromium–molybdenum (casting)	66Co–28Cr–6Mo	235	520–1170	>8	Cr oxide
Stainless steel (316L)	70Fe–18Cr–12Ni	190	480–1000	>30	Cr oxide
Zirconium	99^{+}Zr	100	450–550	>15	Zr oxide
Tantalum	99^{+}Ta	–	170–520	<30	Ta oxide
Gold	99^{+}Au	100	210–310	>30	Au
Platinum	99^{+}Pt	165	130	40	Pt

w/o, weight percent.
[a]Minimum values from the American Society for Testing and Materials Committee F4 documents are provided. Selected products provide a range of properties.

TABLE 2.5.5.2 Engineering Properties of Inert Ceramics Used as Biomaterials[a]

Material	Modulus of Elasticity GPa	Ultimate Bending Strength MPa	Surface
Aluminum oxide			
Poly-crystalline	370	300–550	Al_2O_3
Single crystal (sapphire)	390	640	Al_2O_3
Zirconium oxide (partially stabilized zirconia)	150–240	500–650	ZrO_2
Titanium oxide (titania)	280	70–100	TiO_2
Carbon	25–40 (4–6)	150–250 (22–36)	C
Carbon-silicon (LTI)	25–40 (4–6)	200–700 (29–101)	CSi

[a]These high ceramics have 0% permanent elongation at fracture.

TABLE 2.5.5.3 Engineering Properties of Bioactive and Biodegradable Ceramics[a]

Material	Modulus of Elasticity GPa	Ultimate Bending Strength MPa	Surface
Hydroxyapatite	10–120	15–300	$Ca_{10}(PO_4)_6(OH)_2$
Tricalcium phosphate	30–120	15–120	$Ca_3(PO_4)_2$
Bioglass or Ceravital	40–140	20–350	$CaPO_4$
Apatite–Wollastonite ceramic	125	215	$CaPO_4 + F$

[a]These ceramics have 0% permanent elongation at fracture.

Metals

Metallic implants used in clinical dentistry today are almost exclusively manufactured from titanium and its alloys. The strength of titanium is due to its hexagonal close-packed crystal lattice and crystallographic orientation, whereas its biocompatibility (corrosion resistance) is attributed to its stable, passive oxide layer. Titanium implants are in a passive state (their oxide is chemically stable) in a normal physiological microenvironment. Both CPTi and Ti-6Al-4V possess excellent corrosion resistance for a full range of oxide states and pH levels. The coherent oxide layer and ability of titanium to repassivate results in corrosion resistance. Titanium ions are released from transient chemical dissolution of the oxide. However, the low dissolution rate and relative nonreactivity of titanium dissolution products allow bone to thrive and osseointegrate with titanium.

The mechanical properties of titanium-based materials are well established. Microstructures with small (<20 μm) grain sizes have the highest fatigue strength (~500–700 MPa). Surface roughening results in a reduced fatigue strength compared with smooth-surfaced implants. The Ti-6Al-4V alloy has a 60% greater strength than pure titanium, but it is more expensive. Both CPTi and Ti-6Al-4V alloy have complex, heterogeneous surface oxides. There may be differences in cell adhesion, and tissues may be in closer proximity to pure titanium surfaces than to alloy surfaces; however, there is no difference in implant function between the two types of titanium.

Ceramics

Ceramic implants were introduced because of their relative biologic inertness compared to metals. Ceramics are fully oxidized materials and therefore chemically stable and less likely to elicit an adverse biologic response than metals, which only oxidize at their surface. Ceramics promote osseointegration by the nature of their osteoconductivity (a biomaterial that is conducive to bone growth on its surface or into its pores).

"Inert" ceramics include alumina (Al_2O_3) and zirconia (ZrO_2), which are used as bulk implants. Bioactive and bioresorbable ceramics are used as coatings to accelerate osseointegration. Bioactive ceramics elicit tissue formation, can bond with bone, and be replaced by bone over time. Bioactive ceramics are partially soluble, enabling ion transfer and the formation of a direct bond between implant and bone. Bioactive ceramics are primarily used as scaffold materials or as coatings on more structurally robust substrates. Bioresorbable or biodegradable ceramics have a higher degree of solubility than bioactive ceramics, gradually resorb and integrate into the surrounding tissue, and are used as bone augmentation materials.

The concept of bioactivity was originally introduced with respect to bioactive glasses via the following hypothesis: the biocompatibility of an implant material is optimal if the material elicits the formation of normal tissues at its surface, and, in addition, if it establishes a contiguous interface capable of supporting the loads that normally occur at the site of implantation (Madsen and Kohn, 2019). Examples of bioactive materials are bioactive glasses, glass ceramics, and calcium phosphate ceramics. Bioactive glasses and glass ceramics include bioglass, which is synthesized from several glasses containing mixtures of silica, phosphate, calcia, and soda; Ceravital, which has a different alkali oxide concentration from that of bioglass; and apatite-wollastonite glass ceramic, a glass ceramic containing crystalline oxyapatite and fluorapatite [$Ca_{10}(PO_4)_6(O,F_2)$] and β-wollastonite (SiO_2-CaO) in an MgO-CaO-SiO_2 glassy matrix. Calcium phosphate ceramics are a group of biomaterials with varying calcium-to-phosphate ratios, depending on processing-induced physical and chemical changes. Among the calcium phosphates, the apatites have the largest use in implantology.

The impetus for using synthetic hydroxyapatite (HA) as a biomaterial stems from the perceived advantage of using a material similar to the mineral phase in bone and teeth for replacing these materials and the expectation that better tissue bonding can be achieved. Additional advantages of bioactive ceramics include elastic properties similar to those of bone when not fully dense, control of degradation rates through control of material properties (e.g., crystallinity and Ca/P ratio), and the potential for the ceramic to function as a barrier to corrosion when coated onto a metal implant.

Reactions (ion exchange) at the ceramic surface that dictate mechanical, chemical, physical, and biological properties depend on processing techniques, time, temperature, and atmosphere. Processing techniques used to bond Ca-P powders to implants include plasma and thermal spraying, sintering, ion beam and other sputter techniques, electrophoretic deposition, sol-gel techniques, pulsed laser deposition, and chemical vapor deposition (Madsen and Kohn, 2019). Different structures, compositions, and dissolution rates result from different processing approaches, and modulate biological reactions. For example, increased Ca/P ratios, fluorine and carbonate content, and crystallinity lead to greater stability. Ca/P ratios in the range 1.5–1.67 yield the most beneficial tissue response. Most synthetic HAs contain substitutions for the PO_4^{3-} and/or OH^- groups and vary from the absolute stoichiometry and Ca/P ratios of HA. Oxyhydroxyapatite, tricalcium phosphate (TCP), tetracalcium phosphate, and octocalcium phosphate have all been detected in commercially available apatite implants (Table 2.5.5.3, Madsen and Kohn, 2019). Understanding the processing–composition–structure–processing synergy for calcium phosphates is therefore critical to understanding the in vivo function of these materials.

Each calcium phosphate is defined by a unique set of chemical and physical properties. Physical parameters and properties of importance to the clinical function of calcium phosphate ceramics are summarized in Table 2.5.5.4, along with the functional and biological relevance and techniques used to characterize each parameter.

TABLE 2.5.5.4 Physical and Chemical Properties Important to the Function of Calcium Phosphate Bioceramics

Material Parameter(s)	Functional and Biological Relevance	Technique(s) to Characterize
Particle size, shape, distribution	Strength	Sifting, quantitative stereology
Pore size, shape, distribution	Strength, bioreactivity	Stereology, scanning electron microscopy (SEM)
Specific surface area	Dissolution, precipitation reactions	Brunauer–Emmett–Teller
Phases	Dissolution, protein adsorption	X-ray diffraction, Fourier transform infrared spectroscopy
Crystal structure, grain size, density	Strength, toughness, protein adsorption	Optical microscopy, SEM, transmission electron microscopy
Composition	Solubility	Auger electron spectroscopy, X-ray photoelectron spectroscopy (XPS)
Chemical stability, surface activity	Solubility, dissolution, cell adhesion	XPS, ionic flux, zeta potential
Thickness, hardness, roughness	Cell, protein adsorption	SEM, nanoindentation, profilometry

Future Directions

Advances in materials synthesis and processing, surgical technique, and clinical protocols have enabled dental implants to have excellent clinical success. Nonetheless, clinical failures occur at rates of approximately 2%–5% per year. Causes of failure and current problems with dental implants include:

1. Early loosening, stemming from a lack of initial osseointegration;
2. Late loosening, or loss of osseointegration;
3. Bone resorption;
4. Inflammation and infection;
5. Fracture of the implant and/or abutment and delamination of coatings from the bulk implant.

The most common failure mechanism with endosseous implants is alveolar crest resorption, leading to decreased volume of supporting tissues and ultimately implant loosening. Bone resorption can be mechanically mediated due, in part, to the elastic mismatch between implant and bone. Bone resorption can also occur secondary to peri-implantitis, an inflammatory process affecting hard and soft tissues surrounding an implant, leading to progressive periodontal lesions and loss of supporting bone.

Biomaterials advances include an increased use of implants made from zirconia for improved aesthetics (Roehling et al., 2019), additive manufacturing of implants via digital technologies and computer aided design for custom fitting and more rapid fabrication (Katkar et al., 2018), interfacing manufacturing with imaging for fabrication before tooth extraction and immediate insertion into sockets (Saeidi Pour et al., 2019), nanoscale modifications of implant surfaces, including patterning, functionalization, and molecular grafting (Rasouli et al., 2018), antibacterial coatings, both passive (kills bacteria in contact with biomaterial surface) and active (releases antibacterial agents to kill bacteria at some diffusion distance) (Qin et al., 2018), and drug-eluting implant coatings, including technologies for the controlled release of bisphosphonates and bone morphogenetic proteins (BMPs) (Alenezi et al., 2018).

While these and other strategies have expanded the population of patients that can be treated with an implant, inadequate initial bone stock or loss of bone following implant placement necessitates alternative approaches to treat inflammation and/or regenerate bone. These approaches are discussed in the next section.

Tissue Engineering in Dentistry

Need for Tissue Engineering in Dentistry

Gold standard treatments for the repair of DOC tissues are similar to therapies used elsewhere in the body and include synthetic materials, autografts, and allografts. Each of these reconstructive strategies has limitations and lacks clinical predictability. Only a minimal amount of tissue can be harvested for autografts, the harvesting procedure may lead to donor site discomfort and morbidity, and it may be difficult to form this tissue into desired shapes (Scheerlinck et al., 2013), a problem that is particularly important in the craniofacial region. Autografting, the current "gold standard" for craniofacial bone regeneration, has failure rates as high as 30% (Scheller et al., 2009). Allografts have the potential to transfer pathogens. Freeze drying, demineralization, and irradiation reduce immunogenic potential, but can reduce structural integrity, leading to graft fracture. Use of growth factors relies on the presence of a sufficient population of undifferentiated progenitor cells capable of responding to the inductive cues provided by the growth factor. Such a population may not be available in aged or compromised patients. Complications with synthetic biomaterials include stress shielding, loosening, and mechanical breakdown. These limitations with current therapies have motivated tissue engineering as a solution to DOC problems.

Regeneration of DOC tissues presents a formidable challenge that requires synthesis of engineering, basic science, and clinical expertise. Identification of appropriate scaffolds, cell sources, and spatial and temporal signals (the tissue-engineering triad) is necessary to optimize development of single DOC tissues, hybrid tissues, and graded interfaces between tissues. Dental tissue engineers are interested in the regeneration of teeth, oral mucosa, salivary glands, craniofacial bone, cranial sutures, periodontium, muscle, and the TMJ.

Materials for Engineering DOC Tissue Structure and Function

Regeneration of DOC tissues can be pursued by one or a combination of the three general tissue-engineering strategies: conduction, induction, and cell transplantation. In a conductive approach, a biomaterial provides an appropriate microenvironment for host cells to attach, grow, and differentiate, leading to the formation of new tissue within the material. Conductive materials are the most clinically prevalent in dentistry. In an inductive approach, biologic agents, typically growth factors, induce host cells to form new tissue. Cell-based therapies involve transplantation of uncommitted or differentiated cells, and also genetically manipulated cells, and can be used in combination with a supporting biomaterial (conductive) and inductive agents. Biomaterials used for DOC tissue engineering include synthetic polymers, ceramics and composites, natural materials, and tissue derivatives.

Tissue-engineered products for DOC applications should satisfy the following design requirements (Scheller at al., 2009):

1. Biocompatibility;
2. Conductivity to guide attachment and proliferation of cells and secretion of new extracellular matrix (ECM);
3. Ability to incorporate inductive factors to direct and enhance new tissue growth;
4. Support of vascular ingrowth for oxygen and biomolecule transport;
5. Mechanical integrity to support loads at the graft site;
6. Controlled, predictable, reproducible rate of degradation into nontoxic species that are easily metabolized or excreted;
7. Easy and cost-effective processing into irregular 3D shapes of sufficient size to fill clinically relevant defects.

Integrating all of these criteria into a single biomaterial presents design challenges that require more complexity than simplified ECM mimics can provide.

Synthetic and natural biomaterials that mimic structural and/or functional aspects of natural ECMs and satisfy at least some of these design requirements include both organic and inorganic biomaterials: copolymers of poly(lactic-*co*-glycolic acid) (PLGA), polycaprolactone (PCL), polyethylene glycol (PEG), polyurethanes, poly(propylene fumarate), collagen, starch-based materials, alginate, silk, bioactive glasses and glass ceramics, calcium phosphate ceramics, calcium phosphate/collagen blends, and calcium phosphate/synthetic polymer composites. Varying parameters of the biomaterial, such as composition, topology, and crystallinity, can significantly affect the amount and rate of tissue formation, and intensity or duration of inflammatory response (Madsen and Kohn, 2019; James et al., 1999).

To satisfy a larger number of the design criteria listed in the previous paragraph, biomaterial modification can take on different levels of complexity, resulting in increasing levels of physiological "mimicry" and functionality. In addition to using natural ECMs, surface and bulk chemical modifications of synthetic materials can enhance the ability of a biomaterial to respond to physiological cures. Material modifications include changes in hydrophilicity, surface functionalization with charged groups, incorporation of insoluble ligands and peptide cell recognition sequences, attachment of larger proteins, supramolecular self-assembly, and development of materials that bind and release soluble factors (Mao and Mooney, 2015). Strategies based on physical cues include the reproduction of nanoscale topology, superposition of mechanical cues, and control of degradation. Designing biological recognition into a biomaterial may also obviate the need for therapies based on delivery of cells or recombinant growth factors, which are subject to regulatory constraints.

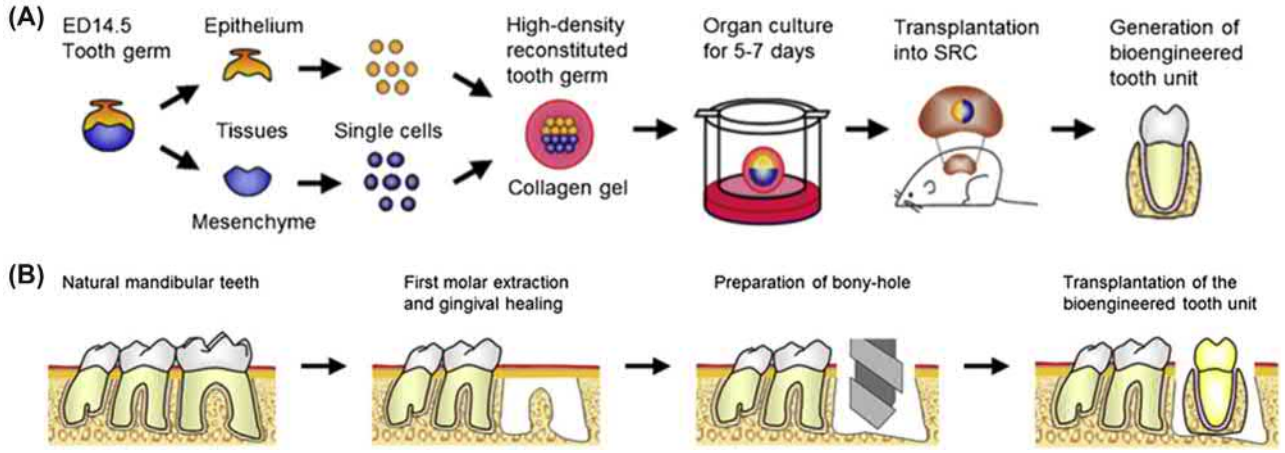
DOC Tissue-Engineering Applications

Teeth

The tooth is composed of four distinct tissues: pulp, dentin, cementum, and enamel. The tooth root is supported by a PDL and encased in alveolar bone. The diversity in tissue types coupled with the need for the tooth to withstand forces of mastication makes engineering a tooth complex. Some groups focus on regenerating one or two of the subtissues for targeted repair, while others aim to engineer an intact tooth and alveolus simultaneously (Nakao et al., 2007).

Complete tooth regeneration is complicated by the fact that regrowth of a tooth is desired at a site where a tooth no longer exists. Thus unlike engineering bone and mucosa, where scaffolds and signals can draw on cues and cells present in the surrounding host tissue, an engineered tooth must be self-reliant. Autologous stem cells are used for whole tooth engineering due to the complex signaling required for shape morphogenesis and tooth eruption. Before eruption of a new tooth, a population of primitive stem cells in the tooth bud is capable of providing the instructions necessary for growth of the entire tooth (Oshima et al., 2011, Fig. 2.5.5.5). Non-stem cell-based approaches are used for regeneration and repair of single DOC dental tissues, including pulp, dentin, cementum, and enamel. Dental pulp stem cells are a unique mesenchymal stem cell (MSC) population that is present in the pulp. A second tooth-associated MSC population has been isolated from the PDL, periodontal ligament stem cells (PDLSCs). Dental pulp stem cells and PDLSCs transplanted on HA, TCP, and other scaffolds can regenerate a vascularized dentin/pulp-like complex.

Biomaterials that guide the engineering of whole teeth or individual tissues parallel those used in engineering other



• **Figure 2.5.5.5** Generation of a bioengineered tooth unit. Schematic representations of: (A) the regenerative technology of bioengineered tooth unit; (B) protocol used to transplant a bioengineered tooth unit in a murine tooth loss model. (Reprinted with permission from Oshima et al. (2011)).

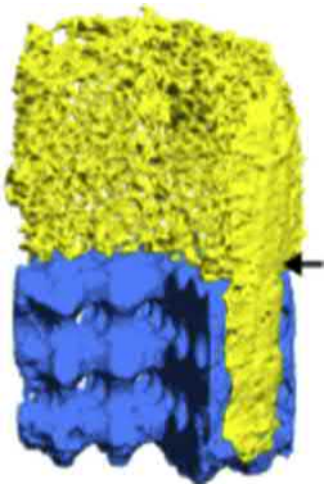
mineralized tissues and include: collagen, poly(glycolic acid), self-assembling peptides, gelatin–chondroitin–hyaluronan tripolymer, and silk. The success of in vivo tooth regeneration in rodents and rabbits is 20%–50% with implanted cell/scaffold combinations, with success defined as regeneration of at least three histologically intact structures, including enamel, dentin, pulp, cementum, and PDL (Scheller et al., 2009).

The acellular nature of enamel enables material-centric approaches to remineralization. Self-assembling peptides or peptide amphiphiles are based on principles of protein–protein interactions and protein folding. By understanding how supramolecular structures are assembled in nature, these processes can be exploited in the design of synthetic materials. In this regard, self-assembling peptides have been used to promote enamel remineralization by providing a biomimetic scaffold capable of HA nucleation, and injectable self-assembling peptide gels applied to carious lesions promote enamel remineralization in humans (Brunton et al., 2013).

Temporomandibular Joint

To overcome drawbacks in surgical methods of TMJ treatment, alternative methods have been developed, such as osteochondral allografts and autografts and delivery of chondrocytes (e.g., Carticel). Chondrocytes seeded on biomaterials like PLGA and collagen develop cartilage-like structures that express markers of chondrocyte differentiation and have compositions similar to normal articular cartilage. While MSCs can be differentiated into chondrocytes in cartilage defects, the regenerated cartilage rarely matches the structure and function of mature endogenous cartilage. Expression of growth factors such as basic fibroblast growth factor, transforming growth factor-β, and Sox9 is necessary for cartilage regeneration. Direct delivery of these factors, as well as in vivo injection and ex vivo delivery of viruses encoding these genes to chondrocytes, can enhance repair of cartilage and osteochondral defects.

Engineering a functional osteochondral graft requires the regeneration of both bone and cartilage with a defined interface.

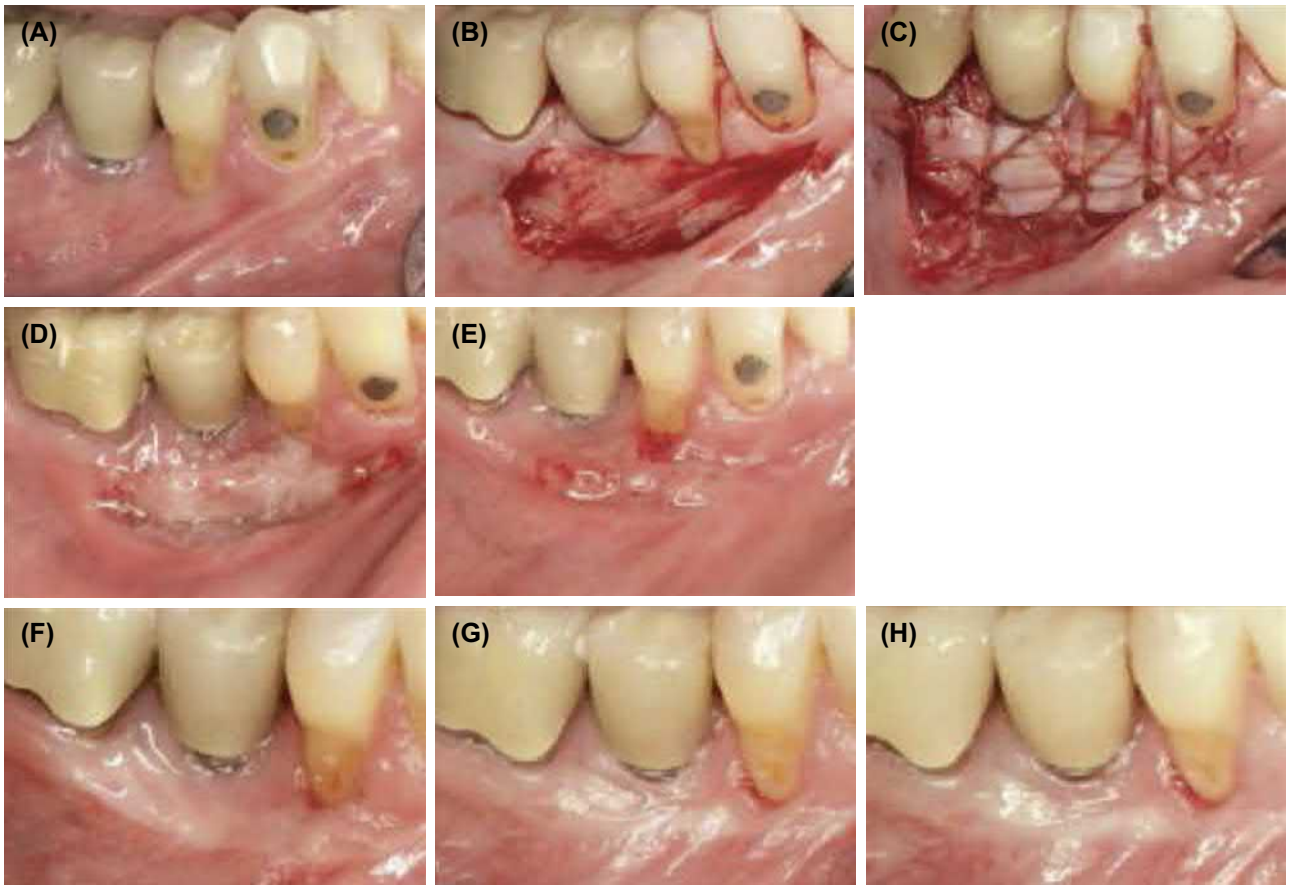


• **Figure 2.5.5.6** 3D reconstruction of computed tomography data showing the polymer phase (*top*), the hydroxyapatite phase (*bottom*), and the polymer struts that transverse both phases (*arrow*). A pie slice portion of the scaffold has been removed from the image to reveal the pore architecture of the scaffold. (Reprinted with permission from Schek, R.M., Taboas, J.M., Segvich, S.J., Hollister, S.J., Krebsbach, P.H., 2004. Engineered osteochondral grafts using biphasic composite solid free-form fabricated scaffolds. Tissue Eng. 10, 1376–1385.)

Strides have been made in engineering these tissues separately and simultaneous formation of bone and cartilage with a mineralized interface has been achieved in animals. Image-based design followed by solid freeform fabrication to control scaffold size and shape has been used to generate a biphasic scaffold (e.g., poly(L-lactide) /HA composite) in which chondrogenic and osteogenic cells are seeded onto the polymer and ceramic, respectively (Fig. 2.5.5.6). Marrow-containing vascularized bone, mature cartilage, and a defined mineralized interface can be engineered via this strategy (Yousefi et al., 2015).

Oral Mucosa

Oral mucosa is a highly specialized tissue made of stratified epithelium overlying a supportive lamina propria. Engineered



• **Figure 2.5.5.7** Clinical views of a patient in the study on intraoral grafting of tissue-engineered human oral mucosa. (A) Preoperative appearance, (B) supraperiosteal recipient site, (C) ex vivo-produced oral mucosa equivalent grafted in place, and appearances at (D) 7 days, (E) 14 days, (F) 30 days, (G) 90 days, (H) 180 days. (Reprinted with permission from Izumi, K., Neiva, R.F., Feinberg, S.E., 2013. Intraoral grafting of tissue-engineered human oral mucosa. Int. J. Oral Maxillofac. Implants 28, e295–e303.)

oral mucosa should reproduce the full-thickness tissue consisting of three distinct layers: the lamina propria, basement membrane, and stratified squamous epithelium. Layered differentiation can be mimicked by culturing keratinocytes with keratinocyte growth factors. Multilayer culture of gingival keratinocytes has met with some clinical success. Commercially available products for mucosal engineering include MatTek's gingival epithelium and keratinized stratified squamous epithelial products EpiOral™ and EpiGingival™.

To move beyond current gingival epithelium products, engineering a full-thickness mucosa with intact lamina propria requires scaffolds capable of supporting fibroblast infiltration with minimum shrinkage and controlled biodegradation. Scaffolds used for mucosal reconstruction include natural derivatives, such as acellular dermis, ECM protein-based scaffolds, synthetic materials, and hybrid scaffolds of both natural and synthetic matrices (Moharamzadeh et al., 2007).

Tissue-engineered human ex vivo-produced oral mucosa equivalents (EVPOMEs) have undergone first-in-human studies in patients with a lack of keratinized gingiva. A punch biopsy of the hard palate is taken to acquire oral keratinocytes, which are expanded, seeded, and cultured on an acellular dermal matrix. EVPOME grafts are applied over an intact periosteal bed and secured in place. Six months postsurgery, keratinized tissue around teeth was augmented by 1 mm (Izumi et al., 2013, Fig. 2.5.5.7).

Salivary Glands

Loss of salivary gland function can result as a pharmacological side effect, from radiation therapy, or as a consequence of autoimmune diseases. Saliva is a complex hypotonic solution that carries water, electrolytes, proteins, and peptides into the oral cavity. Loss of salivary flow (xerostomia) significantly impacts quality of life and predisposes affected individuals to caries, dysphagia (difficulty swallowing), and mucosal infection. Tissue engineering a salivary gland substitute is one way to treat these patients. To accomplish this complex task, three objectives must be satisfied: identification of a cell population capable of differentiation and fluid movement, optimization of scaffold material properties, and definition of ideal culture conditions and ECM components.

Salivary glands are made up of highly specialized cells capable of fluid secretion, modification, and directional movement. The challenge of culturing and implanting cells capable of all of these functions is a primary focus of salivary gland tissue engineers. A human ductal epithelial salivary

gland cell line (human submandibular gland) can form gland monolayers on poly(L-lactide) scaffolds and generate osmotic gradients for saliva formation.

Scaffold design for an artificial salivary gland consists of an end tube made from a porous, biodegradable material (Aframian and Palmon, 2008) coated with matrix components on the inner surface of the tube to promote formation of polarized epithelial cell ducts capable of unidirectional fluid movement (secretion of fluids and salts into the oral cavity). Scaffold selection for salivary gland replacement takes cues from materials used to engineer replacements for other tubular structures such as intestine and blood vessels. Scaffolds designed from poly(L-lactide), PLGA, PEG-terephthalate/poly(butylene terephthalate), chitosan, and collagen have been investigated (Scheller et al., 2009).

Salivation occurs in response to agonists that generate an increase in intracellular Ca^{2+} concentration and is facilitated by osmotic gradient-directed fluid movement through water channels in the apical membrane known as aquaporins (AQPs). Isolated ductal epithelial cells lack expression of AQP and cannot mediate fluid movement. Reintroduction of transient AQP expression using adenoviral transduction has been successful in rat and minipig salivary gland tissue in vivo and was the subject of a recent clinical trial using AQP1 (Baum et al., 2012). The trial demonstrated successful outcomes to increase saliva production after irradiation without major side effects.

Bone and Periodontium

Strategies to engineer craniofacial bone and periodontium follow strategies used for the engineering of long bones, and include a variety of conductive, inductive, and cell therapy approaches. For periodontal therapies, treatment of inflammation often occurs in conjunction with regeneration. Biomaterials advances in the engineering of these two mineralized tissues focus on organic and inorganic nanomaterials and delivery of signals via peptides, proteins, and cell–cell communication.

A variety of cell functions are regulated by topology. Creation of nanofibrous materials from ECM constituents or blends of synthetic and natural polymers can provide a material with both the physical scale necessary to influence biological function and a biochemical composition that is similar to the ECM environment that cells interact with in vivo. Use of nanoscale surface topology to enhance cell adhesion and osseointegration has established itself in polymer scaffolds for periodontal and craniofacial defects. Large periodontal osseous defects in humans have been treated with patient-specific polymer scaffolds that are designed to form multiple tissues (bone–ligament–cementum) (Rasperini et al., 2015). Using 3D printing of PCL scaffolds to capture nanoscopic details of the root surface and PDL, scaffolds can be manufactured to precisely fit the defect and guide PDL formation along with mineralized tissue (Fig. 2.5.5.8). Advances in nanoscale inorganic biomimetic materials also impact bone and periodontium engineering. The self-assembly of nanoscale mineral within the pores of a scaffold enhances cell adhesion, proliferation, and osteogenic differentiation, and modulates cytoskeletal organization and cell motility, leading to larger and more spatially uniform volumes of bone regenerated in vivo (Rossello and Kohn, 2014).

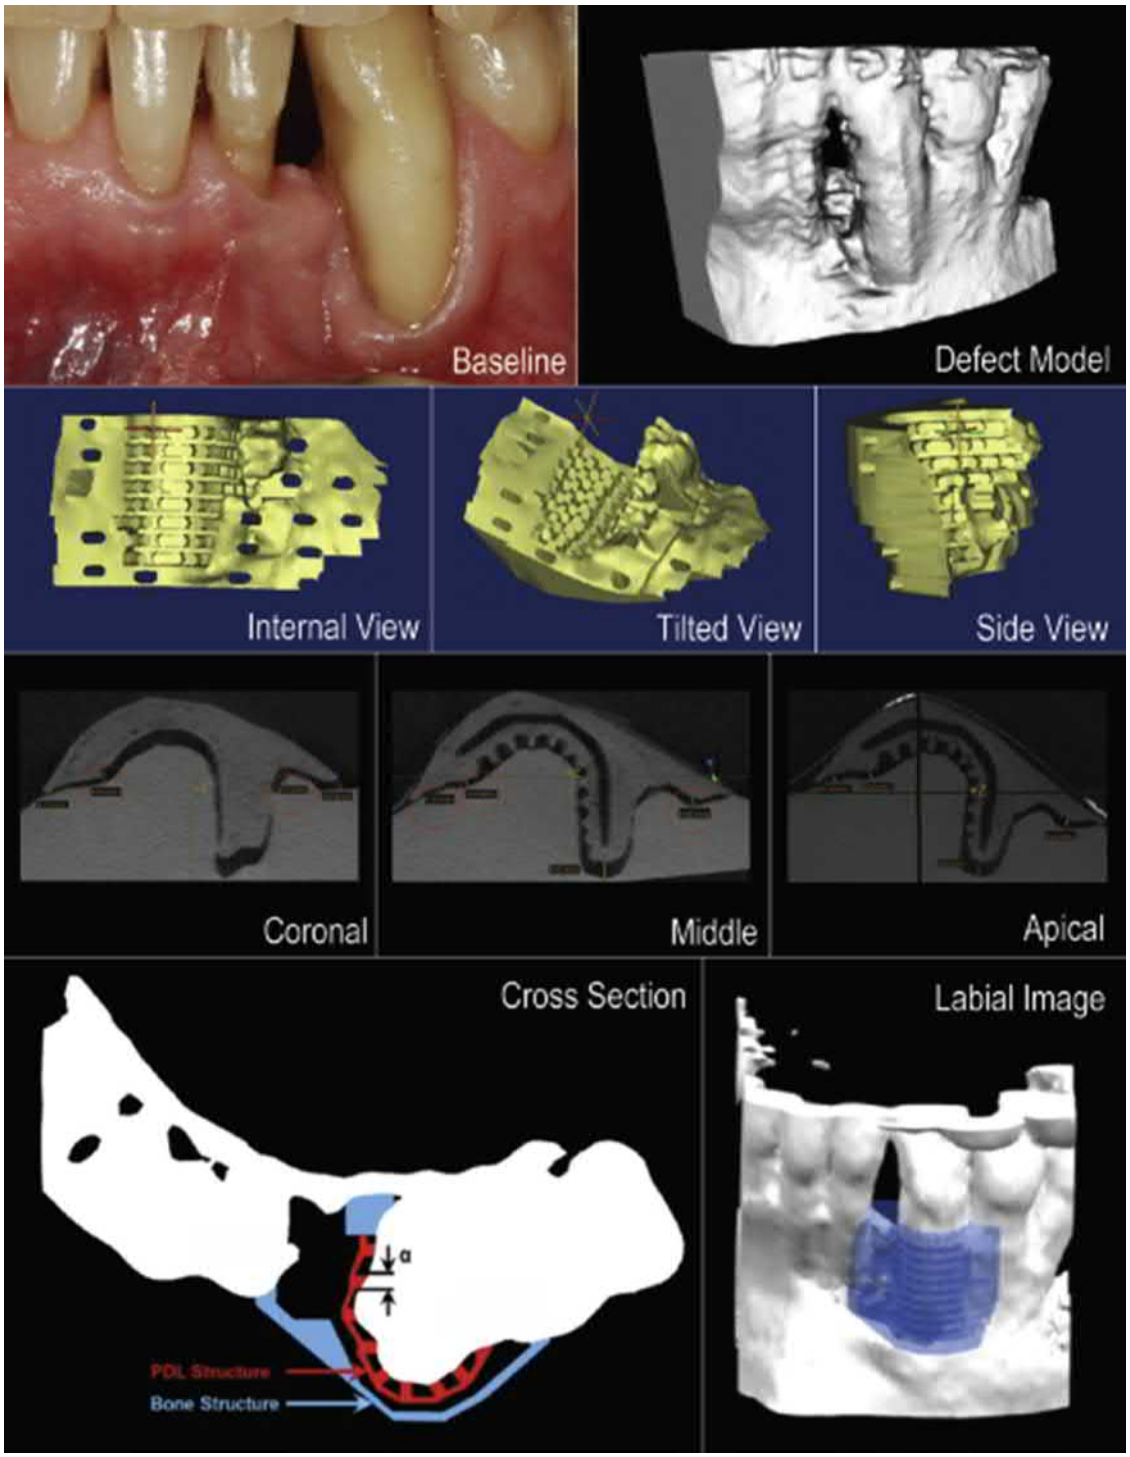
In addition to its structural role, the ECM provides adhesive ligands that direct cell function. Reproduction of these signals on engineered scaffolds can allow a more precise regulation of cell function and tissue formation. Peptide sequences that mimic sections of collagen and noncollagenous proteins, including laminin, bone sialoprotein, osteopontin, statherin, elastin, and osteonectin, increase cell adhesion, proliferation, and differentiation of osteoblasts and promote the function of cells that can form mineralized tissues of the oral cavity.

Inductive properties can be integrated into a material using methods to immobilize proteins, such as adsorption, entrapment, cross-linking, or covalent binding. Controlled release of a growth factor can be achieved by incorporating the factor into the bulk of a scaffold or hydrogel during polymerization and designing a release profile based on drug diffusion and/or material degradation. Adsorbing or covalently binding a drug to each layer of a material created by layer-by-layer assembly can provide temporal control over its delivery. This technology is most widely recognized in dentistry for delivering antibiotics to periodontal pockets.

Direct growth factor delivery and growth factor-containing scaffolds have been used for periodontal regeneration and have progressed to human clinical trials and commercialization. Delivery of recombinant BMPs (BMP-2 and BMP-7), platelet-derived growth factor (PDGF), insulin-like growth factor (IGF-1), and fibroblast growth factor enhance the repair of periodontal alveolar bone defects when delivered locally with defect healing equivalent or better than autografting. In humans, delivery of recombinant human (rh) BMP-2 on the xenogenic bone substitute Bio-Oss™ to alveolar ridge defects regenerates vertical defects. The first human clinical trial for periodontal disease used rhPDGF/rhIGF-1 in a methylcellulose vehicle and revealed twice as large osseous defect fill compared to vehicle controls (Giannobile, 1996). GEM-21S is now a commercial product, consisting of hPDGF in a TCP vehicle (Lynch Biologics).

Summary and How Experience From Dental Biomaterials has Brought Value to Other Areas of Biomaterials

The history of biomaterials in dentistry dates back several thousand years. Many areas of biomaterials have been influenced by materials developed for DOC applications. Dental implant treatments have, in part, contributed to changes in the philosophy of orthopedic and other implant-based therapies. Early reports of tissue integration for dental implants were complicated by nonstandardized clinical placement and time between placement and restoration/loading. Most implants were immediately (hours to weeks) subjected to biomechanical function. Immediate intraoral restoration



• **Figure 2.5.5.8** A customized scaffold was 3D printed using polycaprolactone to fit a periosseous defect using a prototyped model of the defect from a patient's cone beam computed tomography scan. The scaffold's internal region consisted of extended pegs for the support and guidance of periodontal ligament formation, perforations for fixation, and an internal compartment for delivery of recombinant human platelet-derived growth factor -BB, as shown in the cross-sectional view. Microcomputed tomography scans of the polycaprolactone scaffold fitted into the prototyped defect model (see coronal, middle, apical views) were used to determine the topographic adaptation of the scaffold to the root surface. *PDL*, Periodontal ligament. J. Dent. Res. 94 (9 Suppl.), 153S–157S.)

CASE STUDY

What Problem Was Addressed?

Examination of implant/tissue interfaces from early implant materials retrieved from humans showed fibrous soft tissue (dense collagenous scar tissue with limited numbers of cells and blood vessels), but no osseointegration. One of the contributing factors was that abutments and prosthetics were attached and implants were loaded immediately before bone could heal. This observation led to a two-stage procedure in which implants were inserted and allowed to heal for 4–6 months prior to attachment of prosthetics, which, in turn, motivated the development of strategies to accelerate healing and reduce the 4–6-month wait time.

What Properties Were Required in a Material?

A material that is both bioactive and can also deliver biological factors would be desirable. A limiting factor in developing such a material is that most processes used to bond bioactive coatings to an implant require high temperatures, resulting in degradation of the biological agent.

What Material Solution Was Developed?

Low-temperature, low-pressure processes in which bioactive coatings are "biomimetically" formed on an implant surface were developed. Bone-like mineral was formed in vitro at standard temperature and pressure. Synthesis of bone-like mineral is based on principles of biomineralization, in which organisms use macromolecules to control mineral nucleation and growth. Macromolecules usually contain functional groups that are negatively charged at the crystallization pH, enabling them to chelate ions present in the surrounding media, which stimulate mineral crystal nucleation. By adding a biological agent to the ionic solution that the implant is immersed in the biological agent can be incorporated into the biomimetic apatite layer that is thermodynamically driven onto the implant surface. By altering the concentrations and times at which protein is added to the simulated body fluid, spatial control over protein location is achieved. Controlling the loading quantity and localization of the protein through the mineral thickness allows control over its release profile. Thus proteins encapsulated near the surface can be used when a burst is desired, and proteins encapsulated throughout the thickness of the mineral can be used when a sustained release is desired.

resulted in force transfer between the implant body and the supporting tissues during the period of initial tissue healing. The concepts of tissue integration of dental implants evolved to include both biomaterial and biomechanical aspects of device function. The learning curve about how preparation of the surgical bed, precision of insertion, bulk, and surface properties of the implant affect osseointegration provided strategies for the design of implants for other parts of the body.

Accessibility of the oral environment and ability to create minimally invasive models of hybrid tissues render oral tissues convenient platforms for testing tissue-engineered prototypes. Oral and craniofacial tissue engineering can have a twofold impact that extends beyond dentistry. First, advances initially made in dentistry because of the relatively simple surgical models can be translated into other organ systems. Second, technologies developed outside of dentistry can be tested in oral models. One of the common screening tools for bone tissue engineering is the critical size calvarial defect model. The hybrid tissue systems of the periodontium, TMJ, cranial suture, and mineralized tissues of the tooth can provide insight into how to design a composite tissue consisting of multiple cell types. Oral and craniofacial-derived stem cells from the dental pulp, PDL, and cranial sutures have utility in nondental and noncraniofacial applications. The impact of synergy between engineering oral tissues and engineering tissues elsewhere in the body is that oral and craniofacial tissue engineering is an integral component of the larger field of tissue engineering and should not be viewed as dental researchers solving dental problems in isolation.

Chapter Exercises

1. What factors dictate the effectiveness of osseointegration? Who/what controls each of these factors?

Surgical technique—clinician.

Patient's medical and dental status—patient's physiology.

Bone quality—patient's physiology, with decisions on whether degree of bone quality in an individual patient is a contraindication made by the clinician.

Extent and kinetics of healing—patient's physiology, biomaterial (manufacturer).

Implant design factors—geometry, length, diameter, macroscopic and microscopic shapes of implant (manufacturer).

Minimization of interfacial motion—a large number of biomaterial factors, including material choice, mechanical properties of implant, surface topology, chemistry (manufacturer + clinician's choice of specific implant).

Biomechanics—loading patterns, bone quality/properties, loading (patient's physiology, implant material, design determined by manufacturer, time at which prosthesis is attached and patient can begin loading is determined by clinician).

2. What is the difference between an osteoconductive biomaterial and an osteoinductive biomaterial, and how can you demonstrate that a biomaterial is osteoinductive?

An osteoconductive biomaterial is a material that acts as a scaffold for new bone formation by providing an appropriate environment for attachment, proliferation and function of osteoblasts or their progenitor cells, leading to the formation of new bone matrix.

An osteoinductive biomaterial is a material (or biologic agent) that causes the conversion of nonlineage-committed cells preferentially to bone progenitor cells.

The key to demonstrating that a biomaterial is osteoinductive is to show that bone will form in a site that normally does not form bone (i.e., it is the material that triggers bone formation, not factors from the environment). Experiments conducted in a bony site cannot effectively demonstrate that a material is osteoinductive.

3. It is qualitatively understood that excessive micromotion (relative motion between an endosseous implant and adjacent bone) compromises osseointegration. However, few studies have quantified the effect of micromotion on osseointegration. Design an experiment to determine if there is a threshold in motion for osseointegration.

Key to experiments is designing a system in which motion is controlled, such as by creating a standard sized defect in an animal model and inserting different sized implants, and measuring the relative motion when subjected to a controlled load. Relative motion can then be related to histological findings or contact area to create a calibration curve between displacement and % bone contact or thickness of fibrous tissue as metrics for osseointegration.

4. You are starting a job at a new biomaterials startup company. Your first project is to scale up the technologies from an academic project on engineering craniofacial bone using 3D printed ceramic scaffolds and stem cells in a small animal. What are the considerations for scaleup that you should consider?

There are two components to scaleup: from small animal to human and from a small number of samples to a large number of samples.

In scaling from animal to human, the dimensions of your system needed to engineer larger volumes of tissue (size of scaffold, increased number of cells), does scaffold design need to change or just scale proportionally? Will transport considerations and ability to induce vasculature change? Will Good Laboratory Practice manufacturing be required and, if so, will any changes to the processes be needed?

In scaling from lab experiment to mass production, some considerations include: the cost of raw materials, space, and time requirements for manufacturing a much larger number of devices and cells, potential need to redesign bioreactors.

5. Recombinant growth factors are a means of stimulating oral tissue regeneration, and several have advanced to in-human studies and commercial products. What do you think are the advantages and disadvantages of using recombinant factors? What do you think are the key issues that must be thought through/experimentally tested if this application is to achieve greater clinical reality?

Advantages: Potentially unlimited supply; avoidance of transplanting cells/cell culture issues; avoidance of issues of transplant survival; no rejection.

Potential disadvantages/critical issues: safety; efficacy; means of delivery (carrier, implantation); retention of activity upon delivery; specificity of activity to targeted need; off-target effects; off-target effects; functionality/stability of new tissue; cost.

2.5.6 Ophthalmologic Applications: Introduction

HEATHER SHEARDOWN, EMILY ANNE HICKS, AFTAB TAYAB, BEN MUIRHEAD

Department of Chemical Engineering, McMaster University, Hamilton, ON, Canada

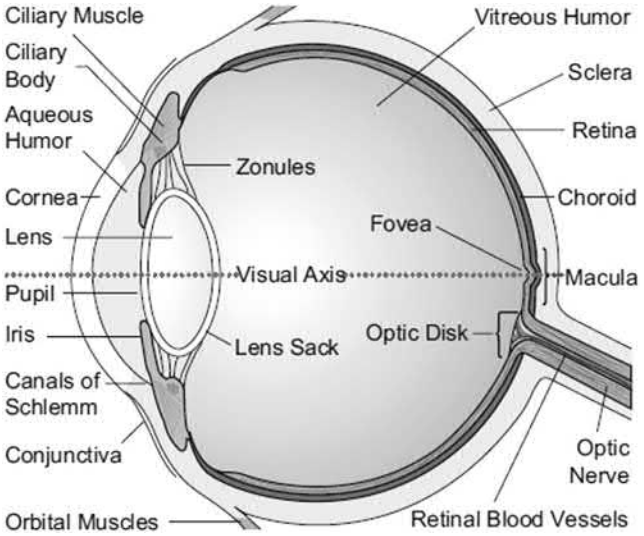
Overview of the Anatomy of the Eye

The purpose of the eye is to generate images from reflected or emitted light, focusing the light, and subsequently converting the images to electrical signals which are transmitted to the brain via the optic nerve. Performing these functions requires the interaction of a complex array of cellular components. The eye itself can be described as a globe within a globe (see Fig. 2.5.6.1), the dimensions of which are summarized in Table 2.5.6.1.

Light enters the eye through the transparent window of the eye, the cornea. With a diameter that typically ranges between 10.5 and 12.5 mm, the cornea serves as both a protective barrier as well as performing a refractive function, providing ~80% of the focusing power of the eye. It has a refractive index of approximately 1.34 and is comprised of five structurally distinct layers. Covering the anterior surface of the cornea are five to six layers of corneal epithelial cells which serve mainly a protective role. The epithelial basement membrane, or Bowman's layer, is comprised mainly of collagen and is thought to represent a transition between the stromal and epithelial layers. The stroma, comprising approximately 90% of the thickness of the cornea, is made up mainly of hydrated (80% water) collagen with interspersed keratocyte cells that produce and repair the collagen matrix as well as producing other components (glycosaminoglycans for example). Descemet's membrane, the basement membrane of the corneal endothelium is comprised mainly of type IV and type VIII collagen. The endothelium is a single layer of quiescent cells which do not regenerate if damaged. It has the important function of maintaining stromal hydration, pumping water to the aqueous layer, while providing nutrients to the keratocytes. The lack of a blood supply to the cornea means that this transport is essential to maintaining corneal health and function. The transparency of the cornea is due to a combination of factors including the organization of the collagen in the stromal layer, the maintenance of hydration due to the endothelial pump, the presence of glycosaminoglycans which reduce light scattering, and the lack of blood vessels in the eye. The structure and layers of the cornea are depicted in Fig. 2.5.6.1.

The iris, responsible for controlling the amount of light that passes through to the retina by varying the size of the pupillary opening, is a vascularized, pigmented tissue. It separates the anterior and posterior chambers of the eye. The ciliary body, also a vascularized pigmented tissue, consists of the ciliary muscle and the ciliary process and has two major functions—the production of aqueous humor and accommodation. The aqueous humor, a clear fluid with a composition similar to blood plasma, that resides in the aqueous chamber, provides nutrients to the crystalline lens and the cornea, neither of which has a direct blood supply. The aqueous humor travels around the lens, through the pupil, and is ultimately drained into Schlemm's canal through the trabecular meshwork. The intraocular pressure of the eye is partially maintained by the balance of aqueous humor production by the ciliary processes and aqueous humor drainage through the trabecular meshwork. Typically, in the human, the intraocular pressure (IOP) is between 10 and 20 mmHg.

The crystalline lens sits in the posterior chamber, behind the iris and the pupil. The structure is shown in Fig. 2.5.6.1. The center of the lens is comprised of a nucleus which is surrounded by lens fiber cells. These cells synthesize crystallin proteins which maintain the refractive index of the lens at approximately 1.42. The lens is connected to the ciliary body by fine suspending ligaments or zonules, which are critical to accommodation. Accommodation is the ability to change the focus of the lens to allow for visualization of both near and distant objects. The ability of the natural crystalline lens to accommodate decreases with age. When the ciliary muscle contracts, the zonule fibers relax their natural state of tension on the lens periphery, which changes the focal length of the lens. Surrounding the natural crystalline lens is a thin collagen membrane known as the capsular



• **Figure 2.5.6.1** Schematic representation of the cross-section of the eye (www.99main.com/~charlief/Blindness.htm).

TABLE 2.5.6.1 Approximate Dimensions of Globe and Ocular Structures

Measurement	Length, Thickness or Diameter (mm)
Axial length of globe	23–26
Corneal diameter (white-to-white)	10.5–12.5
Equatorial diameter	23–26
Anterior chamber depth (ACD)	3–4
Anterior chamber diameter	12.0–12.5
Sulcus diameter	11.0–11.7
Natural crystalline lens diameter	9.0–10.2
Natural crystalline lens thickness	3.5–4.5
Capsular bag diameter after lens extraction	9.2–10.5
Capsular thickness	0.004–0.014
Retinal thickness	0.2–0.25

bag. In the noncataractous lens, the anterior portion of the capsule is coated with a layer of lens epithelial cells; no cells are located on the posterior surface of the lens. With cataract formation, a layer of nontransparent epithelial cells can be generated on the anterior surface of the capsule.

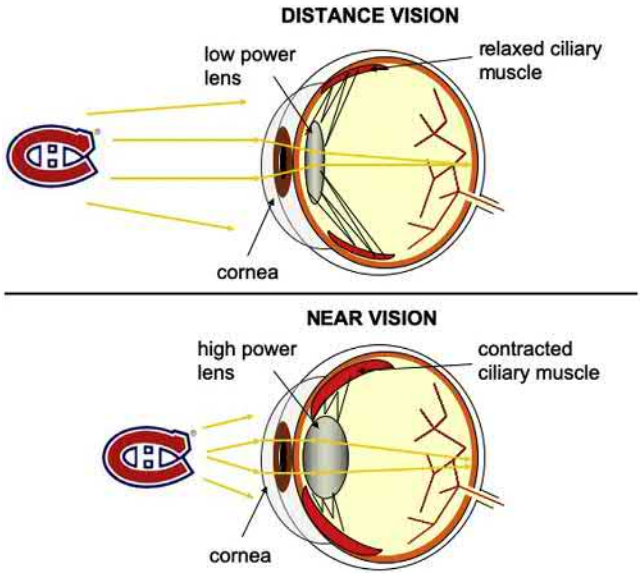
At the posterior of the eye, the retina is up to 10 layers thick and is responsible for capture of the visual image and its translation via the optic nerve. It has a complex structure and consists of numerous cell types. The choroid is the vascular layer behind the retina, supplying oxygen and nutrients to the cellular layers of the retina. The retinal pigmented epithelial layer (RPE), forms a tight junction epithelial layer immediately apical to the choroid. The pigmented nature of these cells means that the absorption of light is among its primary functions. Critical to retinal health, the RPE layer also must provide efficient defense against free radicals, light energy, and photo-oxidative exposure. The tight junctions suggest that the RPE layer also plays a role as part of the blood–retinal barrier and in the immune privilege of the eye. Two types of photoreceptors, rods and cones, sit next to the RPE layer. The cones are concentrated in the macula, the central region of the retina, while the rods are more dominant in the peripheral retina. Cones are responsible for central vision as well as for daytime vision; rods play a greater role in peripheral and dim light vision.

Eye-related Conditions and Statistics

The National Eye Institute in the United States has estimated that there are currently 2.9 million Americans living with low vision, defined as best corrected visual acuity <20/40. This number is expected to increase by 72% by 2030. Approximately one million of these patients are characterized as blind (Varma et al., 2016). Internationally, the World Health Organization estimates that there are more than 1.3 billion people living with some kind of vision impairment and 36 million of these are blind (Bourne et al., 2017, 2019).

The vast majority of vision issues occur in patients older than 50. In the United States, age-related diseases including cataract, glaucoma, and age-related macular degeneration account for almost 80% of all cases of vision-associated disorders (Varma et al., 2016). Diabetic retinopathy, the main vision issue of the working age population, accounts for the other 20% of cases. The economic burden of vision issues in the United States alone has been estimated at more than $139 billion. Correctable and more common vision issues, including myopia, hyperopia, astigmatism, and presbyopia, arise from refractive errors. Myopia, more commonly known as near-sightedness, in which the patient cannot focus on an object in the distance, has reached epidemic proportions in children, particularly in the Far East (Brennan and Cheng, 2019; Greene and Greene, 2018). This is thought to be partly the result of screen time and a lack of outdoor play in children. Hyperopia, or far-sightedness, occurs when one can focus on objects in the distance but not on objects that are close. A schematic of image formation in the myopic and hyperopic eye is shown in Fig. 2.5.6.2. Presbyopia, a condition of aging, occurs as a result of the loss of accommodation in the lens. It typically becomes symptomatic between the ages of 40 and 50 and results in the need for reading glasses to allow for focusing on near objects. Astigmatism, estimated to affect as many as 30% of Americans, occurs when the cornea is no longer spherical.

Cataract, the leading cause of low vision in the United States, refers to clouding or opacification of the lens, typically as a result of aging. However, cataracts can also be due to trauma or injury, congenital, or can result from underlying pathologies or medications. They are highly treatable; affecting more than 20.5 million patients in the United States over the age of 40, more than two million surgeries, involving the replacement of the diseased lens with an artificial intraocular lens, are performed annually. The success



• **Figure 2.5.6.2** Depiction of lens changes during accommodation for distance.

rate is typically greater than 90%, with posterior capsule opacification (PCO) being the most common complication. PCO can be effectively treated with a secondary laser procedure.

Glaucoma, including primary open-angle glaucoma, angle closure glaucoma, and congenital glaucoma, is typically characterized by increased intraocular pressure, changes in the optic nerve head, specifically increased cupping, and/or loss of visual field. Vision loss is ultimately the result of the death of the nerve cells and as such is not reversible. Typically, the treatment strategy is initially pharmacological, with a goal of lowering the intraocular pressure (IOP). However, if the IOP cannot be managed pharmacologically, laser treatment or surgery to implant a glaucoma shunt or a stent is performed. Laser treatments, including argon laser trabeculoplasty or selective laser trabeculoplasty, have the goal of creating space in the trabecular meshwork to facilitate aqueous humor outflow. A glaucoma shunt consists of a plate, which resides in the subconjunctival space, and a tube, which is placed in the anterior chamber of the eye. The shunt aids in aqueous humor drainage by creating another outflow pathway, allowing the flow of aqueous humor out through a sieve into the tissues, where it is absorbed.

Age-related macular degeneration (AMD) is the most common cause of blindness in the aged population (Zhao et al., 2019; Rudnicka et al., 2015). Dry AMD, the most common form, accounts for approximately 90% of all cases and is characterized by the presence of small yellow deposits known as drusen, which accumulate in the retinal pigmented epithelial cells adjacent to the macula. Progression of the dry form to the wet form, which accounts for approximately 10% of all cases of AMD, leads to ~90% of AMD-associated vision loss. Wet AMD is characterized by the growth of abnormal blood vessels, known as choroidal neovascularization (CNV). These blood vessels originate in the choroid under the macula, invading the retinal tissue and leading to major cellular damage and central vision loss. Treatment for wet AMD involves monthly injection of anti-VEGF molecules into the globe of the eye.

Diabetic retinopathy (DR) is the leading cause of blindness among the working age population (Groeneveld et al., 2019). Affecting approximately 7.7 million Americans, a number which is projected to increase to 11.3 million Americans by 2030, DR is associated with both types 1 and 2 diabetes. There are two types of DR—nonproliferative and proliferative. Nonproliferative DR is less severe, and leads to blurred vision as a result of the leakage of edema fluid from the blood vessels into the retina. Proliferative DR is usually more severe and results in neovascularization on the surface of the retina; these vessels can at times reach into the vitreous. These new, poorly formed vessels are leaky, leading to hemorrhage and profound vision loss. As with AMD, approved treatments include injections of anti-VEGF drugs into the back of the eye or in some cases laser treatment of the hypoxic retina.

Considerations for Ophthalmic Materials

Similar to materials used in other areas of the body, biocompatibility, stability, degradation, sterilizability, and manufacturability all must be considered. However, unique to materials to be used in ophthalmic applications, considerations around the optical properties must be taken into account. Optical properties are particularly critical for contact lens materials, corneal inlays or onlays, as well as intraocular lenses. The materials must be transparent, with a refractive index that is equal to or greater than the tissue that is being replaced. In some cases, UV-blocking agents are incorporated into these materials in order to protect the delicate retina from UV light exposure. In addition, any material used in the cornea, such as a contact lens or a corneal inlay, must have sufficient oxygen and nutrient permeability to allow for the maintenance of corneal health due to the lack of vascularization of this tissue. Biomaterials commonly used in ophthalmic applications are outlined in Table 2.5.6.2.

Biomaterials: Contact Lenses

In order to overcome variations in eye length, which can affect the ability of the refractive elements of the eye, the cornea and lens, to focus the image correctly on the retina, lenses, including spectacles and contact lenses, are placed in front of the cornea in order to adjust light refraction. Currently, it is estimated that 45 million Americans wear contact lenses; two-thirds of these wearers are female (Chalmers and Gleason, 2013). The decision to wear contact lenses over spectacles is affected by various factors but it is most often the practicality of lenses or their physical appearance that wearers consider. They are made from a variety of biomaterials, and because they are in intimate contact with the ocular tissues, they are subject to the same federal regulations that govern implant materials.

TABLE 2.5.6.2 Biomaterials Commonly Used in Ophthalmology

Ophthalmic Implants	Materials Commonly Used
Contact lenses	Poly(methyl methacrylate) (PMMA), 2-hydroxyethyl methacrylate (HEMA) copolymers, silicone hydrogels
Inlays or onlays	Hydrogels, collagen, permeable membranes
Intraocular lenses	Optic: PMMA, hydrophobic acrylic, silicone, hydrophilic acrylicHaptic: polypropylene, PMMA, polyimide, polyvinylidene fluoride (PVDF)
Ophthalmic viscosurgical device (OVD)	Chrondroitin sulfate, sodium hyaluronate, hyaluronic acid, hydroxypropyl methylcellulose (HPMS), polyacrylamide, collagen, or combinations of these materials
Glaucoma shunts	Plates: silicone (impregnated with barium), polypropyleneTubing: silicone
Vitreous replacements	Silicone oil, gases

Materials used in contact lens applications must meet a number of requirements to be suitable. As optical devices, light transmission is paramount; the ability to transmit close to 100% of visible light is a key determinant in whether a material will be useful in contact lens applications. The ability to maintain a highly wettable surface is a key criterion in order to maintain the structure of the tear film. Surface properties that minimize fouling with tear components such as lipids and proteins are desirable since it has been suggested that the deposition of these molecules can impact optical properties, wearer comfort, and even the permeability of the lens materials.

Hydrogel materials, which are typically used in lens applications, have an inherently wettable surface, particularly when fully hydrated. However, when placed on the eye, thermodynamic factors can impact the surface properties. Water loss, particularly under adverse environmental conditions such as low humidity, high wind, or high temperatures can lead to wearer discomfort. Furthermore, polymer chain reorientation may occur, depending on such factors as polymer structure, crosslinking and the presence of bulky side groups. When in contact with the aqueous layer of the tears, typically the more hydrophilic groups will migrate to the surface. However, upon exposure to the tear film lipids or an air environment, the more hydrophilic groups are driven into the bulk of the material, exposing the more hydrophobic groups on the surface and leading to changes in biofouling and material performance which can affect eye performance.

Since the cornea is an avascular tissue, it receives oxygen from the ambient air during open eye conditions and from the palpebral conjunctival vessels during closed eye conditions. Diffusion of oxygen through the tear layer occurs with both of these sources. Therefore, contact lenses represent a significant barrier to oxygen transmission. In order to improve oxygen delivery to the cornea, it is necessary to either improve diffusive oxygen transmission through the lens or alter the convective tear exchange under the lens. Oxygen permeability through a contact lens is typically represented as Dk where D is the diffusion coefficient of oxygen in the material in cm^2/s and k is the Henry's law solubility coefficient with units of cm^3 (O_2STP)/[cm^3 (polymer) mmHg]. Often the lens material oxygen transmissibility is normalized for the thickness of the lens (Dk/L), although companies typically report the Dk value for their lenses.

Lack of oxygen to the cornea has been shown to lead to corneal hypoxia, characterized by corneal swelling as well as other conditions including limbal hyperemia, neovascularization, corneal acidosis, epithelial keratitis, and endothelial polymegethism (McKay et al., 2017). Holden and Mertz determined that the oxygen transmissibility necessary to avoid corneal edema for daily wear is $24.1 \pm 2.7 \times 10^{-9}$ (cm × mL O_2)/(s × mL × mmHg) and $87.0 \pm 3.3 \times 10^{-9}$ (cm × mL O_2)/(s × mL × mmHg), although more recent experiments have suggested it may be higher than this (Fink et al., 2006; Gardner et al., 2005; Pilskalns et al., 2007; Harvitt and Bonanno, 1999; Ostrem et al., 1996).

Contact Lens Materials

There are two main categories of contact lenses that are grouped by their basic mechanical properties. Hard contact lenses, more commonly referred to as rigid gas-permeable lenses, are rigid materials with a high modulus, generally containing either silicone or fluorine derivatives to allow for oxygen permeation. Soft contact lenses are hydrogel materials with a low modulus and higher water content. Within this category, silicone hydrogels are newer materials that contain a hydrophobic but oxygen-permeable siloxane component, while conventional materials are typically made of more hydrophilic monomers.

Hard Contact Lenses

Originally made from poly(methyl methacrylate) (PMMA), hard contact lenses are now copolymers of PMMA functionalized with silicone- and fluorine-containing macromers. One of the first monomers to be discovered was methacryloxy propyl tris(trimethysiloxy) silane (TRIS) (see Fig. 2.5.6.3), which significantly increases the oxygen permeability of these materials. Subtle changes in the chemical composition of the lens can impact clinical performance. For example, while silanes are effective at increasing oxygen permeation, their lipophilicity can lead to increased biofouling. Fluorinated polymers can

also improve oxygen permeability but are more resistant to fouling. Therefore currently marketed RGP lenses mainly consist of perfluoroalkyl-siloxyanylalkyl-methyl methacrylate type materials which have both a high Dk and good surface properties (Chalmers and Gleason, 2013). While they make up a small fraction of contact lenses currently marketed (currently approximately 14% of all fits in the United States), hard contact lenses are particularly good for patients with significant corneal astigmatism or non-spherical corneal surfaces, and will therefore continue to have a market. However, materials developments in these materials are virtually nonexistent; wearable biosensors are one area where these materials might see revitalization (Ruan et al., 2017).

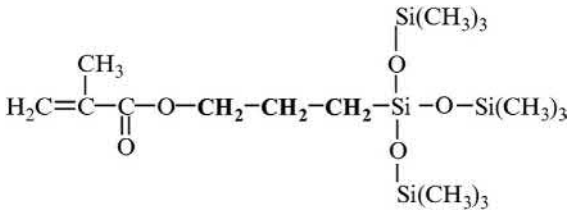
Soft Hydrogel Contact Lenses

Due to the water content of hydrogels, and their resulting low modulus, soft contact lenses have a high degree of comfort that allows them to be worn by a majority of the population. The first commercial contact lens material, poly 2-hydroxyethylmethacrylate (PHEMA), was developed by Wichterle and Lim in 1959. It has a water content of approximately 40% and has such advantages over previously developed materials related to stability to pH, temperature, and osmolarity as are found under physiological conditions. To increase the water content of these materials, a variety of other monomers have been used or incorporated. N-vinyl pyrrolidone (NVP), n,n-dimethyl acrylamide (DMA), vinyl acetate, post hydrolyzed to vinyl alcohol units as well as methacrylic acid (MAA) have proven to be particularly successful.

The Dk of conventional hydrogel materials increases exponentially with water content as delivery of oxygen is through the aqueous component of the lens. Therefore, the oxygen permeability limit of these hydrogels approaches that of the permeability of pure water to oxygen (Dk of water = 125 barrer). However, higher water-content materials, such as those with a water content over 50%, while possessing better O_2 permeability, suffer from a greater degree of dehydration and are more fragile due to low modulus. Decreasing the thickness of these materials can also be used to increase oxygen transmission but, again, mechanical properties suffer with this approach. Typically the Dk of conventional lenses ranges between 8 and 44 barrers (Chhabra et al., 2007; Compan et al., 2004).

Silicone Hydrogel Contact Lenses

As a result of their moderate oxygen transmissibility, conventional hydrogel materials are limited in terms of their ability to be worn overnight or for an extended period, with the risk of adverse effects increasing more than four-fold with extended wear. To overcome the limitations of these materials while maintaining comfort, the contact lens industry developed siloxane-containing hydrogel materials. These lenses are prepared by copolymerizing typical hydrogel monomers with methacrylate or vinyl end capped polydimethylsiloxanes, novel comonomers. and/or hydrophilically modified TRIS. This leads to compatibilization with the more hydrophilic components of the hydrogel. Depending on the composition, the oxygen permeability of these siloxane-containing hydrogel materials ranges between 60 and 160 barrers (Chhabra et al., 2007; Compan et al., 2004) and, unlike conventional materials, there is an inverse relationship between O_2 permeability and equilibrium water content, since oxygen permeation occurs primarily through the siloxane-rich components of the material. However, as described in Nicolson and Vogt (2001), water and ion permeability are also essential in these materials to allow for lens-on-eye movement.

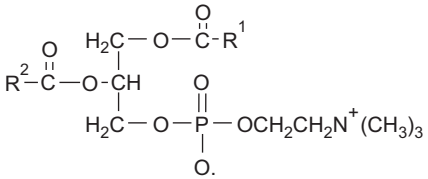


• **Figure 2.5.6.3** The structure of TRIS, used in contact lens manufacture.

The presence of the mobile siloxane groups in these materials increases their surface hydrophobicity and decreases their wettability, leading to increased biofouling and the need for surface modification to alter the surface properties.

Surface Modification

The inherent hydrophilicity of conventional hydrogel materials originally led to the belief that no surface modification was necessary. It was found however, that certain bulk side-chain moieties led to the enhancement of surface properties, resulting in the development of materials with surface-active side groups, surface-modifying endcaps, or interpenetrating networks. The first material of this genre to be approved by the FDA was Omafilcon A (Proclear) lenses which contain a hydrophilic methacrylate monomer containing a zwitterionic side group, modeled after phosphatidyl choline (Fig. 2.5.6.3) that is thought to preferentially hold water on the surface.



R^1 and R^2 – acyl carbon chains

Silicone hydrogel materials, due to the hydrophobic and mobile nature of the siloxane groups, require surface

modification to generate sufficiently wettable surfaces. The first silicone hydrogels on the market were plasma treated to alter the surface properties without adversely affecting the bulk. Balafilcon A (Pure Vision, Bausch, and Lomb) is plasma oxidized, creating glassy silicate islands on the lens surface. The properties of these islands are such that a hydrophilic surface is generated without altering the bulk properties of the material. Lotrafilicon A and B (Night and Day, O_2 Optix, CIBA Vision) has a plasma coating of a hydrophilic polymer approximately 25 nm thick. In both cases, these coatings are designed to lower the mobility of the underlying silicone layer, minimizing the reorientation of the silicones to the surface. However, the lack of chain mobility in these materials increases the lens modulus, leading to stiffer materials.

To overcome patent issues and issues with the use of plasma as a modification tool, Vistakon's first silicone hydrogel materials, galyfilcon A (Acuvue Advance) and senofilcon A (Acuvue Oasys) contain high-molecular-weight poly(vinyl pyrrolidone) (PVP) as an internal wetting agent, creating a wettable, lubricious surface without the need for subsequent surface treatment. Galyfilcon A is packaged with PVP in the packing solution; senofilcon A lenses have the PVP incorporated as polymeric end caps which preferentially migrate to the lens surface. In both cases, the increased wettability does not lead to compromised mechanical properties.

Comfilcon A (Biofinity, Coopervision) deviates from the expected oxygen permeability/water content curve, with a high water content at 48% and an unexpectedly high Dk, presumably the result of the presence of longer siloxane chains. It has no surface treatment or internal wetting agent and is produced by polymerization of two siloxy macromers of different sizes, one of which has only one vinyl polymerization site along with vinyl amides such as n-methyl-n-vinyl acetamide.

Contact Lens Solutions

Depending on the nature of the contact lens, effective daily disinfection and cleaning of the lens is necessary. Among the most popular systems currently are those based on hydrogel peroxide, although other chemically based systems are also common. Multipurpose cleaning solutions perform a myriad of functions including removal of deposits such as protein and lipid that are adsorbed from the tear film, disinfection, and prevention of future biofouling. Product efficacy varies depending on the composition of the solution as well as the lens that is paired with the solution. Most of these systems use hydrophilic polymers to increase cleaning efficiency and to improve lens surface hydration. Some of the polymers used, such as Poloxamer 407, act on the surface of the bacteria and not on the lens. Issues have arisen with lens cleaning solutions however, specifically related to topping up the solution resulting in a decrease in the efficacy of the killing of bacteria.

Intraocular Lens Implants

Introduction to Intraocular Lens Implants, the Optics of the Eye, and Cataracts

Cataracts are the leading cause of preventable blindness in the world (Flaxman et al., 2017). With the aging of the population, the incidence of cataracts is increasing globally, leading to the implantation of more than 10 million lenses annually. The cloudy, cataractous lens removed during surgery is replaced by a polymeric intraocular lens (IOLs) to restore visual acuity. Between 1990 and 2010, the rate of cataract surgeries more than tripled (Wang et al., 2017), making IOLs among the most commonly implanted biomaterials. With technical advancements and the demand for treatment solutions growing, creation of new biomaterials, designs, and applications is becoming increasingly important.

The physiological process of vision is complex. The refractive power of the cornea represents about 70% of the total refractive power of the eye and is fixed at approximately 43 diopters; the lens then provides the remaining variable refraction. The natural lens consists of a cortex-surrounded nucleus within a capsular bag attached to the ciliary muscle by ligaments, called zonules (Fig. 2.5.6.1). When relaxed, the zonules place the lens under tension, providing 20 diopters of refractive power for distant vision. For close-up vision, the ciliary muscle contracts, the zonules relax, resulting in a change in the lens shape which increases refractive power in a process called accommodation. With age, as the lens grows, the ability for accommodation gradually decreases to less than the 3 diopters necessary for reading distance and the eye is considered presbyopic.

Further aging of the lens can result in loss of optical clarity due to cataract formation. Cataract surgery involves the removal of the cataractous lens and the implantation of an intraocular lens. Prior to IOL implantation, thick spectacles were needed to restore the function of the removed natural lens, which had a significantly reduced field of vision and resulted in severe astigmatism from the large incision required for cataract surgery. The size and optic of the modern IOL and its intraocular location have eliminated these setbacks.

IOL Biomaterials and Design

Biomaterials selected for lens production must have such design objectives as targeted incision size for insertion and mechanical fixation, typically via haptics as well as transparency. In 1949, Sir Harold Ridley implanted the first IOL made of Perspex, a PMMA material, after shards of cockpit canopies made from the same material did not elicit the inflammatory response in the eyes of Royal Air Force pilots (Ridley, 1976). The original bulky PMMA lenses were rigid, requiring a large incision for insertion, making them difficult to surgically fix within the eye, and leading to serious post-op complications and ultimately discontinuation of their use. PMMA continued to be the material of choice

when smaller optics and fixation means were being designed (Apple, 1986).

Advances in surgical technique were critical to the development of current IOL materials. Currently, extracapsular cataract extraction (ECCE) removes the opacified lens, while preserving the intact capsular bag, excluding the anterior capsule face (Amon, 2001). However, residual lens epithelial cells (LECs) near the lens equator can undergo epithelial to mesenchymal transition, with a reduction in their transparency resulting in PCO and fibrotic contraction of the capsular bag (Kruger et al., 2001). PCO reduces optical clarity, resulting in the formation of a "secondary cataract." An Nd-YAG laser can be used to create an optically transparent path in the posterior capsule, but there are several disadvantages including cost, damage to the IOL, and retinal detachment (Karahan et al., 2014). To prevent PCO, recent advances have led to changes in the optic shape and haptics to achieve complete contact of the PC-IOL to the posterior capsule, which minimizes epithelial migration and secondary cataract formation (Findl et al., 2010; Matsushima et al., 2008; Nibourg et al., 2015).

The introduction of ultrasonic phacoemulsification, a process providing both irrigation of the eye to prevent anterior chamber collapse and aspiration of the fragmented lens, decreased the rate of surgically induced astigmatisms through the use of a smaller incision while producing a limited inflammatory response (Gills and Sanders, 1991). The 3-mm incision made during this process is self-healing, which eliminates the need for stitches, but introduced a need for a soft, foldable biomaterial that could fit through the small wound. The first foldable IOL, made of transparent polysiloxane introduced by Staar Surgical (Mazzocco, 1985), was followed by several formulations with different mechanical properties and refractive indices from other companies. In 1994, Alcon introduced the first acrylic foldable IOL, AcrySof, a copolymer of phenylethyl acrylate and phenylethyl methacrylate with a cross-linking agent and a bound UV-chromophore (Madrid-Costa et al., 2010). The AcrySof IOL soon became the most widely used foldable IOL, reaching over 100 million implanted by 2017, with satisfactory outcomes.

Newer generations of silicone foldable IOLs and hydrophobic, as well as hydrophilic, foldable acrylates continue to be developed (Table 2.5.6.2). The success of these IOLs requires favorable short-term postoperative results, as well as long-term reduction of PCO formation, with <5% capsulotomy rate for Alcon's AcrySof IOL (Madrid-Costa et al., 2010). PCO and laser capsulotomy rates are influenced by both the IOL biomaterial and optic edge design, with the best outcomes observed in hydrophobic IOLs with sharp edges, while haptic design and optic size also influence PCO formation (Perez-Vives, 2018).

The history of IOL materials can therefore be broken down into nonfoldable or foldable categories, based on flexibility. While nonfoldable PMMA IOLs are seldom used in the developed world due to advancements in surgical techniques, these lenses play an important role in countries where ECCE with manual expression of the lens remains standard practice (Tabin et al., 2008). Foldable IOLs can further be broken down into silicone or acrylate materials. Hydrophobic and hydrophilic acrylic IOLs are currently the most commonly used materials with high refractive indexes and strong biocompatibility (Perez-Vives, 2018).

Current designs in modern IOLs show that the majority of implants are fixated within a capsular bag, as a single-piece IOL of homogeneous material or multipiece IOL with the optic and haptic made from different materials. Common haptic materials include PMMA, polypropylene, polyimide, and poly(vinylidene) fluoride (PVDF) (Izak et al., 2002). Haptic design is an important consideration for maintaining the IOL in a fixed position. Two factors contribute to good haptic design: loop rigidity and memory. Loop rigidity determines the resistance of the haptics to external forces acting to bend the loops centrally, such as the force from fibrotic capsular bag contraction, while memory is the ability of the haptics to reexpand to their original configuration after implantation (Izak et al., 2002).

IOLs With Variations of Optical Function

Traditional spherical IOLs are not mimetic of the asphericity of the natural lens. IOLs with appropriate aspheric optics can more closely match the optical quality of the natural lens and account for corneal aberrations. The first FDA-approved aspheric IOL was the Tecnis IOL by AMO (acquired by Johnson & Johnson Vision, Inc.) followed by AcrySof IQ made by Alcon, and SofPort AO made by Bausch & Lomb. Comparative evaluations are ongoing to determine the advantages and disadvantages of each design (Jia and Li, 2014). However, due to differences in surgical technique and materials, it is often difficult to directly compare different IOL compositions.

Using the same biomaterials as monofocal IOLs, toric IOLs offer an alternative for precise correction of preexisting corneal astigmatism. The first toric IOL was a nonfoldable three-piece PMMA IOL, which required a large incision for implantation (Shimizu et al., 1994). Shortly after, the first foldable, one-piece silicone toric IOL was developed, which required a much smaller incision. Postoperative rotation of toric IOLs significantly compromises the optical objective. The FDA-approved AcrySof IQ Toric, made by Alcon, a single-piece optic with somewhat flexible haptics, has been shown to have good results without significant rotation. TecnisToric, by Johnson & Johnson Vision (previously AMO) and Bausch & Lomb TruLign Tori, is also FDA-approved.

Multifocal IOLs

With the use of computers and screens, satisfactory intermediate distance vision has become as much a requirement as near vision following cataract surgery. Multifocal IOL implantation aims to achieve complete spectacle independence for all viewing distances. Utilizing the same

biomaterials as monofocal IOLs, several designs have been investigated for optical imaging at different focal planes. The first concept of a truly multifocal IOL was conceived by Hoffer in 1983 (Hoffer, 1991) and the first bifocal IOL was implanted in 1986 (Keates et al., 1987).

Multifocal IOLs have distinct focal points and can be provided with various focal lengths. Lenses can be bifocal, trifocal, or the focus can be extended longitudinally with a far focus reaching intermediate distances also known as an extended depth of focus (EDOF) IOL. These IOLs are based on refractive and diffractive optic principles rather than on materials properties. The FDA-approved Array Multifocal IOL, introduced by AMO, had a radial array of alternation variable optical powers, providing distant and near vision (Steinert et al., 1999). A redesign of this IOL, with improvements for night-time driving and halos, is currently on the market as ReZOOM. TECNIS Multifocal (Johnson & Johnson Vision) has a diffractive optic design, which had similar halo effects with night-time driving as the Array Multifocal. A unique optical design combining central apodized diffractive optical zones with refractive optics beyond was introduced by Alcon as the AcrySoftReSTOR (Kohnen et al., 2006).

Newer multifocal IOLs include trifocal IOLs, with the generation of a third focal point. These IOLs have shown excellent levels of corrected distant, intermediate, and near visual acuities and good contrast sensitivity (Kretz et al., 2015a,b). The first EDOF IOL, Johnson & Johnson Vision's Symfony, was approved by the FDA in 2016. Other EDOF IOLs being investigated include LENTIS Mplus (Oculentis) and LenstecMiniwell IOL.

In certain presbyopic, hyperopic, or myopic patients, multifocal IOLs can be used to correct optical refractive errors. Combining different IOLs via bilateral multifocal IOL implantation can improve binocular vision at different distances. Multifocal IOLs provide overall spectacle independence for both distant and near vision in approximately 83% of patients compared to 10% in monofocal IOLs (Alio et al., 2017). Despite negative subjective phenomena, such as glares and halos, overall satisfaction and quality of life after multifocal implantation is generally high.

Phakic IOLs are an alternative to LASIK and photorefractive keratectomy procedures for correcting moderate to severe myopia, in some cases providing better and more predictable visual outcomes (Barsam and Allan, 2014). Currently the two FDA-approved phakic IOLs on the market are Visian ICL (implantable collamer lens) from Staar Surgical and Verisyse from AMO (now Johnson & Johnson Vision). Verisyse, an iris-fixated, rigid PMMA IOL offers a larger optic zone than LASIK, potentially causing less glare with large pupils. Visian ICL, a PC-IOL made of collagen copolymer (collamer), is a foldable implant, highly elastic in nature, and is reported to have fewer complications than its anterior counterpart (Sanders et al., 2004). Both phakic IOLs are capable of treating a wider range of myopic conditions than laser refractive procedures with better contract sensitivity, less visual distortions, and a higher level of satisfaction.

Accommodative IOLs

Providing true accommodation after cataract surgery as well as treating refractive errors with a safe and effective accommodative IOL has been of interest for several years. Single-optic accommodating IOLs, with flexible supporting elements, transmit the contraction of ciliary muscle into a change in anterior displacement of the optic, increasing power for near vision. Several single-optic IOLs are currently being investigated, including the 1CU (Human Optics), Tetraflex KH3500 (LensTec), and Crystalens AT-45 and Crystalens HD (Bausch & Lomb). A major drawback to single-optic accommodating designs is the limited amplitude of accommodation which declines following capsular fibrosis (Liang and Jia, 2018).

Dual-optic accommodating IOLs have a fixed, high-powered positive anterior optic and a negative posterior optic coupled by spring haptics designed to occupy the complete capsular bag to take advantage of natural accommodative mechanisms (Alio et al., 2017). Recent developments of dual-optic accommodating lenses include Visiogen's Synchrony and Bausch & Lomb's Sarfarazi IOL. Similar to single-optic accommodating IOLs, maintaining the elasticity of the capsular bag remains a challenge (McLeod et al., 2007, 2008).

NuLens (NuLens, Ltd.) is an example of a deformable surface-accommodating IOL made with a flexible gel contained in a small chamber made up of a PMMA anterior reference plane with a central hole, and a posterior piston (Alio et al., 2009). As the ciliary muscle contracts, the capsular bag displaces the gel component, resulting in a change in refractive power. Other early-stage accommodative IOLs include magnetic-driven shift utilizing the repulsive forces of magnets implanted under the superior and inferior rectus muscles driving the lens forward during accommodation (Sheppard et al., 2010). In the Fluid Vision IOL (Power Vision Inc.), with hollow optic and haptics, fluid displacement during muscle contraction or relaxation changes the surface curvature of the optic, thereby changing the refractive power (Kohl et al., 2014). Smart IOL (Medennium Inc.) is a thermoplastic hydrophilic acrylic implant that expands from rod-shaped at room temperature to its original shape at body temperature after implantation (Alfonso et al., 2016).

Adjustable-Power IOLs

Errors in IOL power selection from mathematical formulas and deviation in the axial position of the IOL result in postoperative residual refractive error (Werner et al., 2017). Spectacle correction of this error is acceptable, however in some cases explantation of the IOL is necessary. Postoperative adjustable power IOLs have been investigated, although the necessity for surgical reentry is of concern. Approved by the FDA in 2017, RxSight (previously Calhoun Vision, Inc.) created a unique biomaterial-based light-adjustable IOL (Tham et al., 2014). This IOL is implanted as a polymerized silicone matrix

containing nonpolymerized silicone macromers with an attached photoinitiator dispersed throughout for subsequent staged photopolymerization (Brubaker, 1991). Postoperatively, depending upon the sign and magnitude of refractive error, the IOL is judiciously exposed to long UV radiation from a slit-lamp-based LAL light delivery instrument, leading to partial photopolymerization. Exposing the central optical zone increases the power of the IOL, while exposure of the periphery decreases the power of the optic. Adjustments are made until targeted refraction is achieved, at which point the entire optic is exposed to UV radiation to lock-in the shape of the IOL. The procedure has been shown to be well tolerated by patients (Yalvac et al., 2004).

Perfect Lens LLS has developed a femtosecond laser system, Perfector, to adjust the refractive power of any commercially available acrylic IOL (Werner et al., 2017). Using green light (520 nm) at a power level below the threshold for ablation or cuts, the laser induces a chemical reaction in a targeted area of the optic, increasing hydrophilicity and decreasing refractive index (Bille et al., 2017). An in vivo animal model had promising postoperative outcomes without significant inflammatory reaction in the eye or damage to the IOL and showed good uveal and capsular biocompatibility, warranting further evaluations of this technology with clinical assessment (Werner et al., 2017).

Summary and Future of IOLs

While the need for IOLs to meet the demand of the aging population continues to grow, the development of more specialized materials and systems to create specific, functional outcomes along with evolving surgical techniques, has driven the creation of IOLs with optical and mechanical designs to meet these challenges. Development of multifocal and truly accommodative IOLs, mimicking the physiological function of the natural lens, has seen an acceleration along with improving phakic IOLs for correction of refractive errors. The modern IOL has the potential to replace spectacles, contact lenses, and corneal refractive surgeries, allowing for the achievement excellent vision. With improved understanding of the optical needs necessary for outstanding vision, customary IOLs may continue to evolve to target specific functional needs of aphakic and phakic eyes. The success IOLs have achieved in improving vision worldwide, with their continued advancement, will lead to better patient treatments and better outcomes in the future.

Glaucoma Drainage Devices

The World Health Organization (WHO) has identified glaucoma as the second largest cause of blindness in the world, affecting more than 70 million patients worldwide. Popularly known as a "silent disease," due to the absence of noticeable symptoms, glaucoma is the leading cause of visual disability in the United States. There is increasing incidence in Asia and Africa (Quigley and Broman, 2006; Tham et al., 2014), which has been attributed to disproportionate prevalence in Asian and African countries of improper documentation of the disease and a lack of available medical facilities. Glaucoma is often classified into two types, primary open-angle glaucoma (POAG) and primary angle-closure glaucoma (PACG).

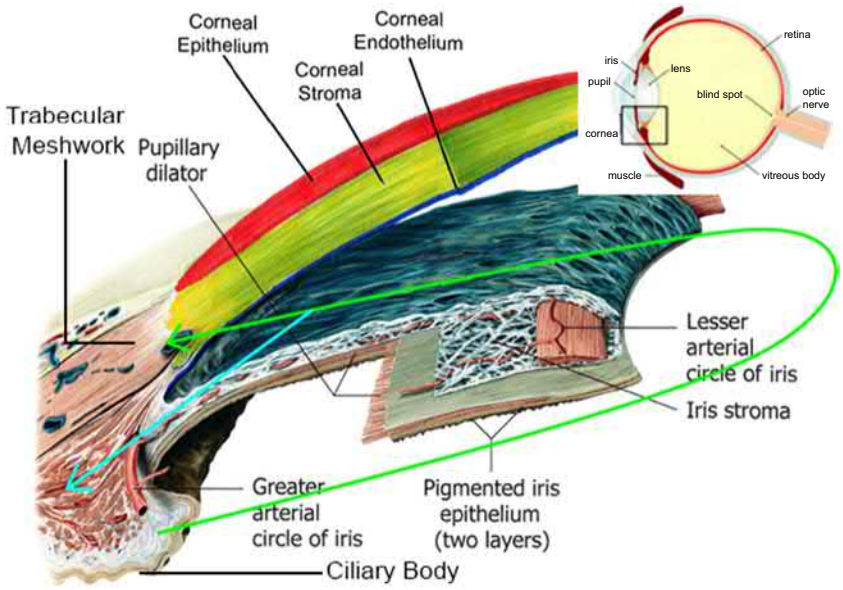
Aqueous Humor Production and Drainage

The development of POAG has been attributed to multiple structures in the anterior segment including the cornea, iris, lens, ciliary body, as well as the ocular drainage structures that make the anterior angle, such as the trabecular meshwork (TM) and Schlemm's canal (SC). The movement of both the aqueous humor (AH), and the nourishing fluid of the anterior chamber, produced by the ciliary body at a rate of about 2.75 µL/min (Brubaker, 1991) is shown in Fig. 2.5.6.4. The resistance in the outflow pathway, mostly the anterior angle, results in the blockade of the AH outflow leading to accumulation of AH and an increase in IOP. This increased IOP in the anterior chamber exerts pressure on the posterior chamber, leading to pressure-induced death of the retinal ganglion cells (Fig. 2.5.6.5), which are responsible for collecting visual signals. However, approximately 25% of glaucoma patients experience a loss of vision without indicating an elevation of IOP, called normal-pressure glaucoma (NPG). Regardless, the focus of glaucoma treatment has revolved around relieving IOP, thus reducing the pressure on the posterior segment of the eye.

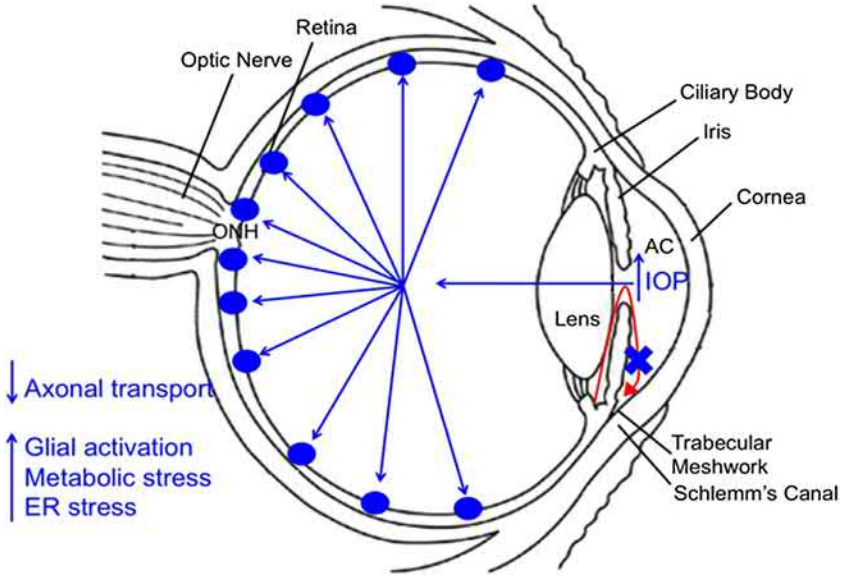
The methods for IOP management involve the following techniques: (1) topical drugs, (2) laser trabeculoplasty, or (3) drainage devices. Administration of IOP-lowering topical drugs is by far the most commonly used treatment method. These drugs typically work by increasing uveoscleral outflow and suppressing aqueous humor production. However, the efficiency of tropical drugs wears off after the initial stage of efficacy, requiring increased drug dosage or an increase in the number of medications to try to control the IOP.

The most commonly practiced surgical method for lowering IOPs is argon laser trabeculoplasty (ALT) or selective laser trabeculoplasty (SLT), requiring at least two sessions to manage IOP. However, approximately 80% of glaucoma patients require continuation of topical medications within 5 years of treatment. A more invasive surgical method known as trabeculectomy, that redirects outflow drainage through a hole punched directly through the sclera, is necessary in approximately 5% of patients, although in many cases IOP is not managed just 3 years post surgery (Yalvac et al., 2004).

With the failure of pharmacological treatments and trabeculectomy to maintain the IOP, aqueous shunts or implants that are placed in the anterior segment using glaucoma surgery were developed. These implants enhance the aqueous



• **Figure 2.5.6.4** General anatomy of the eye. (A) A schematic depicting the anatomical structures of the mammalian eye. The area within the square is magnified in (B). (B) The green arrow traces the pathway of aqueous humor as it is produced by the ciliary body, travels between the lens and the iris to enter the anterior chamber, and continues to the iridocorneal angle where it will drain out of the trabecular meshwork and Schlemm's canal or the uveoscleral pathway (aqua arrow). In the event that either of these pathways is disrupted, an increase in IOP is caused that could lead to glaucomatous features. (Modified and Adapted from Atlas of Anatomy, 2015.)



• **Figure 2.5.6.5** Schematic depicting theories of the relationship between increased IOP and the development of glaucoma. When an impediment of the aqueous outflow pathway (red arrow) occurs (blue X) the pressure within the anterior chamber increases, also known as increased IOP. This increased pressure translates to the back of the eye where it will exert itself upon the retina, particularly at the optic nerve head (ONH). As a result it is thought that axonal transport of trophic factors is decreased, and/or there is an increase of glial activation, metabolic, and ER stress.

outflow by maintaining a patent, surgically created opening and preventing healing. All devices work by increasing the outflow of aqueous humor from the anterior chamber either by directly accessing Schlemm's canal or shunting aqueous humor to the suprachoroidal or subconjunctival space. The first-generation implants that utilized traditional glaucoma surgery were large and bulky, with increased incidence of declining vision and complications. Recent advancements in the biomedical device industry have led to the development of implant devices that are of acceptable size and that can be implanted using an improved glaucoma surgery methodology, microinvasive glaucoma surgery (MIGS).

MIGS is minimally invasive and is known to avoid the complications typically encountered post glaucoma filtration surgery including hypotony, hyphema, infections, and endophthalmitis.

New-generation Microinvasive Glaucoma Surgery (MIGS) Implantation Devices

The Glaukos iStent Series

The **iStent** (Glaukos Inc.) is the first-generation trabecular bypass device that connects the anterior chamber with the Schlemm's canal, approved by the FDA in 2012. The product has a size of 1.0 × 0.3 mm, and is made from heparin-coated, nonmagnetic titanium and is provided preloaded in the inserter. The **iStent Inject** is a much smaller second-generation model. The mechanism of action of iStent inject is the same as the first-generation iStent. The iStent inject stents are delivered in an injector system which injects stents automatically into Schlemm's canal through a stainless-steel insertion tube. The procedure usually includes a clear corneal incision using topical anesthesia followed by a month of topical antiinflammatory and antiseptic medication. The **iStent supra** is a suprachoroidal implant made up of polyethersulfone and titanium that facilitates the transport of aqueous humor from the anterior chamber to the suprachoroidal space.

The **Hydrus** microstent is another trabecular stent that is manufactured by Ivantis Inc., currently in phase IV clinical trials. This 8 mm long stent is made up of nickel–titanium alloy (nitinol). It is inserted into Schlemm's canal, dilating Schlemm's canal in the complete nasal quadrant, thus facilitating aqueous outflow through multiple collector channels and bypassing the trabecular outflow facility. The Hydrus microstent decreased the baseline IOP by 20% in 80% of patients after 24 months following combined surgery using Hydrus microstent and PE/IOL (Pfeiffer et al., 2015). More trials are being conducted to prove the efficacy of the Hydrus microstent.

The Alcon **Cypass** micro polyamide stent creates a controlled cyclodialysis with stented outflow to the suprachoroidal space. The CE-mark was granted in 2008 and the FDA approved its usage in 2016. The Cypass is implanted through a clear corneal incision and requires the surgeon to load the implant in the injector. In a study conducted by Hoeh et al. an approximately 40% decrease in the IOP was noted after 12 months of implantation surgery (Hoeh et al., 2016). The most frequent side-effects involve hypotony, cataract progression, and transient hyphema.

The **XEN** (Allergan) is a subconjunctival gel stent made of porcine collagen cross-linked with glutaraldehyde. XEN was granted the CE-mark in 2013 and has been approved by the FDA for patients suffering from refractory glaucoma where previous surgery had failed and the patient became unresponsive to the maximum tolerated topical drug therapy. The stent facilitates aqueous outflow from the anterior to the subconjunctival space. The implantation of this device results in the formation of a bleb that might lead to scar formation, which is controlled by administration of mitomycin C (MMC). The IOP was observed to be decreased by about 29% after 12 months of implantation surgery (Perez-Torregrosa et al., 2016). On-going studies are focused on ascertaining the side-effects.

Summary

The current management of glaucoma includes such methods as medication, laser, and surgery, with a focus on lowering the IOP. The new-generation glaucoma treatment strategies involving less invasive MIGS seem to be promising. The development of new intraocular pressure-relieving medical devices such as iStent inject and Hydrus have shown promising results. The developments in the field of material science and engineering are also facilitating the development of improved versions of glaucoma implants.

Retinal Implants

The idea of manipulating the eye using electricity was described in 1755, when Charles Le Roy, a French physician, induced an electric current across the ocular surface of a blind patient who reported visual precepts or "phosphenes." Working directly on the brain, in the late 1920s, Otfrid Foerster, a German neurosurgeon, generated a similar subjective experience of phosphenes through external electrical stimulation of the occipital pole where the primary visual cortex is located (Bloch et al., 2019). In 1968, Brindley and Lewin further explored this discovery using an 80-electrode prosthesis to stimulate the visual cortex in a deliberate, grid-like way. Their experiments confirmed a retinotopic map which had been generated after localized head injuries resulting from war (Brindley and Lewin, 1968). The final piece of this puzzle fell into place when it was discovered that electric current across the globe of the eye in blind patients could elicit a downstream effect in the visual cortex that could be recorded using electrodes (Potts and Inoue, 1969). With these experiments, it became clear that electrically stimulating the retina, even in blind patients, could produce both the subjective experience of vision, as well as activate the visual cortex, thus setting the stage for retinal prosthetics which attempt to restore sight by deliberately activating a dysfunctional retina.

Both hereditary diseases, such as retinitis pigmentosa (RP), and acquired degenerative diseases, such as age-related macular degeneration (AMD), can lead to dysfunction or death of light-sensitive photoreceptor (PR) cells, while leaving the remaining retinal circuitry intact. While there are no currently available treatments for late-stage inherited or acquired PR loss, visual information can often be at least partially restored via electrical stimulation of the remaining retinal neurons. The signal transduction cascade necessary

for vision can be recapitulated artificially to an extent; cells can be polarized in an electric field, causing voltage-sensitive ion channels on the depolarized side of the cell to open, thereby increasing cell potentiation and generating an action potential in appropriate neurons. Recent advances in biotechnology have seen extensive human trials and in some cases market approval of retinal prostheses (da Cruz et al., 2016; Stingl et al., 2017).

Current retinal implants are typically classified based on anatomical placement as either epiretinal, subretinal, or suprachoroidal. Epiretinal devices stimulate the RGSs directly through their placement directly on top of the retinal surface (Ahuja et al., 2013). Placing the device in this manner has some obvious advantages and disadvantages. Signals produced by photoreceptors are meant to be regulated and processed to a certain degree by other neural cell types in the retina, particularly horizontal cells, amacrine cells, and bipolar cells. By stimulating RGCs directly, other cells in the neural retina are bypassed. Further, different subtypes of RGCs have different roles when reporting an image (i.e., brightness, outlines, direction of motion, etc.) and require different types of induction signals to activate (Jepson et al., 2013). Identification and selective activation of these RGC subtypes remain a significant challenge, particularly in a dysfunctional retina where cells may not respond as expected. The GCL also contains the axonal processes from millions of RGCs all over the retina in a fibrous layer. It is nearly impossible to stimulate specific RGCs without also activating axons from potentially distant cells which happen to run near the site of electrical stimulation. Taken together, in human trials, patients have reported elongated, distorted visual forms instead of discrete, round spots of light as intended (Nanduri et al., 2012). However, epiretinal arrays can be implanted without extensive surgical effort, and can also be removed in cases of postsurgical complication or device failure.

In a subretinal implant, electrodes occupy the location of degenerated or missing photoreceptors. Unlike with an epiretinal device, electrical stimulation induced in the inner retinal neurons is transmitted through the retinal circuitry to the RGL, preserving as much as possible a healthy retinal signaling process. Consequently, several quirks of human vision are preserved, including flicker fusion (Lorach et al., 2015), edge detection, and contrast enhancements through center–surround antagonism (Ho et al., 2018), nonlinearity, and fine-scale heterogeneity of RGCs (Lorach et al., 2015), as well as ON and OFF responses (Ho et al., 2018). Unfortunately, implantation or removal in the subretinal space is much more difficult than mounting a device on the retinal surface, which may present a barrier to adoption.

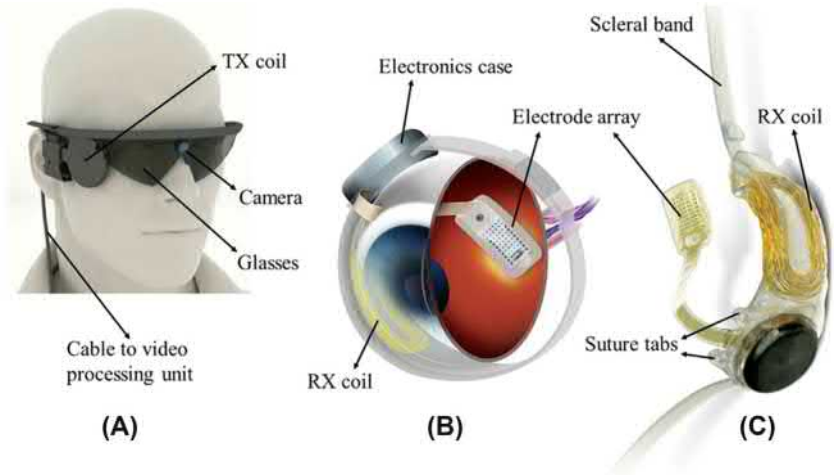
The suprachoroidal approach places the implant behind the choroid in contact with the scleral wall. In this position, the system does not necessitate intraocular surgery and may therefore be less invasive and more easily accessible for subsequent repair or replacement. The suprachoroidal space is extremely vascularized, which creates a significant risk of hemorrhage. Further, the immunoprivileged nature of the eye does not extend to the choroid, increasing the risk of fibrosis or other complications stemming from the foreign body response. Unlike devices in other tissue microenvironments, these implants are mainly purposed to supplement declining peripheral vision. Peripheral vision loss is a symptom in several ocular pathologies, and, while often not blinding, can result in decreased quality of life as normal activities such as driving become impossible or dangerous. Because these implants are meant to help with low-resolution scotopic vision, the relatively large distance between stimulating electrodes and retinal neurons may be acceptable. Implantation into the suprachoroidal space, however, will certainly produce the worst spatial resolution of the three approaches discussed due to current spread (Ayton et al., 2014).

To date, only four devices have been approved for use in humans in any major regulatory environment: Retina Implant Alpha IMS (first-generation device, Retina Implant AG, Reutlingen, Germany), Retina Implant Alpha AMS (second-generation device, Retina Implant AG), Argus II Retinal Prosthesis System (Second Sight Medical Products Inc, Sylmar, CA), and IRIS II (Pixium Vision, Paris, France). The major difference between the Alpha devices and the Argus II and IRIS II systems is that the former has placed a photodiode array subretinally, whereas the latter two are epiretinal (Zrenner, 2013).

Epiretinal Devices

Argus II

The Argus II (Second Sight, Inc, Sylmar, CA), also known as the "Bionic Eye," is a retinal prosthesis approved for use in retinitis pigmentosa in several jurisdictions, including the United States. It uses information from a head-mounted camera which is transferred along with power to a radiofrequency antenna to the implant (Ahuja et al., 2013). Image information is processed and encoded extraocularly before transmission to a 6 × 10 electrode array through a transscleral cable. A flexible foil with an array of 200-μm diameter electrodes spaced by 575 μm is physically attached to the outer retinal surface (Fig. 2.5.6.4). The Argus II has thus far been implanted in over 200 patients with some success. The best visual acuity score the Argus II has produced is 20/1,260, which, while low, can nevertheless greatly improve the mobility and quality of life of someone who is totally blind (Ho et al., 2015). It has been observed that a lack of physical connection between the camera and eye movements creates perceptual confusion where the brain expects an image to shift. Eye-tracking algorithms may offer a solution in the near future. In 2019, the Argus II will reach the end of its 10-year phase II multicenter trial which involves 30 subjects to evaluate safety and functional visual and real-world task performance. At 5 years postimplantation, there were 24



reported serious adverse events in 12 patients (40% of the trial population) including conjunctival erosion, dehiscence, and hypotony (da Cruz et al., 2016).

The Intelligent Retinal Implant System II (IRIS II)

Similar to the Argus II, the IRIS II is characterized by a glasses-mounted camera transmitting to an external "pocket processor," which transmits data to an extra- and intraocular implanted component containing a 150-microelectrode array (Fig. 2.5.6.6). Unlike the Argus II, the IRIS II uses a neuromorphic image sensor to more closely recapitulate how human eyes actually see, providing both the coordinates of changing pixels and their light intensities. The way the IRIS II encodes data, by dividing dynamic images into transient or sustained components, can be algorithmically processed to reduce any scene into its most relevant elements. Further, data generated by the pocket processor travel are transferred optically via infrared (IR) directly to the implant, permitting higher transfer rates and a smaller footprint than the Argus II. Data transfer rates are the typical bottleneck for stimulating greater numbers of electrodes at higher refresh rates, both of which are essential for improvements to visual acuity (Zhang et al., 2015). Power is supplied through a separate transmitter coil using radio frequency transmission, similar to the Argus II. Perhaps most importantly, the IRIS II emphasizes the importance of data processing over raw telemetry of information, and includes a learning retinal encoder, which allows for individualized customization to assign areas as excitatory or inhibitory, thereby mimicking the retinal ON/OFF pathways (Damle et al., 2017).

The IRIS II obtained approval for a clinical trial in 2016 and data for the initial 10 subjects implanted reported improvements demonstrated in square localization, direction of motion, picture recognition, and visual field testing, with a rate of 0.4 serious adverse events per recipient. The unprecedented short lifespan of the device in vivo, however, has led to a postponement of further development.

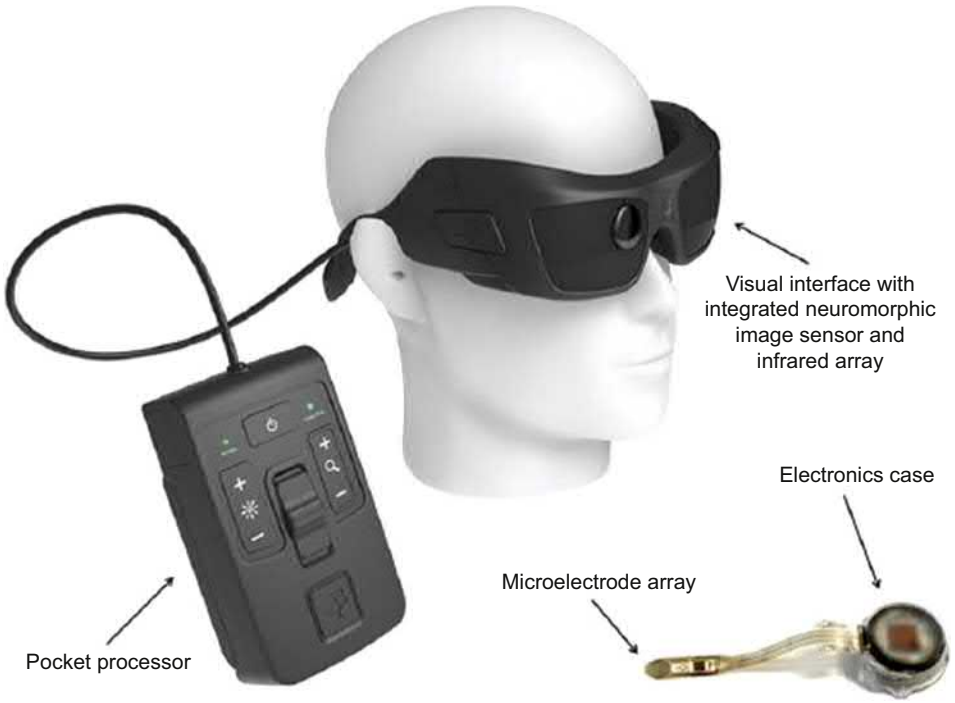
EPI-RET3 Retinal Implant System

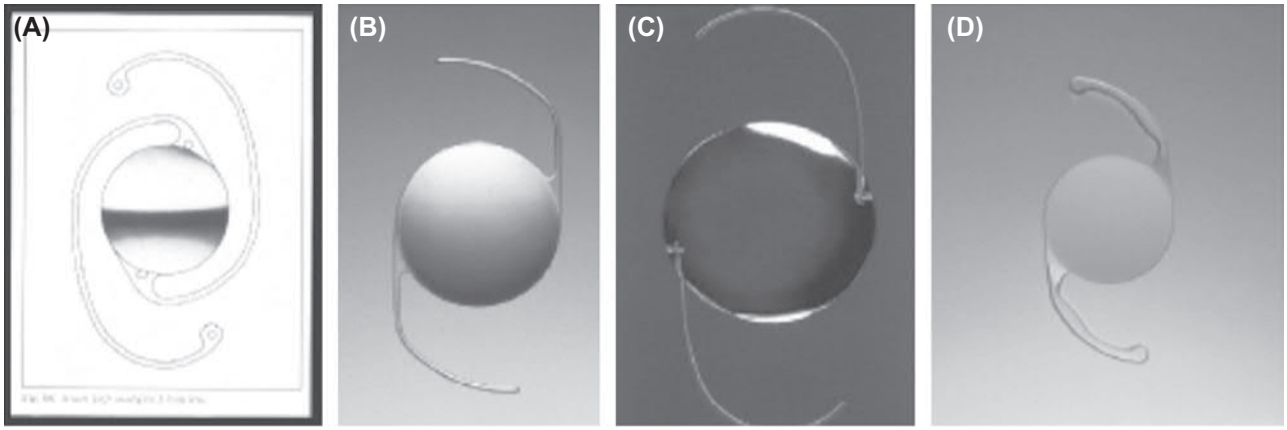
The EPI-RET3 differs from other epiretinal devices by localizing all of its components within the eye. Its receiver coil and chip are placed inside the capsular bag, similar to an intraocular lens after cataract surgery, and is connected to the epiretinal electrode array via wire. By housing the entire device inside the eye, transscleral cabling is no longer required, greatly reducing the risk of infection or tissue erosion. The device is powered inductively when needed. As with other epiretinal devices, the EPI-RET3 requires an external camera and visual processor, which transmit stimulation pulses to the internal components. In a phase I clinical trial, a 25-electrode system was implanted into six patients for 4 weeks and then removed. All six subjects reported patterned phosphenes in regions corresponding to the stimulated retina. A much larger version of the electrode is currently being evaluated for human trials (Klauke et al., 2011).

Subretinal Devices

Alpha IMS/AMS

The Alpha IMS (Retina Implant AG, Reutlingen, Germany) is the only subretinal implant to obtain regulatory approval for human use. It incorporates a photovoltaic array, termed a "multiphotodiode array" (MPDA), which comprises a 3-mm (Bourne et al., 2019) microchip containing 1500 independent photodiode–amplifier–electrode units, each of which will convert ambient luminance into a useable electrical signal (Kuehlewein et al., 2017). It is powered by a subdermal coil, fixed under the temporalis muscle. A removable external coil magnetically attaches to the subdermal coil, allowing electromagnetic power induction and control of contrast sensitivity and brightness from a handheld unit (Stingl et al., 2017). Due

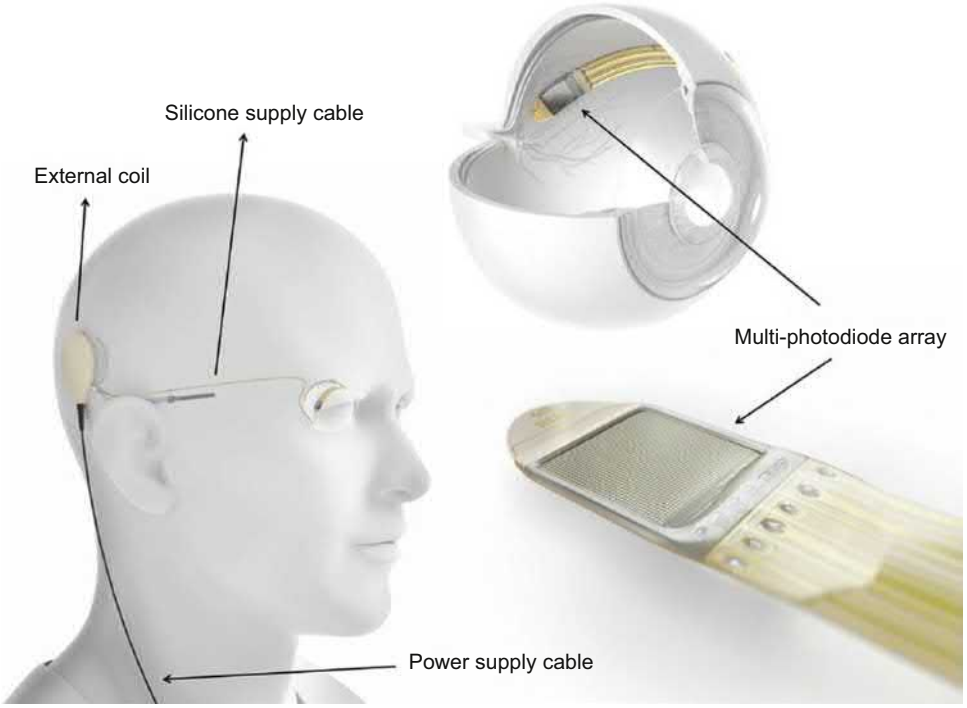




• **Figure 2.5.6.6** The IRIS II system. (A) Past three-piece PMMA IOL; (B) current single-piece PMMA IOL; (C) past three-piece foldable IOL; (D) current single-piece foldable IOL.

to the distal placement of the power coil and the intraocular placement of the MPDA, cooperation between medical teams is required for installation, increasing the costs and complexity of this approach. Furthermore, the delicacy of the subretinal space has been linked to premature device failure, as implants may need to be repositioned or replaced as a result of surgical or postoperative externalities (Kitiratschky et al., 2015).

The Alpha AMS is the second device in the Alpha line, replacing the Alpha IMS. Several vital changes were introduced into the Alpha AMS to improve its clinical efficacy and prolong its functional lifespan. In short, the AMS variant switched from a monophasic to a biphasic pulse, increased the size of the implant to include 1600 stimulation units compared with the 1500 found on the IMS. A huge potential advantage of the Alpha implants over their competition is that they perform both light detection and charge transfer to the overlying inner retina, whereas the Argus II and IRIS II use a head-mounted digital camera to detect incident light that is then transmitted wirelessly to the implant. As discussed above, the Alpha devices eliminate the decoupling of eye movement with camera position, as the device itself is light sensitive, and is implanted where photoreceptors would normally exist (Edwards et al., 2018). The implant is powered through a transscleral cable connected to a radio frequency power receiver positioned behind the ear similar to a cochlear implant (Zrenner et al., 2011). The placement of this device results in greater visual acuity than that of its competitors; typical patients have 20/1200 after successful implantation, with a few demonstrating scores up to 20/550 (Stingl et al., 2015).



Photovoltaic Retinal Implant (PRIMA) Bionic Vision System

In the PRIMA system (Pixium Vision), images captured by an external camera are projected onto the retina using pulsed near-infrared (~880 nm) light. The PRIMA system represents perhaps the most modern approach to retinal prostheses. The implant itself is a modular array of a 1-mm-wide hexagonal chips containing 142 pixel cells each. Each pixel uses the pulsed near-infrared light being transmitted by a pair specially constructed glasses to stimulate phototransduction. Energy from the glasses activates a stimulating electrode, which in turn activates a return electrode, each connected to multiple photodiodes. These photodiodes generate an appropriate electrical current that stimulates proximal neural retina. The modular conformation makes it possible to produce arbitrarily sized implants which maintain spatial fidelity and require no extraneous circuitry or power source, regardless of size (Lee et al., 2016).

Preclinical studies with 70 and 55-μm pixels have been encouraging. Visual-evoked potential (VEP) testing after implantation in Royal College of Surgeons rats produced a similar shape and amplitude to VEPs in wild-type rats. The amplitude of the VEP was also responsive to light intensity or pulse duration (Lorach et al., 2015). It has been suggested that if these results transfer, an equivalent spatial resolution in humans may produce a visual acuity score of 20/250; far better than any other retinal prosthesis currently available (Lorach et al., 2015). Further, with plans to reduce pixel size and increase density, it is possible this prosthesis could surpass the threshold of legal blindness (20/200).

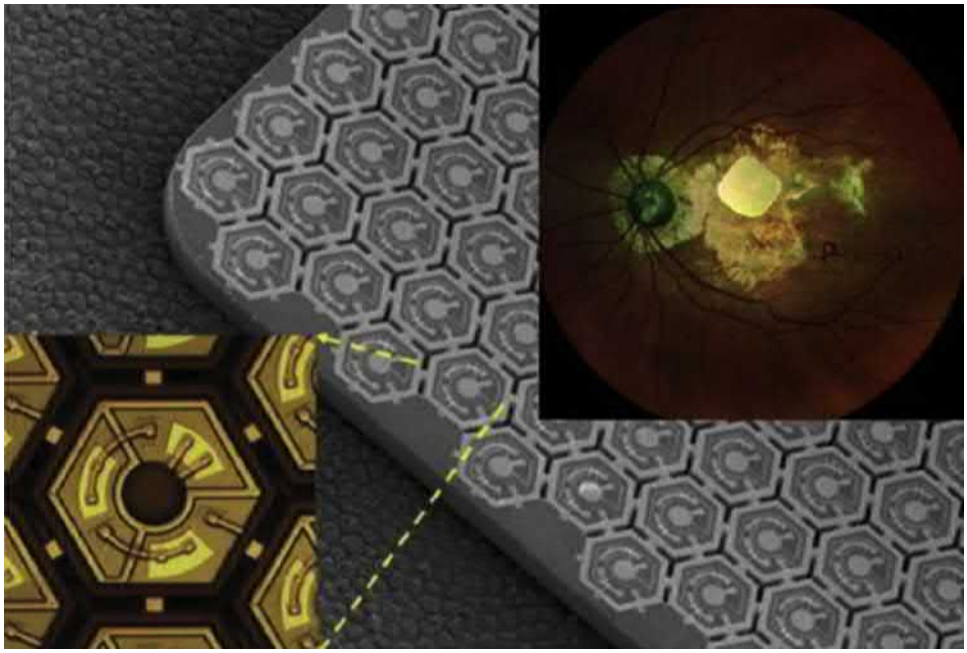
Clinical study began in France (2018) with subretinal implantation of a 2-mm wide 30-μm thick chip in five people with geographic atrophy, with five more Americans added later that year. This safety and feasibility study will last for 36 months, with preliminary results expected in 2019.

Suprachoroidal Devices

Bionic Vision Australia (BVA) Team

The Bionic Vision Australia (BVA) team is a consortium of Australian universities which have produced a number of suprachoroidal implant prototypes over the past 10 years, now being commercialized by Bionic Vision Technologies (BVT). The first of these was a 24-channel system, consisting of 20 stimulation channels and four return electrodes. Similar to the Alpha system, these implants require the dissection of the temporalis muscle for attachment of a transcutaneous module into bone. The array itself, connected by wire to the control module, requires that the lateral muscle is temporarily disinserted to allow for placement of the array into the suprachoroidal space (Saunders et al., 2014). Like the epiretinal devices, this prototype has no photoactive properties, relying on a head-mounted camera and image processor to provide appropriate information to the electrode.

Three subjects with blinding RP were implanted for 2 years as a pilot study in 2012. As expected, all subjects developed hemorrhages in the choroidal and subretinal space following implantation (Ayton et al., 2014). While light localization was better than random chance in all three participants, only one subject was able to complete a



visual acuity assignment, averaging 20/839. By the end of this study, electrical stimulation remained possible, despite the formation of a fibrotic capsule around the implants of all three patients (Saunders et al., 2014). As described, the most significant limitation of suprachoroidal implants is their distance from target tissues being electrically stimulated. A new device is being designed to address this issue, by incorporating a dual monopolar and hexapolar stimulation pattern which is meant to reduce retinotopic discrimination and high stimulation thresholds (Petoe et al., 2017).

Suprachoroidal–Transretinal Stimulation (STS)

A Japanese group in partnership with Nidek Inc. has created a similar device to the BVA system. Similar to BVA's approach, the STS requires a temporalis incision and tunneled connection between a decoder, an internal coil and a stimulating electrode array, and return electrode. Incident light is detected on a head-mounted camera and processed by a computer inside the arm of the spectacle component, which sends the signal to an external coil. This external coil relays the signal to a secondary implanted coil, which in turn generates the biphasic pulses needed to activate array electrodes. Unlike the BVA system, the electrodes on the STS protrude from the array by 0.3 mm, which places them slightly closer to the neural retina than the nonstimulating parts of the implant (Endo et al., 2018).

Following successful implantation of both single and dual 49-electrode arrays in animal models, three human patients were given the device. While the safety profile of the device seemed better than the BVA system, with no significant adverse effects after 1 year, the performance of the implant was less convincing. Subjects were able to walk along a high-contrast white line and recognize some everyday objects better than chance, but without statistical significance over several time points (Fujikado et al., 2016). Clearly, larger studies are needed for both the STS device and the BVA devices to produce firmer conclusions, but with the evidence available so far placing devices across the sclera from the neural retina is fundamentally less effective than episcleral or subretinal localization.

Conclusions and Future Directions

While retinal protheses can be grouped based on the tissue microenvironment in which they are meant to function, all devices currently in development face their own set of challenges. All devices are trying to replace the function of the retina by capturing light and transducing this signal into a subjective experience of vision. The density of rods or cones, particularly in the foveal pit where focal vision is produced, exceeds 150,000 cells per mm^2. This pixel pitch far exceeds even the most ambitious electrode array, which is only capable of producing a coarse approximation of real vision. Existing electrode arrays are thought to have a theoretical maximum resolution that is at least 12 times less than that of the normal retina (Zrenner, 2013). As with most electronics, head dissipation is a physical bottleneck toward increasing electrode density arbitrarily. Even if it were possible to recapitulate the sensory density of healthy photoreceptors, generating useable signals which are able

to propagate through the neural retina to the visual cortex remains an unsolved challenge.

Regardless, the past decade has seen enormous progress in materials science, image processing and accompanying algorithms, data transfer rates, and miniaturization, which continue to drive the field forward toward genuine visual restoration. Unlike stem cell or genetic therapies, retinal prostheses hold the promise of producing meaningful impact in the near future. It is likely that the future will see combination devices which include a biological component along with a bioengineered substrate to break through the inherent limitations of completely artificial prosthetics.

Introduction

It has been reported that 38.3M Americans have a severe disability of some kind. Over 22.4M individuals have physical disabilities (i.e., a condition that substantially limits one or more basic physical activities such as walking, climbing stairs, reaching, lifting, or carrying), and 14.9M individuals have sensory disabilities (i.e., blindness, deafness, or a severe vision or hearing impairment) (Brault, 2012). Disabilities of this kind can have a significant impact on one's daily activities. For example, 10.1M limit their ability to go outside the home alone, even for basic needs. Additionally, another 9.4M Americans report on limitations in an activity of daily living, such as bathing, dressing, or eating.

Conventional treatments are, in many cases, ineffective, leaving many disabled individuals highly dependent on full-time caregivers for even simple daily activities. Requiring a full-time caregiver results in enormous costs to society for daily care and lost productivity. The causes of many movement disabilities are neurological disorders such as spinal cord injury, stroke, Parkinson's disease, epilepsy, and others. Such disorders can often be mitigated by the careful application of electrical stimulation to specific neural structures.

Bioelectronic neural devices (or implants) were originally conceived as basic science tools. Such devices have been used extensively to enhance our understanding of how the nervous system works in both normal and diseased states. However, for nearly 50 years, clinicians, scientists, and engineers around the world have been developing and applying technologies to manipulate the nervous system for therapeutic and rehabilitative purposes. As the sophistication of available neural stimulation technology continues to increase, the opportunities for increasing functional performance and targeted applications also increases. Despite this, the Research Plan for the National Center for Medical Rehabilitation Research specifically states that a shortage of appropriately trained engineers and scientists is a primary obstacle to improving the effectiveness and efficiency of rehabilitation.

Therefore the focus of this chapter is to introduce readers (students) to the fundamentals to bioelectronic neural devices, with an emphasis on what materials are being used for an application, the neuroinflammatory response to the implants, evaluation criteria for materials selection, why historic devices have failed, and how one with an understanding of biomaterials science can develop solutions to enable this promising technology. The goal is that readers establish a base knowledge that can be supplemented with more in-depth readings provided in the references. Much of the background content will be fundamental to applications of bioelectronic neural devices regardless of the targeted tissue (see the Sections "Bioelectronic Devices" and "Technologies"). After some fundamentals are explained, we will briefly introduce several applications of the technology, followed by a more in-depth description of the current failure modes for the devices (see the Section "Applications") and biomaterials-based approaches to mitigate and overcome the most common failure modes (see the Section "Failure Modes"). The content in "Applications" and "Failure Modes" will be delivered in the context of brain-dwelling bioelectronic neural devices due to the more dominant nature of the problems, the research activity of biomaterials engineers to overcome these limitations, and the timeliness of the growth of the brain–computer interfacing field and commercial industries.

Bioelectronic Devices

Electrode Materials

Factors That Influence Materials Selection

The factors that influence materials selection are informed by the intended use within the system. For complex devices with multiple components (e.g., leads, wires, battery/circuitry, etc.), implanted medical devices typically involve

the use of several classes and types of materials to achieve different objectives. Some of the most common factors for consideration include:

- Electrical requirements (conductivity, capacitance)
- Location of use in the body/local anatomy (internal/external, flexibility, size, geometry)
- Duration of use and biocompatibility (temporary, implanted ±30 days)
- Manufacturability and packaging (including sterilization)
- Costs

Since electrodes serve two primary purposes in the body, electrical stimulation and recording electrophysiology, one of the first material properties for consideration is their ability to carry (or impede) electrical current, i.e., whether they should be an electrical conductor or insulator. Some examples of common choices are described in more detail next.

Conducting/Capacitive Materials

The conductive components of electrodes have historically been made of metals and their alloys: platinum, platinum/iridium, gold, tungsten, stainless steel, and others. While functional and used in the mainstay of clinically used devices, these common metals have a number of drawbacks, including their inherent stiffness and their propensity to form reactive species during electrical stimulation. Material stiffness creates a mechanical mismatch between the tissue and the device, which is thought to exacerbate the inflammation in surrounding tissues (discussed in more detail in the Section "Biological" later) (Goldstein and Salcman, 1973; Harris and et al., 2011; Hess et al.; Subbaroyan et al., 2005). Many new materials have been investigated to overcome the limitations of the traditional metals. Ultrasmall carbon fibers, shape memory polymers, and conductive polymers have been investigated to establish softer, and in some cases, ionically conductive materials to serve as electrode conductors (Stocking et al., 2019; Patel et al., 2016; Kolarcik et al., 2015). Carbon is particularly attractive as it is very cheap, easy to manufacture at scale, and is thought to have low reactivity in the body under stimulation.

The formation of reactive species when voltages are exceeded above the so-called "water window," a threshold above which hydrogen/oxygen gas is formed, is thought to contribute to neural damage near the electrode site (Kovach et al., 2016). The amount of damage that occurs is a function of the amount of charge that is injected through the electrode as well as its surface area. The higher the "charge density," the more likely neural damage will be incurred (Shannon, 1992). Shannon (1992) helped to define the safe level of charge/charge density that can be applied through a platinum electrode. While the Shannon plots should not be overextrapolated, particularly to metals other than platinum, they do provide a framework for evaluating the safety of stimulating electrodes (Hudak et al., 2017; Kumsa et al., 2017; Cogan et al., 2016). Cogan additionally provides a detailed framework for evaluating neural stimulation electrodes on the benchtop with electrochemistry (cyclic voltammetry, electrochemical impedance spectroscopy, and voltage transient analysis) (Cogan, 2008). Novel materials that have been tested to attempt to increase the charge injection limits include iridium oxide, titanium nitride, tantalum oxide, carbon, rough Pt/Pt-Ir, poly(3,4-ethylenedioxythiophene) (PEDOT), polypyrrole, and conductive hydrogels (Hudak et al., 2017; Kumsa et al., 2017; Ludwig et al., 2006).

Insulating Materials

The insulator is typically chosen based on the fabrication technique used to make the electrode. The most common insulators include polyimide, parylene-C, polydimethylsiloxane (PDMS), SU-8, and liquid crystalline polymer (Hassler et al., 2011). Wire-based electrodes have typically comprised extruded or dip-coated polymers for insulation: polytetrafluoroethylene, parylene-C, polyimide, poly(methyl methacrylate), epoxy, glass, and isonel. Micromachined electrodes have included silicon oxynitride, glass, parylene-C, polyimide, and silicones (Szostak et al., 2017). Polymer-based electrodes have included silicon, polyimide, benzocyclobutene, SU-8, parylene-C, liquid crystal polymers, and shape memory polymers (Szostak et al., 2017; Ware et al., 2012).

Total insulation impedance is a function of the material resistivity, as well as the insulation thickness and signal properties, amplitude, and frequency. In most cases the dielectric breakdown voltages are not exceeded for common insulations chosen for in-body applications. However, with very thin material coatings particularly used to manufacture miniature devices, it may be an important consideration. Furthermore, at very high frequencies, most insulating materials pass more current. Therefore insulation requirements may be different for a 30 Hz, 100 μs pulse versus the very high MHz frequencies used in radiofrequency heating and ablation applications.

Unfortunately, materials implanted in the body for long durations are vulnerable to hydrolytic, oxidative, and enzymatic degradation, similar to biological molecules. Naturally, such activity is important for tissue remodeling and tissue repair, and dominates the chronic foreign body response activated upon device implantation. Therefore the degradation of bioelectronics implants is due in part to the chronic foreign body response that is elicited upon implantation, as well as simply the normal aqueous/saline environment of the body (Hassler et al., 2011; Jorfi et al., 2015). Once insulation materials begin to break down, fluid ingress into the insulation can dramatically alter the function and lifespan of a bioelectronic neural electrode.

Equivalent Circuit Models

The first description of the chemistry of the electrode–electrolyte surface was provided by Helmholtz in 1879. At that time, Helmholtz also described the first equivalent circuit model for the electrode–electrolyte surface as a parallel plate capacitor. This oversimplified model described the electrode as positively or negatively charged due to an excess or lack of electrons. Likewise, the countercharge in the electrolyte

is due to the excess of charged ions in close proximity to the electrode surface. The alignment of charges at the electrode–electrolyte surface is known as the electrical double layer. Over the next 100 years, many other groups contributed to the further development of the equivalent circuit models, each focusing on different specific conditions.

Bioelectronic devices can interact with the body through either charge transfer faradaic processes or nonfaradaic adsorption and desorption events. An electrode can behave as either a polarizable or a nonpolarizable electrode under specific conditions at the interface, based on the materials used for the specific electrode design. However, most materials will also exhibit a minimal amount of the other process during use. A more detailed description of the electrode–electrolyte interface can be found in earlier editions of this book (see Chapter 11.5.10 Bioelectrodes by Venugopalan and Ideker). Within their chapter, Venugopalan and Ideker led readers to a detailed analysis of different types of recording and stimulation electrodes, and corresponding equivalent circuits discussed by Geddes and Baker (1989) and a review article by Geddes (1997).

Technologies

A typical implanted stimulation system includes an implantable pulse generator (IPG) containing a battery and circuitry, insulated lead wires, and electrodes with uninsulated metal contacts that inject charge into the body. Recording electrode systems are typically very similar in terms of electrode contacts and lead wires. In some cases, the recording lead wires are tunneled either to a percutaneous port to be fed to an amplifier and recording system, or they are connected to a telemetry system that performs signal conditioning and wirelessly transmits information to a receiver.

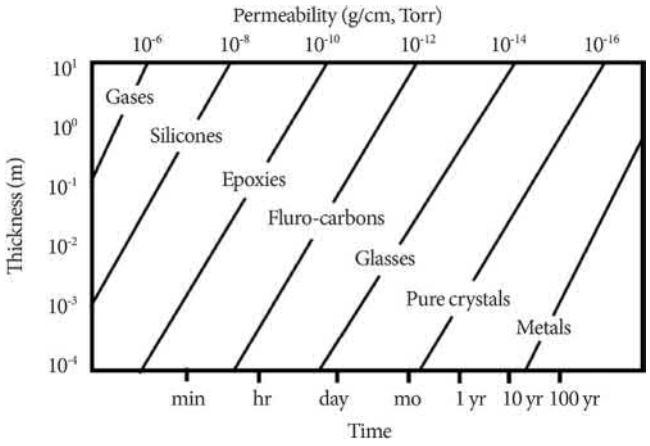
In both cases, several common key material challenges include reducing fluid ingress into protected circuitry and wires, maintaining electrical insulation integrity, preventing lead breakage, and optimizing the electrode–neural tissue interface, e.g., minimizing foreign body response and fibrosis through material selection. The latter challenge, the electrode–tissue interface, is the subject of extensive research. The "last-mile" connection is an important one that can determine the function of the overall system.

Each element in the system has different material requirements to achieve functional long-term performance. General descriptions of the system components and their material considerations are discussed next.

Battery, IPG

For implanted neural stimulation systems, there is typically an IPG, resembling a pacemaker. The IPG houses the battery and any circuitry required to control the device. The major material considerations for the IPG include:

- Battery composition
- Hermeticity
- Size and geometry
- Biocompatibility



• **Figure 2.5.7.1** Permeability of various materials used in bioelectronics device design. (Figure originally published in https://www.ncbi.nlm.nih.gov/pmc/articles/PMC3797898/#!po=4.54545, reproduced with permission.)

The primary purpose of the battery is to power the device and provide electrical impulses to the body. The design consideration is to allow maximal energy storage, recharging performance, and longevity. Current high-energy density IPG batteries are rechargeable lithium-ion (lithium-iodine polyvinylpyridine, lithium-carbon monofluoride, or lithium-polycarbon fluoride) (Joung, 2013).

As the lithium in the batteries is highly reactive with water, it is important to maintain a perfectly hermetically sealed device. The circuitry may also contain volatile or toxic (e.g., lead) compounds, which are important to isolate from the body. This is often accomplished by either encapsulating the device in silicones, epoxies, or other materials, or most effectively by laser welding the metal can together (Joung, 2013). The graph reproduced from Joung (Fig. 2.5.7.1) provides a qualitative/directional insight into the water permeability of various classes of materials as a function of thickness. Most existing pacemakers on the market today consist of a welded titanium package.

Leads and Interconnects

Typical lead architectures include single or multifilar wire arrangements that can be helically wound into strands and/or coils, which may include fluoropolymer insulation and an outer silicone tube. Material selection for the wire varies according to application and ranges from stainless steel and cobalt-chromium alloys to metallic composites (i.e., drawn filled tubes) and shape memory alloys (Gbur and Lewandowski, 2016). Additional considerations for material selection in neural electrode applications are discussed by Geddes and Roeder (Geddes and Roeder, 2003). The electrodes should be small and flexible, biocompatible, and demonstrate long-term reliability without degradation of the protective tubing or insulating layers. They must be able to undergo many mechanical fatigue cycles as would be endured in the body. A comprehensive review of materials used in biomedical applications and their mechanical testing

TABLE 2.5.7.1 Common Peripheral Nerve Stimulation Electrode Types per Application

Application	Electrode Types
Neuromuscular stimulation	Epimysial Intramuscular Nerve cuff Miniature radiofrequency coil
Spinal cord stimulation	Percutaneous Paddle
Peripheral nerve stimulation	Percutaneous Paddle Cuff In-body curing/conformal
Cranial nerve stimulation	Cuff (Huntington)
Genitourinary nerve stimulation	Disk Book Cuff Percutaneous

methods is provided by Gbur et al. (Gbur and Lewandowski, 2016).

The primary role of an interconnect is to allow for connection of the leads to the IPG during implantation. To allow for interchangeability, the leads are typically not soldered and therefore rely on mechanical contact. One standard connector used in neural prostheses is the inline "Letechepia" connector (Letechipia et al., 1991). Material considerations for interconnects include allowing electrical connection between the two contacts while maintaining an electrically and fluid isolated environment. Fluid ingress, in particular, leads to oxidation and rapid corrosion of the contacts.

Electrode Contacts

The last-mile connection to the nerve and central nervous system tissue can be very challenging. The ideal electrode for most applications is one that remains as close as possible to the target, induces little inflammatory response, minimizes mechanical strain on the tissue, and is easily deployable during surgery. Because the ideal interface is a challenge, there have been dozens of electrode designs specialized for each individual application (Table 2.5.7.1). The reader is referred to other resources for a more in-depth discussion, including the previous editions of this book (Tyler, 2018; Peckham and Ackermann, 2018; Peckham et al., 2013; Russell et al., 2019; Kim et al., 2019).

In general, the material constraints are informed by the anatomy with which the electrode is to interface. For example, for spinal cord stimulation, electrodes are implanted through surgical placement within the spinal column or around spinal roots exiting the foramen. Tight small spaces and a high degree of selectivity are required to achieve the desired effect without stimulating other nerves in proximity that may cause undesired side effects.

In selecting an electrode, there is an inherent tradeoff between invasiveness, safety, selectivity, and interface robustness. Current peripheral nerve stimulation (PNS) devices broadly fall along a spectrum of invasiveness, each with specific tradeoffs in safety versus sustained efficacy and robustness (Fig. 2.5.7.2).

Transcutaneous electric nerve stimulation is potentially the least invasive form of PNS, consisting of externally placed skin electrodes that stimulate superficial nerves (Fig. 2.5.7.2B). Fully implanted systems with cuff or intrafascicular electrodes are likely the most invasive, requiring full surgical access and freeing of the nerve from surrounding tissues to allow placement (Fig. 2.5.7.2F). Other systems that are available include: percutaneous systems (Fig. 2.5.7.2C), wirelessly coupled permanent implants (Fig. 2.5.7.2D), and fully implanted systems (Fig. 2.5.7.2E,F). The pros, cons, and other considerations for each approach are heavily debated among the field and are discussed in detail elsewhere. Practically speaking, stimulation device selection currently involves a balancing act between tradeoffs in safety, including implantation invasiveness, efficacy, and robustness. There remains an unmet need for implantable devices capable of maintaining robust connection with peripheral nerves while not requiring invasive surgery. To this end, a number of groups have attempted to develop miniaturized or otherwise injectable electrodes (Liu et al., 2015; Loeb et al., 2006; Seo et al., 2016; Trevathan et al., 2019).

Applications

The FDA does not approve materials as a wholesale class. Instead, they approve finished medical devices on the basis of safety and efficacy within a specific application for an intended use. Therefore it is important to carefully consider the application in which a neural implant is going to be used. There are dozens of clinical indications that already utilize electrical stimulation, with dozens more in preclinical development and/or undergoing commercialization (Fig. 2.5.7.3). While the breadth and depth of applications cannot be fully covered in this chapter alone, the following are a few applications of bioelectronic neural implants, which are briefly discussed.

Research

Neural electrodes play a role in basic neuroscience, electrophysiology, and biophysics. Common biopotentials measured in the body include:

- Muscle (electromyography)
- Nerve (electroneurography)
- Scalp/brain (electroencephalography)
- Cardio (electrocardiography)
- Intraocular and retinal (electrooculography and electroretinography)
- Cortical (electrocoricography and intracortical microelectrodes)

• **Figure 2.5.7.3** Small sample of marketed and in-development indications for therapeutic electrical stimulation of neural targets. (Compiled from references and cited company websites. Güemes and Georgiou (2018), Bonaz (2018), Pavlov and Tracey (2012), Koopman et al. (2016), Heiduschka and Thanos (1998), Tracey (2014), Humayun et al. (2016), Famm et al. (2013).)

Such signals can be used to interpret the status of the patient or subject, and can be used to interpret disease state, serve as objective outcome measures, or provide other feedback. The material considerations vary by application, e.g., whether the electrode is external or internal, and whether the electrode must be implanted over long duration. In general, an ideal recording electrode is one that (1) does not extensively disturb the existing biological systems they are intended to measure or stimulate, and (2) maintains performance over long periods of time for chronic applications.

Stimulating electrodes can be used in research to evoke a particular pathway or neural circuit. The combination of stimulating and recording electrodes makes a powerful basic science tool to investigate neuropathology and physiology.

Rehabilitation

Sensory Restoration

Sensory information is transduced by receptors and organs into neural signals that are transmitted along nerves, and interpreted and acted upon by the central nervous system. When these highways of sensory information are damaged, it results in significant disability. In some cases, the sensory system can be augmented or partially rehabilitated through the use of neural recording and stimulation electrodes.

Visual

An in-depth case study is presented by Humayan et al. in the previous version of this textbook, which the reader is referred to for more information (Humayun et al., 2013). A brief overview is provided here.

Light is transmitted through the lens of the eye and interacts with the retina, which acts as a transducer of the light to neural signals. The neural information is then transmitted through the optic nerve to the visual cortex where it is processed, interpreted, and acted upon by the brain. A visual prosthesis provides the concept where a digital camera is used to record the environment and convert the pixels into neural stimulation signals, which are projected as a pixel array on the retina. The number of electrodes and their density dictates the pixel resolution of the image the person is able to see. The Argus II implant, in development by Second Sight Medical Products, Sylmar, CA, is comprised of 60 electrodes that can be independently stimulated (Dagnelie et al., 2017; Stronks and Dagnelie, 2014).

To interface with the visual system, the options include implanting an electrode in the retina, the optic nerve, or the visual cortex. Several types of visual prostheses have been made. Due to the location and challenge with interfacing with the optic nerve, the two primary targets that have been investigated have been the retina and the visual cortex. In both cases, the tissue–electrode interface is a substantial materials challenge. The proximity of the interface to the retinal cells is important to maintain a low-impedance connection and reduce current spread. However, over time, the arrays become encapsulated with fibrous scar tissue leading to the spread of current, which limits the pixel resolution of the retinal prosthesis. A substantial need in retinal prosthesis is the search for smaller, higher density arrays that adhere closely to the retina with limited fibrosis.

Tactile

While advanced prostheses can improve function for those with lost limbs, the prostheses are still identified as being unnatural or not fully integrated with the human body. Substantial progress has been made toward restoring the sensation of touch by using electrical neural stimulation (Tan et al., 2014; Graczyk et al., 2016). The prostheses incorporate pressure sensors to measure the forces experienced by the prosthesis, and then convert those into neural signals that can be felt by the user with applied electrical stimulation via nerve cuff electrodes implanted in the stump (Graczyk et al., 2018).

While the materials currently in use with the peripheral nerve interface have been adequate to restore significant function to the people receiving them, there is still progress that can be made. The overarching goal is to develop a prosthetic that fully integrates with the wearer. To achieve this task, there is a need for higher density and bidirectional arrays capable of producing prosthetics with even finer resolution tactile feedback.

Auditory

The cochlear implant is one of the best established and widely used neural prosthetic devices on the market. It involves the implantation of a small stimulator in the scala tympani of the cochlea and is controlled by a sensor and IPG located above or behind the ear. A more comprehensive case study of the material considerations with the cochlear implant can be found in an earlier edition of this book in a chapter by Spelman (2013).

The auditory system is complex and involves an intricate organ (the cochlea) to convert sounds of differing frequencies into neural signals. The conversion relies on small hairs as transducers whose small deflections originate the neural signal. Different frequencies cause different hairs along the organ to vibrate. The stimulating electrode is inserted into the scala tympani, and has multiple stimulation contact sites that each correspond to a region sensitive to different sound frequencies. The interleaved stimulation of these different contacts is able to reproduce sounds recorded by the microphone.

The materials used in the IPG, lead wires, and electrode have all been relatively well established; however, there are always opportunities for improvement (e.g., higher density arrays, lower power consumption, etc.) (Clopton and Spelman, 2003). The development of the cochlear prosthesis is widely regarded as "*the* case study" in the development of a neural prosthesis.

Genitourinary, Bladder Dysfunction

The lower urinary tract has two major functions: to store and void urine, referred to as continence and micturition, respectively. Smooth muscle in the bladder wall is

innervated by parasympathetic neurons stemming from the sacral spinal segments S2–S4. For the bladder to effectively empty, simultaneous contraction of the bladder and relaxation of the urethral sphincter must occur. However, in spinal cord injury, other neurological disorders can disrupt the co-occurrence of these events, leading to a condition called "bladder dyssynergia." Currently, the clinical management of bladder dyssynergia relies on patients emptying their bladders through catheterization. Electrical stimulation (or inhibition) of these pathways has the potential to restore bladder control.

Disk, book, cuff, and percutaneous electrodes have all been used to treat bladder dysfunction. One of the primary approaches is to stimulate the sacral roots, the pudendal nerve, and/or the external urethral sphincter. The Medtronic peroneal tibial nerve stimulation (PTNS) system for the treatment of an overactive bladder is potentially one of the most widely used, and works by stimulating a spinal reflex that inhibits bladder voiding. PTNS currently relies on the use of a temporary percutaneous lead to provide stimulation. While this is not ideal, it has thus far been challenging to develop a fully implanted system due to the mechanical and space constraints of the anatomy. Ultrasmall, flexible, or other novel electrode designs may be able to address this challenge.

Motor Function

Motor function has been augmented through the use of "functional electrical stimulation" systems, and has been largely aimed at restoring function to those with paralysis or amputations. For example, trunk control, upper and lower limb, gait, and other neuromuscular stimulations have been applied to restore patient control of the muscular system. In most cases it is easier to stimulate large nerve fibers that innervate muscles rather than directly stimulating muscles or neuromuscular junctions. Therefore it is desirable to have electrodes that have high specificity that can engage specific groups of nerve fibers within a nerve trunk. For this purpose, the flat interface nerve cuff electrode has been developed from pliant PDMS-based structures. These enable greater specificity by reshaping the nerve within the cuff and provide access to individual fascicles with increased spatial resolution. Penetrating intrafascicular electrodes, which puncture the epineurium, has also been investigated. These electrodes have even greater material requirements as they must be stiff enough to pierce and be inserted through the thick epineurium, but soft enough not to overly stress the very low stiffness and easily damaged nerve tissue, and can be made from encapsulating microwires within silicone tubes.

Brain–Computer Interface

Intracortical microelectrodes for brain–machine interfacing have significant implications for reducing the burden associated with paralysis and limb loss. Notably, achievements have led to advanced control of prosthetics, which feel more natural and integrated with patients' bodies. By bypassing damaged regions of the nervous system, brain–computer interfaces (BCIs) offer the promise of reducing the burden of injury and enabling injured individuals to live more full and interactive lives (Pancrazio and Peckham, 2009). Unfortunately, implantable microelectrode arrays used in BCIs do not demonstrate long-term robustness, an observation that has been hypothesized to be due in large part to inflammation and neurodegeneration of brain tissue surrounding the implant (Goldstein and Salcman, 1973; Subbaroyan et al., 2005; Harris et al., 2011).

Common failure modes of intracortical microelectrodes for BCI and new materials-based approaches to improve the performance of BCIs are described later in the Sections "Failure Modes" and "Biomaterial-Based Strategies to Enable Neural Implants".

Bioelectronic Medicine, "Electroceuticals"

The field of bioelectronic medicine has received a substantial amount of attention. Compared to pharmaceutical agents that travel throughout the entire body via the bloodstream, electrical stimulation of nerves has the potential to more directly treat certain pathologies in the body at the specific time and location it is needed (Sanjuan-Alberte et al., 2018). The stimulation may also be turned off at will, yielding some degree of reversibility of the treatment. As a result of their potential benefits, so-called "bioelectronic medicines" or "electroceuticals" are being studied and explored for numerous indications by commercial and government agencies (Tracey, 2014; Famm et al., 2013; Reardon, 2014; Koroshetz et al., 2018; French et al., 2018).

There are dozens of clinical indications currently being pursued with a nerve stimulation approach, some in preclinical stage and others already en route to commercialization (Fig. 2.5.7.3). Autonomic nerve stimulation (e.g., vagus nerve stimulation [VNS]) is a major player in the development of bioelectronic medicine technology. VNS has been proposed to produce benefits for a number of conditions (epilepsy, sepsis, lung injury, rheumatoid arthritis, stroke, traumatic brain injury, obesity, diabetes, cardiovascular control, pain management, and others) (Johnson and Wilson, 2018). Other peripheral nerve stimulation approaches have been used successfully to treat pain, develop motor and sensory prostheses, and restore bladder control (Heiduschka and Thanos, 1998; Humayun et al., 2016; Dones and Levi, 2018). Emerging areas of research include the use of therapeutic electrical stimulation to treat inflammation, metabolism, and endocrine disorders (Güemes and Georgiou, 2018; Bonaz, 2018; Pavlov and Tracey, 2012; Koopman et al., 2016). The indications are numerous and may help address otherwise challenging-to-treat conditions (Tracey, 2014; Sanjuan-Alberte et al., 2018).

In terms of material considerations for bioelectronic medicine applications, there is a substantial unmet need for electrode designs capable of interfacing with a broad range of targets. Given the many unique anatomical targets under consideration, it would be extremely valuable to have

a class of electrodes that is capable of interfacing with multiple conformations. This may come in the form of either flexible thin films (e.g., shape memory polymer electrodes) (Ware et al., 2012, 2013), highly conformable, injectable electrodes (Trevathan et al., 2019), or other novel concepts (Capadona et al., 2019; Wirdatmadja et al., 2016).

Regeneration

It has long been thought that electrical signals from nerve innervation play a role in growth, development, and the wound-healing process (Jaffe and Vanable, 1984; Electrical Stimulation for Pressure Injuries: A Health Technology Assessment, 2017). The most widely available of such approaches is the stimulation of bone growth (Kuzyk and Schemitsch, 2009; Zhou et al., 2019). While the efficacy of such treatments is debated (Aleem et al., 2016; Mollon et al., 2008), the applications are FDA approved and continue to be used to a certain extent in the United States and other countries. The devices rely on the application of low-intensity electric fields, including DC, high-frequency (>20 kHz), and low-frequency pulsed electromagnetic fields. While bone regeneration is one such example of the use of electric fields to direct or improve tissue regeneration, there are other examples (Yao and Li, 2016).

In terms of material considerations for regenerative stimulation, one can consider whether the electrode must be permanent, or whether it can be transient or allow itself to be remodeled as the growth occurs. At the cellular and molecular levels, everything within the body is in a permanent state of flux and remodeling. Dynamically changing materials and systems may therefore have an advantage in their interaction with living neural tissue.

The ultimate electrode for tissue regeneration purposes may incorporate actual living elements, or simply allow the body to remodel them as the scaffolding degrades. At the very least, osteointegrated electrodes appear to have some advantages: mechanical stability, insulation from other tissues, and a tight association with tissues (Dingle et al.). Additionally, cells attached to the electrode surface or incorporated into a scaffold have the advantage of being able to dynamically respond to changes in the local environment. Goding et al. developed a construct for seeding cells onto extracellular matrix components (Goding et al., 2017). Cui's group developed PEDOT/graphene oxide materials that may improve the stability of neural stem cells during transplantation (Weaver and Cui, 2015). While the study was performed for a different purpose, the substrate may also be used for camouflaging implanted microelectrodes or providing sustained release of factors from an attached layer of mesenchymal stem cells. Macroporous nanowire nanoelectronic scaffolds allow for the ingrowth of tissues (Tan et al., 2015; Tian et al., 2012), such that after the device is implanted it becomes tightly incorporated in the tissue environment. Having the biology interface well with the device opens up possibilities for introducing therapeutic cells (e.g., stem cells) or engineered cells as well as physiological recording with minimal disturbance to the tissues (Zhou et al., 2019; Leppik et al., 2018). A challenge for dynamic or integrated electrodes that will have to be grappled with is the possible complication of the device needing to be removed.

Failure Modes

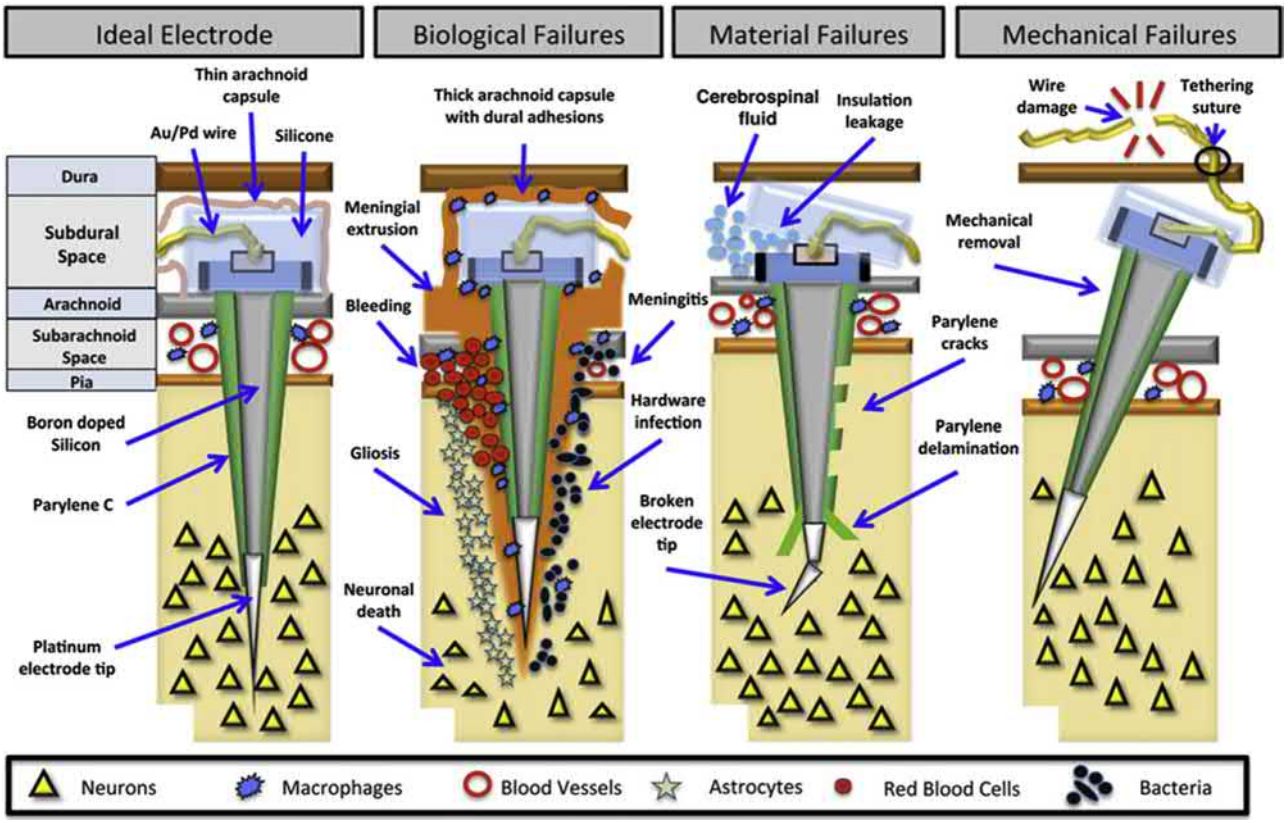
Bioelectronic neural implants can be placed in numerous locations in the body, see Table 2.5.7.1 for examples. Regardless of the location, the devices will eventually fail for one or a combination of reasons. In peripheral nerve electrode systems, the most common hardware failure modes are lead migration, lead fracture and malfunction, and battery failure (Eldabe et al., 2016). They also often suffer from other complications such as pain related to device components, infection, and skin breakdown. More rarely, complications include skin erosion, dural puncture, or other neurological injury related to insertion or postimplantation trauma (Eldabe et al., 2016).

However, the application that is the least stable, and has thus had the most focused research into understanding and combating failure modes, is intracortical microelectrodes for brain–computer interfacing applications. Therefore this section will describe failure modes for intracortical microelectrodes implanted into cortical brain tissue.

Intracortical microelectrodes have shown chronic cortical recording to be inconsistent in a variety of species and with multiple electrode types (Jorfi et al., 2015). In 2013, John Donoghue and his team published a retrospective analysis of the failure modes of several decades' worth of silicon-based intracortical microelectrode arrays implanted in nonhuman primates (Barrese et al., 2013). The team led by Donoghue converged on three main failure modes: mechanical, materials, and biological (Fig. 2.5.7.4). Two years later, the Capadona lab discussed subgroupings within these three groups to more specifically identify methods for preventing microelectrode failure (Jorfi et al., 2015). Here, due to the limited scope of this chapter, we will briefly discuss the major and minor failure mode classifications, and encourage readers to seek more detailed descriptions within the references and listed reviews.

Mechanical

Mechanical damage is defined as physical damage to the implants themselves, not the tissue. Mechanical damage to the tissue is grouped with biological response to the implant (see later). Traditional intracortical microelectrodes are derived from historically brittle materials: silicon-based materials, for example. Therefore it is not surprising that several studies have indicated that mechanical damage during or following insertion can lead to microelectrode failure. In 2009, Ward et al. implanted several different types of intracortical microelectrodes into rats and found mechanical failure in seven of 19 devices (Ward et al., 2009).



• **Figure 2.5.7.4** A summary of major failure modes to intracortical microelectrodes found by the Donoghue group's retrospective analysis from nonhuman primate studies. (Figure originally published in Barrese, J.C., et al., 2013. Failure mode analysis of silicon-based intracortical microelectrode arrays in non-human primates. J. Neural Eng. 10, 066014. https://doi.org/10.1088/1741-2560/10/6/066014 , reproduced with permission.)

Interestingly, of all the mechanical failures described by Ward, only one failure of the implant shank was documented, meaning that the devices were failing in other places in higher numbers (Ward et al., 2009). Other groups have also reported on mechanical failures of the nonpenetrating components of the microelectrode array systems (Barrese et al., 2013; Prasad et al., 2012, 2014). In a summary of decades of nonhuman primate work, the Donoghue group found more than twice as many mechanical failures in the acute phase than biological or materials-based failures combined. Thus improvements in the mechanical stability of the entire system is an important area of research. Finally, as the field is driving toward smaller and smaller devices, the vulnerability of the implants to damage from improper handling, implantation into the neural tissue, or by the animal after implantation is increasingly important to consider.

Materials

The explantation of bioelectronics devices clearly demonstrates that the materials used are imperfect at preventing all damage to the device. Damage is typically more severe for simulating devices than for recording devices. This is most evident in the evaluation of intracortical microelectrodes. Intracortical microelectrodes suffer a variable amount of damage to the materials that comprise the device, depending on the choice of materials and the extent of the biological response to the implant. The connection between materials failure and biological-mediated failure will be further explored in the next section. Here, we describe materials damage to the microelectrode components as either corrosion of the electrical contacts, or damage to the insulating coatings. Electrode recording sites and/or the passivation layers and insulating coatings commonly incorporated into microelectrodes may degrade over time, which could reduce an electrode's ability to detect local ionic signals (Jorfi et al., 2015).

Corrosion to the electrical contacts is exacerbated when charge is injected into the materials. However, the same materials may experience faradaic charge transfer and corrosion over time (Merrill, 2010). A sequence of studies by the Sanchez group demonstrated that recording site deterioration is metal specific (Prasad et al., 2012, 2014). For example, tungsten microwires displayed progressively more severe structural changes with time of implantation (Prasad et al., 2012), while platinum/iridium (Pt/Ir)-based devices showed little structural changes to the metal recording site (Prasad et al., 2014). However, both studies demonstrated evidence that polyimide insulation was peeled away from the recording site and had signs of cracking.

The rate of corrosion and peeling/cracking of insulating layers is likely environment and material specific. In fact, several groups have demonstrated just that. For example, while bare tungsten and gold-plated tungsten wires corrode readily in phosphate-buffered saline, corrosion rates are accelerated in the presence of reactive oxygen species (ROS) (Patrick et al., 2011). Metals that form natural passivation layers are naturally more resistant to oxidative corrosion and have begun to be developed into microelectrode arrays (McCarthy et al., 2011). While accelerated aging methods are being developed for high-throughput in vitro/ex vivo evaluation of electrode materials (Takmakov et al., 2015), information regarding the corrosion rates of many common microelectrode materials under nonstimulating conditions is not readily available (Jorfi et al., 2015).

A number of mechanisms may influence the degradation of traditional insulating layers used as electrode materials: mechanical stress, film defects, as well as chemical or electrochemical reactions. For example, traditional passivation layers of silicon (Wang et al., 2007), silicon oxide (Hammerle et al., 2002), and silicon oxide/nitride stacks (Maloney and Baldwin) degrade within days (Wang et al., 2007) to months (Hammerle et al., 2002) of implantation, as fast as 1 mm/year (Maloney and Baldwin). Due to the chemical vulnerability of dielectric passivation layers originally designed for other industries, further encapsulation of microelectrodes with insulating polymers has become common practice (Schmidt et al., 1988; Hsu et al., 2009; Loeb et al., 1977). While the incorporation of polymer coatings has little impact on the neuroinflammatory response (compared to traditional passivation layers), several studies have demonstrated in vivo deterioration, resulting in compromised recording qualities (Prasad et al., 2012, 2014).

Among the most promising solutions is the development of amorphous silicon carbide (a-SiC) dielectric film for microelectrodes (Cogan et al., 2003). A-SiC has a dissolution rate of only 0.1 nm/h at 90°C (1/20th that of silicon nitride)—most importantly with no measurable dissolution at 37°C. More recently, in vivo evaluation of a-SiC intracortical microelectrodes suggests that a-SiC may provide a stable biocompatible substrate for the chronic recording and stimulation of neural structures (Deku et al., 2018; Knaack et al., 2016).

Biological

Several studies have demonstrated the connection between neuroinflammation and penetrating microelectrode performance, regardless of the materials used or the design of the implant (Kellis et al., 2010; Nolta et al., 2015; Prasad and Sanchez, 2012; Saxena et al., 2013). However, the exact mechanism or feature of the inflammatory response that is the most connected to device performance is still under debate. For decades, many labs have performed histological evaluation of the inflammatory response to devices placed into or near neural tissue structures. It has become increasing clear that the brain's response consists of an interconnected network of molecular and cellular components. Ultimately, the persistent presence of the implant in the brain tissue results in a self-perpetuation of the response (Potter et al., 2013) and prevention of device integration into the surrounding tissue, while the initial trauma from device implantation has been shown to heal (Potter et al., 2012; Hampton et al., 2004). For detailed reviews of the events following microelectrode implantation into neural tissue, in the context of the brain, readers are referred to the previous reviews of the topic (Jorfi et al., 2015; Tresco and Winslow, 2011; Michelson et al., 2018; Pancrazio et al.).

One of the leading theories for the prolonged proinflammatory state surrounding neural devices that penetrate neural tissue is repetitive motion-induced damage (Goldstein and Salcman, 1973; Harris et al., 2011; Hess et al.; Subbaroyan et al., 2005; Ware et al., 2012; Mahi and Rodrigue, 2012; Kim et al., 2004; Hess et al., 2011). The original idea can be traced back to Goldstein and Salcman's work in 1973 (Goldstein and Salcman, 1973), suggesting that motion of the brain with respect to the microelectrode may induce damage to the surrounding tissue. Approaches to overcome this theory are discussed later. Alternatively, in 1999, Norman suggested that the proximity of an implant in relation to the blood vessels can affect the foreign body response (Normann et al., 1999). A brief history of approaches to minimize damage to the blood–brain barrier will be presented later.

The final overarching mechanism discussed here is the impact that inflammatory-mediated oxidative events have in both materials degradation and tissue viability. The accumulation of oxidative stress events at the device–tissue interface has been suggested to occur as early as 2 weeks after implantation through the accumulation of ROS in activated macrophages responding to the implant (McConnell et al., 2009), and exist as long as the device is implanted (Prasad et al., 2012, 2014; Prasad and Sanchez, 2012). The in vivo evidence was extrapolated to suggest the correlation between oxidative events and corrosion of both insulating and conductive microelectrode material components. Takmakov et al. took the idea that oxidative stress causes damage and developed an accelerated aging method with hydrogen peroxide to study electrode degradation. They found that hydrogen peroxide-rich environments are especially damaging to polymer insulating layers, causing structural damage and changes in electrical properties in all types of electrodes (Takmakov et al., 2015), suggesting confirmation of the early in vivo studies in a more controlled setting.

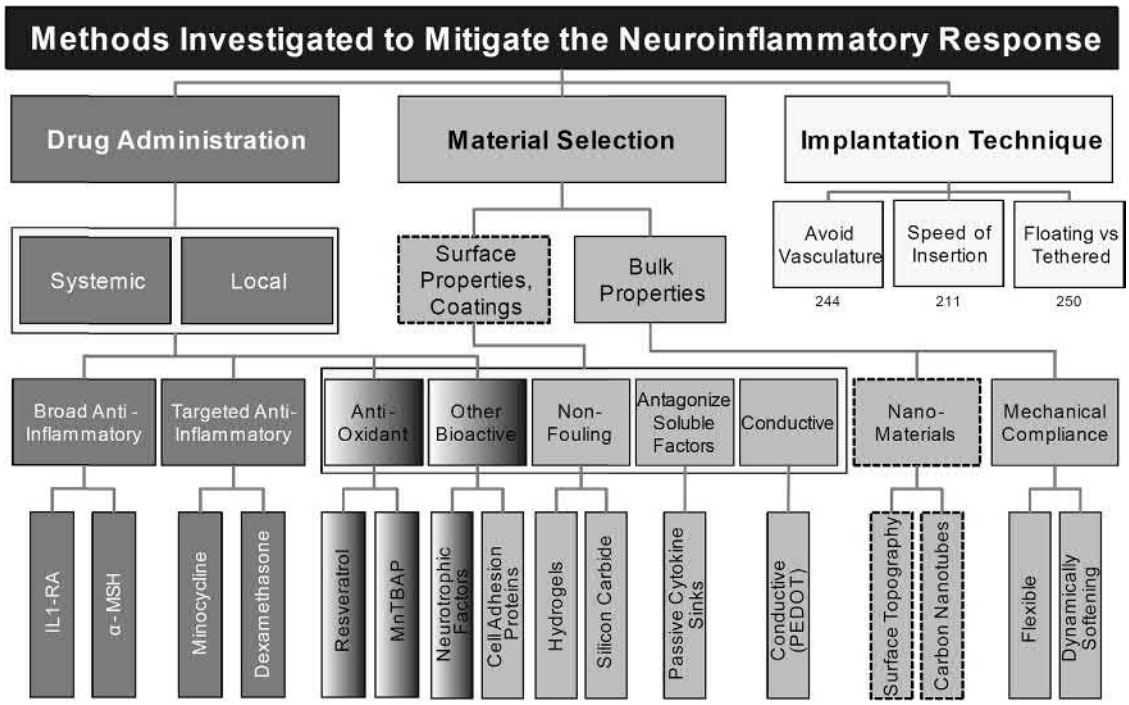
The release of ROS around implanted intracortical microelectrodes can be caused by both material and biological sources. First, as a result of being in an aqueous environment, electrochemical reactions on the surface of the electrode can attribute to the conversion of water to hydroxyl radicals (Schmitt et al., 1999). In the case of electrical contacts (e.g., gold), chemical redox reactions at the surface can result in the oxidation of the electrode surface. The oxidation reactions can result in corrosive materials breakdown (Schmitt et al., 1999) seen in vivo (Prasad et al., 2012, 2014) and in vitro (Takmakov et al., 2015).

Additionally, the extent of inflammatory response occurring after implantation is strongly correlated to the formation of ROS around the device (He and Bellamkonda, 2008). ROS is released from cells due to an imbalance in the redox state of the cell (Balaban et al., 2005; Ray et al., 2012; Turrens, 2003). A simplified progression of the formation of ROS can be described as superoxide anion → hydrogen peroxide → hydroxyl anion that occurs during the conversion of oxygen to water. Particularly, mitochondrial dysfunction and heavy metals (e.g., copper and iron) within the cell are key contributors to driving the formation of ROS (Melo et al., 2011). Thus since all cells possess metal ions and mitochondria, unlike other proinflammatory molecules, ROS can be released by any cell type, not only inflammatory cells (Melo et al., 2011). To that end, several groups have confirmed that multiple cell types within the brain are capable of releasing ROS and other proinflammatory molecules (Abbott et al., 2006; Kettenmann, 2007; Kettenmann et al., 2011). Therefore an understanding of the series of cellular and molecular events involved in the inflammatory response is key to designing engineering strategies to combat failure modes caused by the formation and accumulation of ROS.

As the failure modes of intracortical microelectrodes are further elucidated, one mechanism that has been suggested to play a key role in several failure modes is oxidative stress and/or Fenton chemical reactions (iron-catalyzed peroxide formation) at the microelectrode–tissue interface (Barrese et al., 2013; Prasad et al., 2014; Prasad et al., 2012; Ereifej et al., 2018). Specifically, oxidative stress can (1) facilitate corrosion and delamination of the microelectrode surface, (2) perpetuate the foreign body response to the implanted device through disruption of the blood–brain barrier, which is directly and indirectly linked to microelectrode performance (Nolta et al., 2015; Saxena et al., 2013), and (3) directly facilitate neuronal death and viability. Therefore oxidative events are directly or indirectly a part of most, if not all, events following neural electrode implantation into neural tissues.

Biomaterial-Based Strategies to Enable Neural Implants

There is increasing consensus that poor materials quality in conjunction with neuroinflammatory response to intracortical microelectrodes is a primary hurdle preventing neural technologies from reaching their full potential. Therefore improving the understanding of the neuroinflammatory response that develops following device implantation into neural tissues and developing strategies to reduce its impact are critical to achieving the promise to enable longer recording durations for basic science experiments and clinical applications. Many attempts at reducing the implications of the neuroinflammatory response on neural device performance can be grouped categorically by approach (Fig. 2.5.7.5) (Shoffstall and Capadona, 2018). For a more in-depth discussion on each, see Shoffstall and Capadona (2018). Here, we will briefly introduce attempts



• **Figure 2.5.7.5** Summary of leading methods to mitigate the biologically driven failure modes of an intracortical microelectrode. *α-MSH*, alpha-Melanocyte-stimulationg hormone; IL1-RA (interleukin-1 receptor antagonist); *MnTBAP*, Mn(III)tetrakis(4-benzoic acid)porphyrin; *PEDOT*, poly(3,4-ethylenedioxythiophene). (Figure originally published in Shoffstall, A., Capadona, J.R., 2018. In: Neuromodulation. Academic Press, pp. 393–413, reprinted with permission.)

to reduce the role of micromotion (one of the longest-standing hypotheses) and antioxidative strategies (in our opinion, among the most comprehensive approaches to mitigating tissue and device damage).

Micromotion and Tissue Mechanics

As discussed earlier, traditional microelectrodes have been composed of extremely stiff materials such as metals or silicon. The high stiffness has facilitated microelectrode implantation into the cortical tissue (Bjornsson et al., 2006) without the need for external insertion guides (Shoffstall et al., 2018). In silico modeling has suggested that creating neural devices from materials that more closely match the stiffness of neural tissue will relieve tissue strain caused during brain and device micromotion (Subbaroyan et al., 2005). However, simply making softer implantable neural devices has proved difficult for many reasons. First, softer devices are more difficult to implant with insertion aids (Shoffstall et al., 2018). Often, insertion aids are not translatable from single shank devices to multishank arrays used in clinical models. Additionally, traditional lithography techniques have taken over a decade to adapt to the materials of interest for neural applications (Ware et al., 2013; Hess et al., 2011; Yang et al., 2019), and many of the current device configurations are unlikely to translate well into clinical use due to poor device stability or the inability to retrieve the implant without damage to surrounding tissue. Therefore while "off-the-shelf" polymers are currently gaining the most attention (Capadona et al., 2019), they are unlikely to win out in the end for devices that dwell within the tissue. Consequently, the persistence to develop specialized materials for applications may provide the long-term solution to minimizing tissue and device damage due to compliance mismatch (Ware et al., 2013; Capadona et al., 2008).

Antioxidative Strategies

Given the role oxidative stress plays in several failure modes of intracortical microelectrodes, one group has been among the first to elucidate the role of oxidative stress events occurring around implanted microelectrodes (Dagnelie et al., 2017; Stronks and Dagnelie, 2014; Tan et al., 2014). As a proof of principle, their first strategy demonstrated that a two-dose intraperitoneal injection regime of antioxidant (resveratrol) at the time of implantation was capable of mitigating oxidative stress events, neuronal degeneration, and neuronal cell loss up to 4 weeks after implantation (Dagnelie et al., 2017). However, short-term antioxidant administration was unable to provide sustained neuroprotection (>4 weeks) around implanted devices. They hypothesized that the lack of sustained neuroprotection was based on fast clearance rates and low bioavailability (Geddes and Roeder, 2003; Letechipia et al., 1991; Tyler, 2018). Thus their next approach was to deliver the antioxidant treatment daily for 4 months (Potter-Baker et al., 2015). While regular administration of resveratrol provided neuroprotection, repetitive systemic administration resulted in side effects (Potter-Baker et al., 2015).

In an attempt to combat the limitations of systemic antioxidant delivery, multiple groups have demonstrated the success of immobilized antioxidative approaches in mitigating inflammatory pathways following device implantation (Jorfi et al., 2015; Potter-Baker and Capadona, 2015). While many natural and synthetic antioxidants are available for attachment to biomedical device substrates, it is important that the appropriate chemistry be available within the chemical structure of the antioxidant itself. One synthetic antioxidative molecule that has gained attention for its ability to be covalently bound to surfaces is Mn(III) tetrakis(4-benzoic acid)porphyrin (MnTBAP). MnTBAP was developed as a synthetic antioxidant mimetic enzyme to superoxide dismutase (SOD) (Batinic-Haberle et al., 2009).

To date, the development of a sustained antioxidative coating for intracortical microelectrode applications based on the immobilization of the MnTBAP SOD mimetic has only been reported in vitro (Potter-Baker et al., 2014). Their initial system utilized a coating of covalently immobilized MnTBAP (or SOD mimetic) designed to provide a sustained immobilized layer of antioxidant. Surfaces coated with the antioxidant demonstrated a significant reduction in accumulation of intracellular and extracellular ROS produced by adherent microglia (Potter-Baker et al., 2014). Results indicated that antioxidant-modified surfaces maintain beneficial levels of antioxidative activity (Potter-Baker et al., 2014). Based on these results, other groups are now also developing antioxidative coatings from melatonin, curcumin, estrogen, and other naturally derived antioxidants.

Conclusions and Future Directions

Again, the focus of this chapter was to introduce readers (students) to the fundamentals to bioelectronic neural devices. Here, our goal was to place an emphasis on the role of biomaterials in device design and performance. When the field of neural interfacing began around 50 years ago, the role of materials in neuroelectronic device performance was downplayed, especially as it related to the neuroinflammatory response. Over the last few decades, however, the bioelectronics field has grown to appreciate the importance of understanding mechanistically how materials interact with the neural environment under passive and active conditions. Therefore there is an increasing demand for individuals with a deep understanding and appreciation for biomaterials in the growing field of bioelectronics.

2.5.8

Burn Dressings and Skin Substitutes

STEVEN BOYCE, PHILIP CHANG, PETRA WARNER

Department of Surgery, University of Cincinnati and Shriners Hospitals for Children – Cincinnati, Cincinnati, OH, United States

Burn Wounds

Burn injuries to the skin have several causes including physical (i.e., flame, scald, electrical radiation, friction, frostbite) or chemical (i.e., strong acids or alkalis) agents, and may result in skin loss extending to superficial, partial-thickness, or full-thickness depths. Superficial burns (e.g., severe sunburn) tend to regenerate a functional epidermal barrier in a few days, and often require limited protection from infection and fluid loss (Herndon, 2012; Jan et al., 2018). In addition, skin loss involving sloughing of the interfollicular epidermis may occur after the immune response to infectious organisms, or to reactions to drugs or chemical toxins (Rogers et al., 2017; McCullough et al., 2017). These kinds of conditions have been treated effectively as partial-thickness burns that will often reepithelialize in less than 3 weeks with few long-term complications from scar because the anatomy of the dermis is well preserved. Partial-thickness burns involve the external epidermis and varying depths of dermis, but retain viable sources of cutaneous epithelial cells and melanocytes which will migrate and proliferate to restore the epidermal barrier and pigmentation to the surface of the wound. Until the epidermal barrier is restored, partial-thickness wounds will produce granulation tissue which promotes formation of scar. Some partial-thickness burns may also progress to full-thickness burns if vascular perfusion in the deep dermis becomes compromised. In that event, or if the burn destroys most or all of the epithelial sources at the site, then the epithelium must be restored by conventional grafting of split-thickness skin, or application of autologous epithelial cells as part of a skin substitute. Donor sites for autologous split-thickness skin grafts qualify as partial-thickness surgical wounds because they have some injury to the dermis, and retain sources of epithelial cells (Sidebar 2.5.8.1).

Surgical Planning for Wound Care

Clinical objectives for skin wound closure include, but are not limited to: (a) survival; (b) the earliest possible wound closure; (c) the least amount of donor skin harvesting; (d) minimum scar; and (e) the best functional and cosmetic outcomes. Accomplishment of these goals requires careful planning after initial assessment of cutaneous burn injuries. The initial assessment identifies the magnitude, depth, and distribution of the wounds, availability of donor sites, as well as comorbid conditions that may delay or compromise healing. Important distinctions can be made for different anatomic sites. For example, the face, hands, feet, and perineum usually have the highest priority due to their functional and cosmetic importance to burn survivors. In many cases, the greatest absolute area involves the anterior and posterior torso, and extremities over the long bones. Part of the plan may require grafting of the back, which may involve prone positioning of the patient which may be complicated if support of the patient includes mechanical ventilation. Grafting over joints may require immobilization to minimize graft loss from shear during patient positioning and early physical therapy. In addition, the capacity of the patient to heal may be impacted negatively if there is lung injury with compromise of pulmonary function.

After this assessment is completed, an approach to permanent, stable wound closure should be specified, and timelines estimated. Because early excision of burn eschar has become a prevailing standard of care, full-thickness and deep partial-thickness wounds are excised to viable tissue, and partial-thickness wounds are debrided to remove necrotic tissue as early as possible after hospital admission. Together with excision and/or debridement, selection of wound dressings and skin substitutes must be determined.

Ideal Properties of Dressings and Skin Substitutes

The ideal properties for wound dressings and skin substitutes have been understood for many years (Pruitt and Levine, 1984; Yannas and Burke, 1980), but differ somewhat for dressings which provide temporary protection to the wound, and therapies which contain or recruit

SIDEBAR 2.5.8.1

Burn injuries vary greatly in etiology, magnitude anatomic location, and depth. Most burns are small in area, and superficial or partial-thickness in depth. These wounds can reepithelialize from the uninjured parts of epidermal glands and follicles, and often do not require hospitalization. Full-thickness burns lack epithelial sources, and usually require grafting of split-thickness skin, or engineered epithelium to accomplish wound closure. Deep burns are known to form thicker scar, which may require reconstructive surgery and additional therapy subsequently to acute hospitalization (American Burn Association, 2017; Stone Ii et al., 2018).

TABLE 2.5.8.1 Ideal Properties of Burn Dressings and Skin Substitutes

Ideal Qualities of Burn Dressings and Skin Substitutes
• Inexpensive
• Single application
• Bacterial barrier/microbicidal
• Semipermeable to water vapor
• Conformable and elastic
• Easy to apply (and remove)
• Reduces pain
• Nonimmunogenic and nontoxic
• Extended shelf life
• Maintains moisture and limits drainage
• Promotes tissue restoration and limits scar

Adapted from Helm, D.L., Orgill, B.D., Ogawa, R., Orgill, D.P., 2013. Burn dressings and skin substitutes. In: Ratner, B., Schoen, F., Hoffman, A., Lemons, J. (Eds.), Biomaterials Science: An Introduction to Materials in Medicine, third ed. Elsevier.

autologous cells and may persist indefinitely. These properties are listed in Table 2.5.8.1, and include: (a) provision of a barrier to environmental microorganisms and fluid loss; (b) adherence; (c) durability to mechanical loading and shear; (d) biocompatibility (i.e., nonimmunogenic, nontoxic); (e) resistance to microbial infection; (f) ease of application and/or removal; (g) reduction of pain; (h) ease of storage and extended shelf life; and (i) cost-effectiveness (Helm et al., 2013; Kempf et al., 2011). Although all dressings and skin substitutes may be considered to stimulate a reaction from the wound, materials containing allogeneic or autologous cells have been shown to deliver biologically active compounds, including growth factors, cytokines, and extracellular matrix peptides. These compounds may stimulate responses that are beneficial to wound healing, such as vascularization and epithelialization, and may inhibit negative responses, such as excessive granulation tissue and scar. In addition, if the dressing or engineered graft is intended to incorporate into the wound, it must also have sufficient porosity and pore fraction to allow rapid vascularization of the material. The variety of materials that are currently available (see Tables 2.5.8.2 and 2.5.8.3) provide a broad spectrum of approaches to wound management from excision and debridement to final closure, restoration of function, and improvement of cosmesis.

Topical Microbial Management

By definition, burn wounds are not sterile, and may be anticipated to become contaminated over time with multiple strains of Gram-negative (e.g., *Pseudomonas* sp.), Gram-positive (e.g., *Staphylococcus* sp.), yeast (e.g., *Candida* sp.), and fungal (e.g., *Aspergillus* sp.) organisms. If microbial contamination develops, it may lead progressively to infection, invasion of the circulatory system, bacteremia, and sepsis. Clinical contamination of burn wounds is defined as 1×10^5 organisms per gram of tissue (Monafo and West, 1990; Pruitt et al., 1998), but virulence of the organisms must also be considered (Gallagher et al., 2012; Church et al., 2006). With these risks, alternatives for topical antimicrobials must be readily available, have broad microbicidal activity and low toxicity to wound tissue, and be relatively cost effective (Sidebar 2.5.8.2). Simultaneous antimicrobial activity and low toxicity to wound tissue will promote more rapid wound closure, and restoration of tissue integrity (Boyce et al., 1995, 1999a,b, 2006, 2017). Silver-containing compounds, such as silver-sulfadiazine cream and silver nitrate solutions have provided a prevailing standard of care for conventional treatment of bacterial and fungal organisms in burn wounds. In addition, mafenide acetate solution (5% Sulfamylon) has high antibacterial activity against Gram-negative bacteria. However, both ionic silver and mafenide acetate have been shown to be highly cytotoxic to skin substitutes that contain cultured cells (Cooper et al., 1991; Boyce et al., 1995, 1999a,b, 2006, 2017). By comparison, dressings that incorporate and release elemental, nanocrystalline silver exhibit lower cytotoxicity, with retention of antimicrobial activity against selected bacterial and fungal organisms. These types of dressings have an advantage that they require less nursing care because they can remain in place without changes for up to 1 week. Limited testing of one of those dressings (Acticoat) showed lower toxicity to engineered skin substitutes with cultured cells, and no impact on engraftment in full-thickness surgical wounds in preclinical studies (Supp et al., 2005).

Simple, inexpensive topical antimicrobials, such as dilute sodium hypochlorite (i.e., 0.5% Dakin's solution) (Lewandowski et al., 2013; Heggers et al., 1991), or dilute hypochlorous acid (0.033% Vashe solution) (Day et al., 2017; Nerandzic et al., 2013) provide broad-spectrum antimicrobial activity with limited cytotoxicity to wounds. These agents act principally by delivery of bacteriocidal concentrations of chlorine to suppress microbial growth. Because these agents are in aqueous solutions, applications must be repeated or dressings changed periodically, but they are widely available. Naturopathic compounds, such

Model	Composition	Indications for Use
Biobrane (Lesher et al., 2011; Arevalo and Lorente, 1999)	Nylon mesh on silicone sheet with collagen coating	Partial-thickness burns and donor sites
Suprathel (Rahmanian-Schwarz et al., 2011; Hundeshagen et al., 2018) Mepitel (Campenella et al., 2011; Gotschall et al., 1998)	Poly-lactic acid fabric Poly-amide net with a soft silicone layer	Superficial and deep dermal partial-thickness burns Partial-thickness burns and grafted full-thickness burns
ActiCoat (Honari et al., 2001; Verbelen et al., 2014)	Nanocrystalline silver on poly-ethylene fabric	Partial-thickness burns, skin graft donor sites, skin graft application sites
Mepilex Ag (Hundeshagen et al., 2018; Barrett, 2009)	Nanocrystalline silver on an absorbent foam fabric	Partial-thickness burns, pressure ulcers, leg and foot ulcers
Aquacel Ag (Haith et al., 2015; Verbelen et al., 2014)	Ionic silver in carboxy-methyl cellulose with an absorbant foam and water-proof surface	Partial-thickness burns, skin graft donor sites, chronic wounds
Cadaver allograft (Kagan et al., 2005; May and Declement, 1981)	Human split-thickness skin, unfrozen or cryopreserved	Partial- and full-thickness burns, reconstructive surgery
Human amnio-chorionic membrane (Reilly et al., 2017; Tenenhaus, 2017)	Dehydrated amnio-chorionic membrane	Partial-thickness burns, chronic wounds and ophthalmic injures
Porcine xenograft (Hermans, 2014; Burkey et al., 2016)	Porcine split-thickness skin, cryopreserved or lyophilized	Burns, reconstructive surgery
Piscine xenograft (Magnusson et al., 2017; Kerecis, 2018)	Fish skin from cod or tilapia	Partial-thickness burns, skin graft donor sites, excised full-thickness burns
Apligraf (Carlson et al., 2011; Bett, 2005)	Allo hF in collagen gel plus stratified allo hK	Diabetic foot ulcers
StrataGraft (Schurr et al., 2009; Centanni et al., 2011)	Allo hF in collagen gel plus stratified allo hK	Deep partial-thickness burns
DermaGraft (Stuart, 2008; Harding et al., 2013)	Allo hF on poly-galactin mesh	Diabetic foot ulcers

TABLE 2.5.8.3 Grafts and Permanent Skin Substitutes

Model	Composition	Indications for Use
Integra dermal regeneration template (Heimbach et al., 1988, 2003)	Lyophilized bovine collagen and chondroitin-sulfate with a silicone outer layer	Excised, full-thickness burns, reconstructive surgery
NovoSorb biodegradable temporizing matrix (Greenwood and Dearman, 2012a,b)	Bilaminate (film on foam) degradable polyurethane	Excised, full-thickness burns, reconstructive surgery
AlloDerm (Jansen et al., 2013; Ellis and Kulber, 2012)	Decellularized cadaveric skin	Reconstructive surgery
MatriDerm (Ryssel et al., 2010a,b)	Native collagen and elastin	Full-thickness burns and skin wounds (not available in United States)
EpiCel (Gallico et al., 1984; Sood et al., 2010)	Sheets of cultured autologous epidermal keratinocytes	Excised full-thickness burns of 30% TBSA or greater
ReCell (Gravante et al., 2007; Wood et al., 2012)	Suspensions of autologous keratinocytes, isolated and sprayed intraoperatively	Partial thickness burns
SkinTE (PolarityTE.com, 2018)	Disaggregated full-thickness autologous skin	Excised, full-thickness burns; and recalcitrant chronic wounds
Autologous engineered skin substitute (Boyce et al., 1995, 1999a,b, 2006, 2017)	Autologous fibroblasts and keratinocytes attached to a degradable collagen-glycosaminoglycan scaffold	Excised, full-thickness burns of 40% TBSA or greater (investigative)
Composite cultured skin (Dearman et al., 2013, 2014)	Autologous fibroblasts and keratinocytes attached to a degradable poly-urethane scaffold	Excised, full-thickness burns (investigative)
Reconstructed skin (Germain et al., 2018; Duranceau et al., 2014)	Autologous fibroblasts and keratinocytes combined without a degradable scaffold	Excised, full-thickness burns (investigative)

SIDEBAR 2.5.8.2

Management of microbial contamination in wounds is pivotal to the accomplishment of timely, stable wound closure. Topical compounds are known to reduce microbial loads, but may also inhibit the beneficial activities of wound healing. Optimal antimicrobial agents deliver specific inhibitory or microbicidal activities that penetrate the wound tissue, and have low cytotoxicity to fibrovascular and epithelial tissues that promote wound closure (Van Langeveld et al., 2017; Gallagher, 2012).

as Manuka honey, have been described as having antimicrobial activity for partial-thickness burns or skin wounds, and activity against organisms that are resistant to conventional antimicrobials (Ranzato et al., 2013; Mullai and Menon, 2007; Cooper et al., 2002). Another mixture of natural ingredients (honey, lanolin, olive oil, wheat germ oil, marshmallow root, aloe vera gel, wormwood, comfrey root, white oak bark, lobelia inflata, glycerin, bees wax, and myrrh) has been formulated by the Amish community as a burn wound ointment (Rieman et al., 2014; Kolacz et al., 2014). Claims of this ointment's medicinal benefits are balanced with disclaimers that the compound "… has not been evaluated by the US Food and Drug Administration …," and that it is "… not intended to diagnose, treat, cure or prevent any disease …." Therefore, use of these kinds of naturopathic compounds for hospital inpatients requires a physician's order.

Application of topical antimicrobials, such as equal parts Neosporin, Bactroban, and Nystatin ointments, and/or parenteral antimicrobials as topical solutions, such as ciprofloxacin (Boyce et al., 1995, 1999a,b, 2006, 2017), satisfy the requirements for low toxicity to grafts with cultured cells, but are off-label uses, and introduce risks of promoting resistant strains of organisms. This important issue deserves additional attention as the field of cellular therapy for burn care continues to advance.

Negative-Pressure Dressings

Wound treatment with subatmospheric pressure has been in practice for more than 20 years, and has demonstrated benefits for inhibition of burn depth progression from partial- to full-thickness wounds (Morykwas et al., 1999; Banwell, 1999). Negative-pressure wound therapy (NPWT) has been reported to facilitate and improve closure of chronic wounds of diabetic, venous stasis, and decubitus origins. More recently, NPWT has been shown to promote healing and early closure of partial-thickness burns, and to secure split-thickness skin grafts to increase engraftment over large wound areas (Kamolz et al., 2014; Nuutila et al., 2018). Although metastudies have suggested no conclusive benefits for closure of partial-thickness burns, it was noted that there have been insufficient numbers of controlled, randomized, prospective clinical trials from which to develop conclusions (Dumville et al., 2014). A more recent review of NPWT in treatment of burns supported the use of negative pressure for securing split-thickness skin grafts in large burns. As more uniform protocols develop for the use and assessment of NPWT in burn care, it is likely that the reported benefits of more rapid healing and less frequent dressing changes may occur with greater frequency in burn care.

Degradable Polymers

As the culture of human epidermal keratinocytes (hK) became practical (Karasek and Charlton, 1971; Rheinwald and Green, 1975; Peehl and Ham, 1980; Boyce and Ham, 1983), it was recognized that combining hK with a dermal substitute might facilitate transplantation of hK for wound closure (Hansbrough and Boyce, 1984). Beginning in the 1970s in Boston, two models of dermal substitutes using xenogeneic collagen were developed (Bell et al., 1981; Yannas and Burke, 1980). As transplantation of hK began to be studied more actively in the 1980s, other biopolymers, such as fibrin, derivatized hyaluronic acid, and elastin from xenogeneic or allogeneic sources became more prevalent (Ter Horst et al., 2018; Idrus et al., 2014; Myers et al., 1997, 2007) in experimental models. These early studies identified the high compatibility of biologically derived polymers, but also identified the limitations of lot-to-lot variability in composition and performance, inconsistent availability due to biologic sources, and degradation by enzymatic mechanisms from tissue inflammation and microbial contamination. Despite these limitations, collagen-based and hyaluronic acid-derived polymers have become commercialized for multiple applications in wound care.

In response to these limitations, fully synthetic biopolymers were studied for cellular transplantation. These included FDA-approved polymers, such as poly-glycolic acid/poly-lactic acid (PGA/PLA) (Harding et al., 2013), poly-caprolactone (PCL) (Mahjour et al., 2015; Augustine et al., 2015), polyethylene-oxide/polybutylene terephthalate (PEO/PBT) (Beumer et al., 1993, 1994), and more recently, poly-urethane (PUR) (Greenwood and Dearman, 2012a,b; Dearman et al., 2013). These materials addressed effectively the variability from biologic sources, and offered degradation by chemical hydrolysis rather than by enzymes that reduce degradation by microbial and cellular activities. However, other limitations, including release of acid from PGA/PLA copolymers, and protracted degradation times of PCL and PUR, have reduced the broad adoption of these kinds of polymers as scaffolds for cell transplantation.

Currently, the number of commercial uses for degradable polymers continues to increase. For treatment of partial-thickness wounds, degradable polymers in combination with allogeneic skin cells have been shown to promote reepithelialization of wounds without the need for excision (Schurr et al., 2009). For excised full-thickness burns, acellular scaffolds of collagen-glycosaminoglycan (i.e., Integra Dermal Regeneration Template), or poly-urethane (Novosorb Biodegradable Temporizing Matrix) can act to attract and guide the development of fibrovascular tissue as a vascularized dermal tissue in preparation for grafting of split-thickness skin autograft (Sidebar 2.5.8.3). It may

SIDEBAR 2.5.8.3

Degradable polymers are often combined with skin cells for delivery to sites of tissue injury or necrosis. Polymer properties that impact survival and integration of transplanted cells include the abilities to vascularize within a few days, and be fully degraded within a few months of transplantation. Current and investigational skin substitutes have been reported to contain degradable polymers from biologic or synthetic sources (Shevchenko et al., 2010; Ulery et al., 2011; Boyce and Lalley, 2018).

be expected that advanced synthetic, or synthetic/biologic blends of polymers (Powell and Boyce, 2009; Kim et al., 2017), will continue to be developed until an optimal composition for temporary or permanent skin substitutes is tested and approved for burns and/or other skin wounds.

Temporary Skin Substitutes

A broad spectrum of materials has become available for partial- and full-thickness burns after consideration of the requirements for optimal wound closure. These materials may be categorized generally into acellular and cellular types with multiple examples in each category. Acellular materials are represented by those without delivery of silver, such as Biobrane, Suprathel, or Mepitel, which have been shown to provide effective protection during reepithelialization of debrided, partial-thickness wounds or donor sites for skin grafts, or as a temporizing dressing for coverage after excision of full-thickness burns (Lal et al., 2000; Rahmanian-Schwarz et al., 2011; Campanella et al., 2011). Biobrane is a nylon mesh bonded to a silicone sheet that is coated with porcine collagen peptides. It is either shed as epithelialization proceeds, or is removed prior to grafting. It is available in nonperforated or perforated formats, the latter to allow drainage, and to avoid suppuration. Suprathel is a poly-lactic acid sheet indicated for partial-thickness burns and donor sites for skin autografts. In a comparative study with OmniDerm, Suprathel recorded lower pain scores, better adherence to wounds, fewer dressing changes, and no differences in time to epithelialization. Mepitel is a silicone rubber dressing that is reported to reduce pain and promote healing of partial-thickness burns in comparison to silver sulfadiazine (Gotschall et al., 1998; Campanella et al., 2011). These kinds of materials can be effective in wounds with low levels of microbial contamination, or clean, surgical wounds.

For partial-thickness wounds that are colonized with microorganisms, silver-containing dressings are often used to limit the progression of wound contamination and to promote epithelial healing. Examples of these kinds of dressings include ActiCoat, Mepitel Ag, and Aquacel Ag (Honari et al., 2001; Choi et al., 2018; Verbelen et al., 2014). Silver-containing materials offer comparable antimicrobial activity to silver sulfadiazine, but with less toxicity to wound tissue and inhibition of wound repair. Advantages of silver-releasing dressings include broad-spectrum coverage, fast-acting reductions of microbial contaminations, and few dressing changes with some silver dressings able to release monocationic silver for up to 7 days. These advantages have contributed to the cost-effectiveness of silver-releasing dressings, and to their increased adoption in burn care.

Although these kinds of advanced dressings have found utility in developed countries, they are not always available or affordable in many developing countries. In those kinds of environments xenogeneic skin substitutes are often more abundant and less costly than banked human skin, or than medicated dressings. Examples of xenografts that have been reported as temporary covers, include but are not limited to porcine xenograft (Hermans, 2014; Busby et al., 2014), fish-derived skin from tilapia or cod (Magnusson et al., 2017; Kerecis, 2018; News, 2017), or banked skin from other animals (e.g., frogs, rabbits, or sheep). Animal xenografts may also present risks of pathogen transfer, such as endogenous retrovirus (Kimsa-Dudek et al., 2015). Potato skins have also been used as a temporary cover for scald injuries (Keswani et al., 1990). In more developed countries, banked cadaveric human split-thickness skin is often available (Kagan et al., 2005; Kagan, 2000), and is used as an effective cover until split-thickness skin autograft is available. Several reports describe the use of human amniochorionic membrane as a temporary skin wound cover, or for wounds with critical impacts such as the eyes (Reilly et al., 2017; Tenenhaus, 2017; Magnusson et al., 2017). Because collection and distribution of human amnion may transmit disease, pathogen testing or sterilization during processing is required to maintain safety for transplantation to vulnerable patients with extensive burns. These kinds of biological dressings are known to deliver growth factors, matrix molecules, and essential nutrients to wounds to promote wound closure, and may have extended benefits if living cells are preserved.

In analogy, engineered skin allografts (i.e., StrataGraft; Apligraf; DermaGraft) offer days to weeks of wound protection for large TBSA partial-thickness burns (Schurr et al., 2009; Cavallaro et al., 1994), or small TBSA full-thickness chronic wounds (Edmonds, 2009; Harding et al., 2013). Engineered allografts may be generated from sterile scaffold materials and cell banks that are tested and determined to be disease free. During fabrication, immune cells and vascular elements from the donor are depleted from these materials which renders them less immunogenic. Although the allogeneic epidermal keratinocytes are immunogenic, they are usually not sufficient to stimulate a robust T-cell-mediated rejection, such as host-versus-graft disease (Hu et al., 2006; Centanni et al., 2011). Rather, these less immunogenic materials either degrade on the wound, or are exfoliated by migrating keratinocytes during reepithelialization of the wound within a few weeks. Definitive advantages of these materials include continuous availability, and consistency of composition due to their fabrication in vitro. These advantages are offset by high cost, needs for multiple applications, and limited benefits in long-term outcomes.

Permanent Skin Substitutes

Long-term durability of wound closure after full-thickness burns requires both restoration of dermal connective tissue, and autologous keratinocytes to restore the natural epidermal barrier. This may be accomplished by several approaches. Conventional treatment of small total body surface area (TBSA), full-thickness burns (e.g., less than 30% TBSA) with split-thickness skin autograft may be accomplished promptly and effectively, but requires harvesting of autologous donor skin. As the wound area increases, donor skin availability decreases, which requires larger expansion ratios for skin autografts up to a typical limit of approximately 1:4. Because open wounds generate granulation tissue which leads to scar (Robson et al., 1992; Porres-Reyes et al., 1991), the time to reepithelialization should be minimized to reduce scar. To address the needs for restoration of dermal connective tissue, and stable epidermal barrier, three categories of permanent skin substitutes have emerged.

Acellular dermal scaffolds have been commercialized to promote the development of a uniform layer of fibrovascular tissue to support and stabilize epidermal substitutes. Manufactured dermal substitutes may be composed of bovine collagen and glycosaminoglycan with a silicone cover (i.e., Integra Dermal Regeneration Template) (Heimbach et al., 2003; Boyce et al., 1995, 1999a,b, 2006, 2017), and recently, degradable poly-urethane (i.e., Biodegradable Temporizing Matrix) (Greenwood and Dearman, 2012a,b; Wagstaff et al., 2017). These materials may be applied to excised burn wounds at the time of excision of eschar to reduce the release of inflammatory cytokines, and the progression of microbial contamination and infection. They require 2 weeks or more to become vascularized sufficiently to support a thin, split-thickness skin graft. Favorable outcomes with these materials have been reported that may reduce long-term morbidity, such as wound contractures, and needs for scar reconstruction. Simultaneous application of a scaffold consisting of bovine collagen and elastin (i.e., MatriDerm) with split-thickness skin autograft has shown improved range of motion and smoother appearance than with meshed and expanded autograft alone (Bottcher-Haberzeth et al., 2012; Ryssel et al. 2010a,b). Similarly, decellularized human dermis (i.e., AlloDerm) or fetal bovine dermis (i.e., PriMatrix) have been described as dermal substitutes together with split-thickness skin autograft for burn reconstruction, and other soft tissue augmentation (Wainwright, 1995; Strong et al., 2016).

Because these acellular scaffolds recruit cells from the recipient wound bed, are slowly degraded, and replaced with recipient extracellular matrix, they may be categorized as "autologous" and "permanent" because the tissue restoration is of indefinite duration. Also, because the tissue restoration is guided by each of these scaffolds in a context of granulation tissue, the resulting anatomy of the fibrovascular tissue is not identical in the uninjured dermis. Therefore, the use of these kinds of dermal substitutes reduces variability of the tissue formation compared to granulation of the wound, and confers a regulatory function that increases the predictability of the outcomes.

After restoration of a highly viable, vascularized wound bed, restoration of the epidermis is required to close the wounds long term. Widely meshed (i.e., 1:6) split-thickness skin autograft was covered with narrowly meshed (i.e., 1:1.5) cadaver skin allograft to protect and promote epithelial coverage, and conserve autologous donor skin (Alexander et al., 1981). For more than 30 years, cultured epithelial autografts (i.e., EpiCel) have been available for wound closure. However, those grafts are known to repeatedly blister and ulcerate, which predisposes them to high morbidity and risks of development of squamous cell carcinoma (Woodley et al., 1988; Kowal-Vern and Criswell, 2005). Suspensions of autologous epidermal keratinocytes (i.e., ReCell) may be prepared intraoperatively, and sprayed on deep, partial-thickness burns, or in combination with meshed, split-thickness skin autograft on excised, full-thickness burns. This approach has shown favorable outcomes, but is limited by the absolute numbers of viable keratinocytes that can be isolated intraoperatively, and by the random distribution of cells by the spraying process (Wood et al., 2012; Gravante et al., 2007). In a similar approach, the population of keratinocytes was increased by expansion in culture, and was applied with a pressurized pneumatic sprayer to facilitate surgical application (Schlabe et al., 2008; Hartmann et al., 2007). Because the culture process may expose the keratinocytes to hazardous compounds or procedures, a more complex path to regulatory approval can result. A recent approach has become available in which a small biopsy of full-thickness skin is collected, sent to a central laboratory, morselized, combined with a viscous vehicle (SkinTE), returned to the hospital in 1–3 days, and applied to prepared, full-thickness acute or chronic wounds (PolarityTE.com, 2018). Because the starting biopsy is full-thickness skin, this model claims to restore all of the anatomy and physiology of uninjured skin. This claim has not yet been well-substantiated, and the approach is also limited in its absolute ability to expand the biopsy. Due to an expedited regulatory pathway, this technology is being commercialized, but has not yet been compared to any standard-of-care treatment in prospective, multicenter studies (PolarityTE.com, 2018).

Autologous dermal–epidermal skin substitutes comprise combinations of dermal fibroblasts and epidermal keratinocytes with or without a degradable scaffold. Similarly to allogeneic models described above (see Temporary Skin Substitutes), skin substitutes containing mesenchymal and epithelial cells can organize into a stratified, keratinized epidermal component, can develop a basement membrane to form a biological bond between the epidermal and dermal substitutes, and a dermal component that can vascularize rapidly due to its porous structure and delivery of angiogenic factors to the wound. These models utilize culture in vitro to expand the cell populations to sufficient numbers to cover skin wounds up to 99% TBSA. This is the essential advantage provided by cultured epithelial autografts, but

this is improved by including a dermal substitute to promote formation of basement membrane, increase the mechanical strength of the material, and facilitate transplantation and attachment to the wound with staples or sutures. Autologous, bilayered models of engineered skin have been described in preclinical (Dearman et al., 2014) and clinical trials (Boyce et al., 1995, 1999a,b, 2006, 2017; Germain et al., 2018), but none is yet available commercially. Outcomes from clinical trials have been favorable in the accomplishment of stable, long-term wound closure, lower mortality in pediatric subjects compared with corresponding populations in the National Burn Repository, and functional range of motion. Similarly to split-thickness skin autograft, the resulting skin does not develop epidermal appendages (hair, sebaceous, or sweat glands), and pigmentation is deficient. These results offer reductions in requirements for donor skin, less long-term morbidity, and improved quality of life in comparison with widely meshed, split-thickness skin autografts. Ongoing research is addressing these deficiencies, and continued progress is expected toward a model of autologous engineered skin with the anatomy and physiology of uninjured skin. Beyond that long-term goal, experimental models that express specific genes or correct gene defects (Dakiw Piaceski et al., 2018; Comer et al., 2014) are under development to restore or enhance normal properties of the skin.

Cost Considerations

In addition to medical and surgical considerations, the relatively high cost of cell therapies requires careful consideration. Depending on the composition and labor intensity of the therapy, unit costs (i.e., per cm^2) for cell therapies can range between US$10–100. If the patient is an adult, and the total body surface area (TBSA) is extensive (e.g., greater than 50%), the total costs for skin substitutes can rise to more than US$100,000. To justify these costs, there must be sufficient reductions in medical risks, such as requirements for time in intensive care, and/or long-term benefits, such as reductions in morbidity, needs for reconstructive surgery, or greater quality of life. These determinations of the cost effectiveness of burn dressings or skin substitutes appear only infrequently in the literature, but may contribute to planning of specifications for wound care, and priorities for long-term outcomes. Two studies (Schiavon et al., 2016; Hop et al., 2014) evaluated the total cost of acute care after use of acellular dermal substitutes, and found no differences in total costs for acute care of burns, but had wide ranges of costs that may have obscured differences attributable to the skin substitutes. Economic considerations must include not only costs for acquisition of the materials, but also procedural time for their application and care until completion of wound closure. Because of the multiple factors that contribute to total cost for use and care of cellular and noncellular burn dressings and skin substitutes, performance of prospective studies and collection of conclusive data are difficult. Together with the fact that cost effectiveness is not required to receive marketing approval or reimbursement, determination of cost effectiveness becomes a secondary priority behind the more immediate needs of patients during acute care of burn wounds.

Regulatory Considerations

The safety and efficacy of skin substitutes are regulated in the United States by the US Food and Drug Administration (FDA). Wound dressings and biologic skin substitutes have increased in complexity from models that protect wounds and release antimicrobials to those that: replace either dermis or epidermis; to dermal–epidermal models; to delivery of combinations of biopolymer scaffolds, multiple cell types or multiple cell sources; to expression of gene products for therapeutic improvements in wound healing (Boyce and Lalley, 2018). This spectrum of unprecedented materials presented questions regarding the regulatory framework within which each model would be evaluated for consideration of permission to market. Traditionally, the FDA has consisted of three centers for evaluation of human therapeutics: the Center for Devices and Radiologic Health (CDRH), the Center for Biologics Evaluation and Research (CBER), and the Center for Drug Evaluation and Research (CDER). Availability of cadaveric allograft has been provided under regulations for tissue banking, which are administered by CBER. As the spectrum of research models of skin substitutes broadened during the 1980s and 1990s, several investigative therapies had components that required review by multiple centers at the FDA. The agency responded proactively with two initiatives that have contributed to greater clarity of the regulatory process, and with Guidances to Industry (US FDA, 1996, 1998, 2006, 2011) on how to propose a path to market.

An early initiative was the FDA's participation in the establishment of definitions and standards for Tissue Engineered Medical Products (TEMPs) through formation of Division IV of Committee F04 for medical devices through the American Society for Testing and (ASTM, 2007) (ASTM) (Materials). Beginning in 1997, this organization has had members from academic institutions, government, and industry participating in a consensus process for composing definitions of materials, and provision of methods for calibration and testing of the materials. With regard to skin substitutes, the ASTM process has resulted in a Standard Guide for Classification of Therapeutic Skin Substitutes (ASTM, 2009), providing consensus definitions and nomenclature. The second initiative was the FDA's establishment in 2002 of the Office of Combination Products, by which investigative therapies are reviewed initially for their *primary mode of action*. This office confers with the Centers for Human Therapeutics to designate new therapies at a lead center at the FDA with participation from other centers as appropriate. Together, these initiatives have added clarity to the assignment of novel therapeutics to a designated regulatory path (Witten et al., 2015). In addition to providing a framework for innovative investigative therapies, the FDA provides "expanded access" or "compassionate use" permissions for treatment of selected conditions

that present high risks of mortality or morbidity to patients (US FDA, 2014c, 2017a).

More recently, the 21st Century Cures Act (Cures Act) was signed into law in the United States in December 2016. As the name implies, this law is intended to facilitate and expedite the availability of novel therapies to patients with serious, or potentially life-threatening, conditions. The Cures Act provides for expedited therapeutic development programs including the Regenerative Medicine Advanced Therapy (RMAT) designation for eligible biologics products, and the Breakthrough Devices program which is designed to facilitate the review of certain innovative medical devices (US FDA, 2016). These new designations by FDA are in addition to previous expedited regulatory pathways of Fast Track development (US FDA, 2017b), Breakthrough Therapy designation (US FDA, 2014a), Accelerated Approval (US FDA, 2014b), and Priority Review designation for drugs (US FDA, 2014d). Together, these alternative pathways to provisional or full marketing are likely to increase access to the most advanced therapies by patient populations with the greatest medical needs.

Conclusions and Future Directions

Future prospects for burn dressings and biologic skin substitutes are extensive and diverse. Advances in the use and regulation of stem cells in skin are highly likely to lead to autologous skin substitutes with greater homology to uninjured skin by providing restoration of skin pigmentation, epidermal appendages (hair, sebaceous and sweat glands), a vascular plexus, nerve, and subcutaneous tissues (Boyce and Supp, 2016; Boyce and Lalley, 2018). Genetic modification of autologous cells opens tremendous opportunities for regulation of wound closure, reductions in scar formation, and correction of congenital diseases (Hirsch et al., 2017; Siprashvili et al., 2016). Balancing with these exciting prospects are economic considerations that often constrain decisions, and favor low-cost alternatives over high-cost technologies. Because these advanced technologies have high costs of product development and acquisition, the relatively small size of the burn market may not be sufficient to support all of these products. Therefore, successful delivery of these kinds of novel therapeutics will be more likely in broader applications than burns alone, or by companies with additional products to subsidize revenue from burns. With effective management of these economic considerations, translation of advanced burn dressings and biologic skin substitutes into clinical care can be predicted with confidence to lead to reductions in morbidity from traumatic injuries and congenital diseases of the skin.

Acknowledgments, Disclosures and Disclaimer

This contribution was supported by grants #85200 and #84050 to Dr. Boyce from the Shriners Hospitals for Children. Dr. Boyce performs paid consulting services that are reviewed and approved by the University of Cincinnati Office of Research. Dr. Boyce is employed by the University of Cincinnati, and has multiple patents that are licensed for development, and may generate royalties or other payments prospectively. Drs. Chang and Warner declare no financial conflicts of interest. Descriptions of commercially available products by the authors are based on published literature, and do not constitute a recommendation for whether or not any of the products are appropriate for specific uses. Chapter Exercises

1. Based on developments in wound dressings and skin substitutes during the past 30 years, what kinds of new products would you expect to see in the next 30 years? Write a one-page summary.
2. Perform one or more literature reviews to extend your perspective beyond this chapter's references. Consider presentation of the review(s) in a journal club or study group.
3. Perform lab exercises (e.g., antimicrobial testing, cell growth, and tissue morphogenesis) to gain experience with basic procedures related to the topics presented in this chapter.
4. Consider arranging a clinical shadowing assignment, independent study course, or internship to gain first-person experience with the subject matter of this chapter.
5. Register for an elective course related to the subject matter of this chapter that is outside of, but complementary to, your major field of study.

2.5.9

Description and Definition of Adhesives, and Related Terminology

Introduction

Description and Definition of Adhesives, and Related Terminology

In the context of biomaterials, adhesion science and technology assume high importance. It is useful to commence with the slightly wider concept of *bonding*. It is evident that many biomaterial devices are structured from multiple components, and these need to retain their mutual integrity during clinical service.

The most challenging issue is the creation of a durable interfacial bond between a biomaterial and its host tissue. In addition to the function of bonding, per se, an adhesive biomaterial may be required to fulfill a *space-filling* role—replacing some or all of any lost natural tissue. A further ideal function of an adhesive is that of *sealing*; that is, the prevention of ingress of other substances through the bonded zone.

Adhesive is a general term, and in specific contexts may be replaced by designations such as cement, glue, paste, fixative, and bonding agent. Some adhesives may be designed to exhibit further functions, such as antibacterial action, delivery of drugs or beneficial ions, such as the antibacterial ion Ag^+ or fluoride (F^-).

The aim of this chapter is to give a sound introduction to the physicochemical and materials science aspects of adhesives, sealants, and sutures, together with a description of current systems utilized in a range of surgical practice. It does not attempt a detailed study of the molecular biological interactions of adhesives.

The Logic of Adhesion Procedures

Our starting point is the existence of *electromagnetic forces* between and within molecules. In addition to the *primary* bond types, *secondary* intermolecular forces include hydrogen bonds and van der Waals bonds, both dipolar and dispersion types. There is a wide variation in the relative strength of these bonds; even weak bonds can have a massive cumulative effect if they are present in a high enough density.

Nevertheless, there is a further topological factor: macroscopically smooth surfaces are often microscopically rough. The actual contact regions between the two solids are restricted to the "mountain peaks," and a major proportion of each total solid area is not in contact and is held apart *beyond* the distance zone over which the interaction energies are significant. The *effective intimate contact area* between the two surfaces is then too small to *directly* realize the potential of the intermolecular forces. It follows that rigid contact between the two solids fails to deliver an appreciable net interaction force. However, there are some exceptions to this outcome when one or more of the contacting solids exhibits plastic flow under mechanical stress. For example, pieces of gold foil may become self-adherent under compressive stress. Similarly, waxes can mutually bond when temperature is raised slightly.

To achieve adhesive bonding in the general case of two rigid solids, such as a tooth enamel surface and an orthodontic bracket, it is necessary to apply a fluid adhesive between them. Moreover, the fluid must be of appropriate chemical formulation to initially wet both surfaces, exhibiting a low *contact angle*. One or both surfaces may have been subjected to some form of pretreatment or *conditioning* with

an *etchant* or *primer* that, inter alia, may have modified the surfaces' porosity. In this case, the adhesive fluid may be drawn into the solid surface layers by capillary action. Capillarity is the process by which fluid and bacteria are carried into the interstices of multifilament fibers.

The presence of a suitable fluid between two solids greatly enhances the potential for intermolecular force interactions at each solid–fluid boundary.

To achieve an adhesive bond zone that is stable against shear forces, it is imperative to convert the adhesive agent from a fluid to a solid. In this process, it is desirable for the adhesive agent to exhibit high dimensional stability in relation to the interface with one or more adherends. There are several physicochemical mechanisms available for achieving adhesive solidification, or *setting*, including:

- Phase transformation on cooling;
- Solvent evaporation;
- Polymerization (and cross-linking) of fluid monomers or oligomers;
- Acid–base reaction.

Phase transformation has not been applied with biomedical adhesives, as the requisite temperatures (normally above 100°C) are beyond the biologically tolerable range. Polymerization of monomer systems is the most widely used approach. However, this is susceptible to *polymerization shrinkage phenomena* and thus stress-development. Acid–base reactions are present in the setting of polycarboxylate and glass–ionomer cements.

The resultant interfacial bonds, generated by the above adhesion strategy, can be analyzed into different micro- or nanostructural contributions. These may include *micromechanical bonds* created by the interlocking of solidified adhesive "tags" (extensions) into surface porosity or roughness of the adherend. Where the microadaptation of the solid adhesive and the adherend remains molecularly intimate, the intermolecular forces can contribute; and where specific primary bonds are generated, especially with metallic adherends, their contribution is significant.

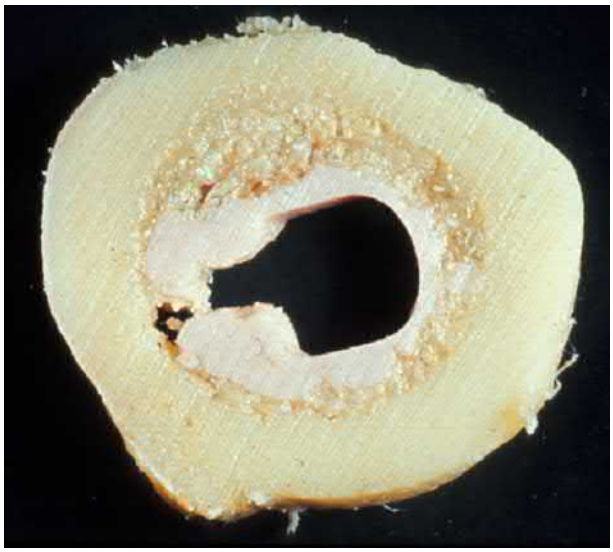
Given the foregoing general scheme of how adhesive bonds can be generated, many of the factors that can weaken or compromise these bonds will be obvious. These include air voids, contaminants, and weak boundary layers.

Hard-Tissue Adhesives: Bone and Tooth Cements

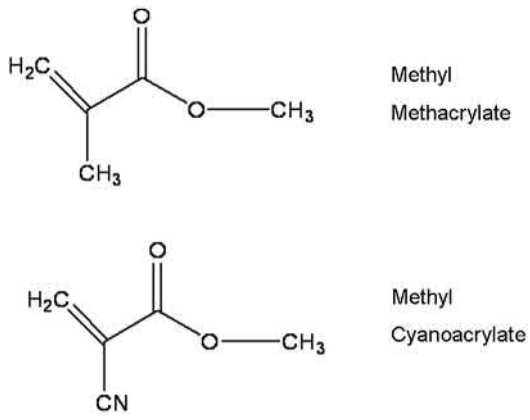
Autopolymerizing PMMA Bone Cement

Historical Background

In 1936 it was noted that mixing ground polymethylmethacrylate (PMMA) powder with its monomer, methyl methacrylate (MMA), produced a doughy material which could be manipulated and molded. Hence, it became one of the first biomaterials (Weber and Chapman, 1984; Donkerwolcke et al., 1998; Kühn, 2000; Webb and Spencer, 2007). The major breakthrough in the use of PMMA/MMA bone cement in total hip replacement (THR) was its use for secure fixation of the acetabular and femoral components to bone, and to transfer loads to bone (Charnley, 1960, 1970) (Fig. 2.5.9.1).



• **Figure 2.5.9.1** Cross-section of femur and interlocking bone cement showing good adaptation of the cement to the prosthesis (now removed), and a zone of interaction with the inner surface of the compact bone. (Courtesy of J. Charnley, personal communication.)



• **Figure 2.5.9.2** Methyl methacrylate and methyl cyanoacrylate.

Mechanism of Setting of PMMA/MMA Dough

MMA liquid (Fig. 2.5.9.2) is rapidly absorbed into PMMA powder, creating a tacky material that progresses to a non-tacky dough stage. These can be considered merely *physical* changes. However, benzoyl peroxide (BPO) initiator, mixed in with the powder, can be chemically activated to form free radicals, either by heating to above 60°C or by the incorporation of a suitable amine activator into the monomer, to enable room temperature autopolymerization or "cold-cure." As activation generates free radicals from BPO, these start to react with the MMA molecules. The free radical polymerization reaction thus continues through the *propagation* stage—where chain growth occurs from multiple radical initiation sites—until this reaches the *termination* stage, where polymerization is either fully complete or the free radicals are consumed. MMA polymerization is a highly exothermic process, arising from the conversion of C═C bonds. Hence, in the constrained intrafemoral environment there is normally a significant temperature rise, which autoaccelerates the setting process, peaking above 56°C for 2–3 min in vivo. Sometimes higher temperatures

TABLE 2.5.9.1 Classification and Composition of Tissue Adhesives

Type	Components	Setting Mechanism
Hard-Tissue Adhesives		
Bone		
Acrylic bone cement	Methyl methacrylate and polymethylmethacrylate	Peroxide-amine initiated polymerization
Teeth		
Dental cements: zinc phosphate	Zinc oxide powder, phosphoric acid liquid	Acid–base reactions; Zn complexation
Zinc polycarboxylate	Zinc oxide powder, aqueous poly(acrylic acid)	Acid–base reactions; Zn complexation
Glass ionomer (polyalkenoate)	Ca, Sr, Al silicate glass powder aqueous poly(acrylic acid-itaconic acid)	Acid–base reactions; metal ion complexation
Resin modified glass ionomer	Dimethacrylate monomers. Aqueous poly(acrylic acid-methacrylate) comonomers. Silicate or other glass fillers	Peroxide-amine or photo-initiated polymerization
Resin-based	Aromatic or urethane dimethacrylates, HEMA	Photoinitiated addition polymerization
Dentin adhesive	Etchant: phosphoric acid (aq.). Primer: HEMA in ethanol or acetone bond. Resin: dimethacrylate monomers	Photoinitiated addition polymerization
Soft-Tissue Adhesives		
Cyanoacrylate	Butyl or isobutyl cyanoacrylate	Addition polymerization
Fibrin sealants	A. Fibrinogen, factor XIIIB. Thrombin, $CaC1_2$	Fibrin clot formation
GRF glue	Gelatin, resorcinol, formaldehyde	Condensation polymerization
Hydrogel	Block copolymers of PEG, poly(lactic acid) and acrylate esters	Photoinitiated addition polymerization

are reached, up to 90°C, which can volatilize unreacted monomer (the boiling point of MMA is 101°C). This creates voids that can later lead to mechanical failure.

Mechanism of "Bonding" or Grouting

As the cement flows under pressure to penetrate the interstices of cancellous bone and adapts to the surface of the femoral stem, it can achieve microinterlock with the bone when solidified. Nevertheless, PMMA bone cement undergoes a degree of shrinkage on polymerization. Hence another benefit of pressurized injection is partial compensation for this effect. Shrinkage is a potential major source of porosity (Gilbert et al., 2000).

Alternative Bone Cements: Calcium Phosphate

In orthopedic surgery there are some alternatives to PMMA bone cement, and there is also the option of cementless fixation. Inorganic cements, notably from the Ca–P system, include hydroxyapatite (HA) [$Ca_{10}(PO_4)_6OH_2$] and tricalcium phosphate (TCP) [$Ca_3(PO_4)_2$]. The biocompatibility of HA and its similarities to bone mineral have led to the study of dense HA for the augmentation of osseous defects.

Classical and Modern Dental-Bonding Cements: Conventional Acid–Base Cements

Dental cements are, traditionally, fast-setting pastes obtained by mixing solid and liquid components. Most of these materials set by an acid–base reaction, and subsequently developed resin cements harden by polymerization (Smith, 1971, 1991, 1998). The composition of these materials is shown in Table 2.5.9.1. The classes and typical mechanical properties are given in Table 2.5.9.2. The relationship between principal categories is illustrated in Fig. 2.5.9.3.

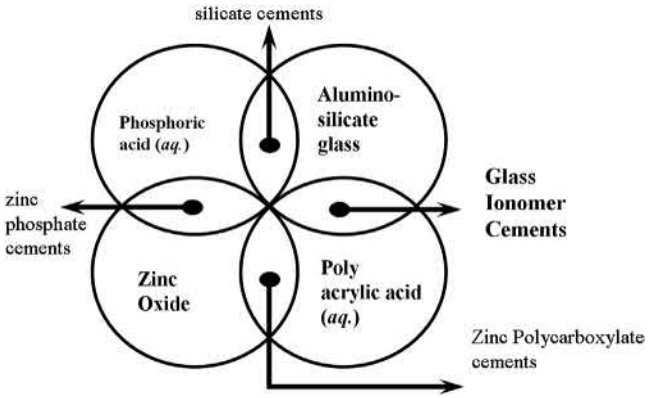
Zinc phosphate cement is the traditional standard. This material is composed primarily of zinc oxide powder and a 50% phosphoric acid solution containing aluminum and zinc. The mixed material sets to a hard, rigid cement (Table 2.5.9.1) by formation of an amorphous zinc phosphate binder. Although the cement is gradually soluble in oral fluids and can cause pulpal irritation, it is clinically effective over 10–20-year periods. The bonding arises entirely from penetration into mechanically produced irregularities on the surface of the prepared tooth and the fabricated restorative material. Some interfacial leakage occurs because of cement porosity and imperfect adaptation, but this is usually acceptable since the film thickness is generally below 100 μm.

Polyelectrolyte Cements: Zinc Polycarboxylates and Glass Ionomers

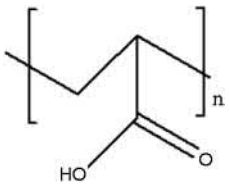
Poly(carboxylic acid) cements were developed in 1967 (Smith, 1967, 1998) to provide materials with properties comparable to those of phosphate cements, but with adhesive properties similar to those of calcified tissues. Zinc polyacrylate (polycarboxylate) cements are formed from zinc oxide and aqueous poly(acrylic acid) solution (Fig. 2.5.9.4). The metal ion cross-links the polymer structure via carboxyl groups, and other carboxyl groups form

TABLE 2.5.9.2 Properties of Dental Cements and Sealants

Dental Cement/Sealant	Strength		Elastic Modulus (GPa)	Fracture Toughness ($MN^{-1.5}$)
	Compressive (MPa)	Tensile (MPa)		
Zinc phosphate	80–100	5–7	13	~0.2
Zinc polycarboxylate	55–85	8–12	5–6	0.4–0.5
Glass ionomer	70–200	6–7	7–8	0.3–0.4
Dimethacrylate sealant unfilled	90–100	20–25	2	0.3–0.4
Dimethacrylate sealant filled	150	30	5	–
Dimethacrylate cement	100–200	30–40	4–6	–
Dimethacrylate composite	350–400	45–70	15–20	1.6



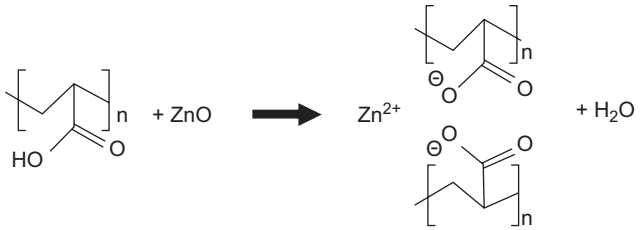
• **Figure 2.5.9.3** Classification of major types of acid–base dental cement based upon the combinations of basic powders of either zinc oxide or alumino-silicate glass with two aqueous acidic liquids.



• **Figure 2.5.9.4** Structure of the polyelectrolyte:poly(acrylic acid), as present in aqueous solution, in polycarboxylate and glass ionomer cements. The carboxyl anions COO^- are bridged by divalent or trivalent metal ions during the setting process, forming a salt matrix.

complexes with calcium ions on the surface of the tissue (Fig. 2.5.9.5). The zinc polycarboxylate cements have adequate physical properties, excellent biocompatibility with teeth, and proven adhesion to enamel and dentin (Smith, 1991), but they are opaque. The need for a translucent material led to the development of the glass–ionomer cements (GIC).

GICs are also based on poly(acrylic acid) or its copolymers with itaconic or maleic acids, but utilize a calcium aluminosilicate glass powder instead of zinc oxide. GICs set by cross-linking of the polyacid with calcium and aluminum ions from the glass, together with formations of

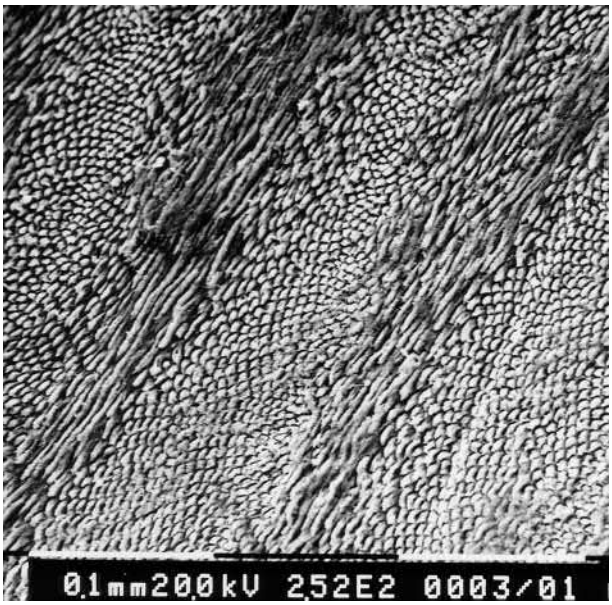


• **Figure 2.5.9.5** Neutralization of poly(acrylic acid) by zinc oxide to form zinc polycarboxylate cement, in which Zn^{2+} functions as a bridging ion between pairs of carboxylate groups, concurrently with ionic salt bridges with metal ions derived from an ion-leachable glass.

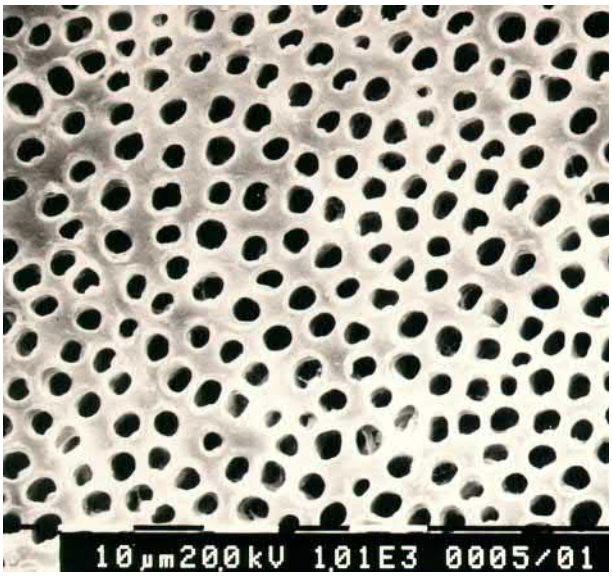
a silicate gel structure. The set structure and the residual glass particles form a stronger, more rigid cement (Table 2.5.9.1), but with similar adhesive properties to the zinc polyacrylate cements. Both cements are widely used clinically.

Acid-Etch Bonding to Enamel

Dental enamel is a hard, stiff substrate of generally uniform chemical composition. Bonding to enamel is required either in conjunction with bonding to dentin, for cavity restoration, or for bonding veneers or orthodontic brackets directly to the enamel of teeth in the upper or lower dental arch. In both cases, the modern approach was pioneered by Buonocore (Roulet and Degrange, 2000; Eliades et al., 2005). This involves conditioning with an aqueous phosphoric acid etchant for about 60 s. Subsequent water-rinsing and air-drying leaves a visibly matte surface on the enamel that is now differentially etched, with either the enamel-prism cores or the prism peripheries exposed (Fig. 2.5.9.6). Application of an unfilled resin (monomer mixture) or a moderate-viscosity resin-composite allows this to flow across the enamel, penetrating surface porosity. Subsequent hardening of the resin results in its retention via a multitude of microscopic tag-like resin extensions into the enamel surface.



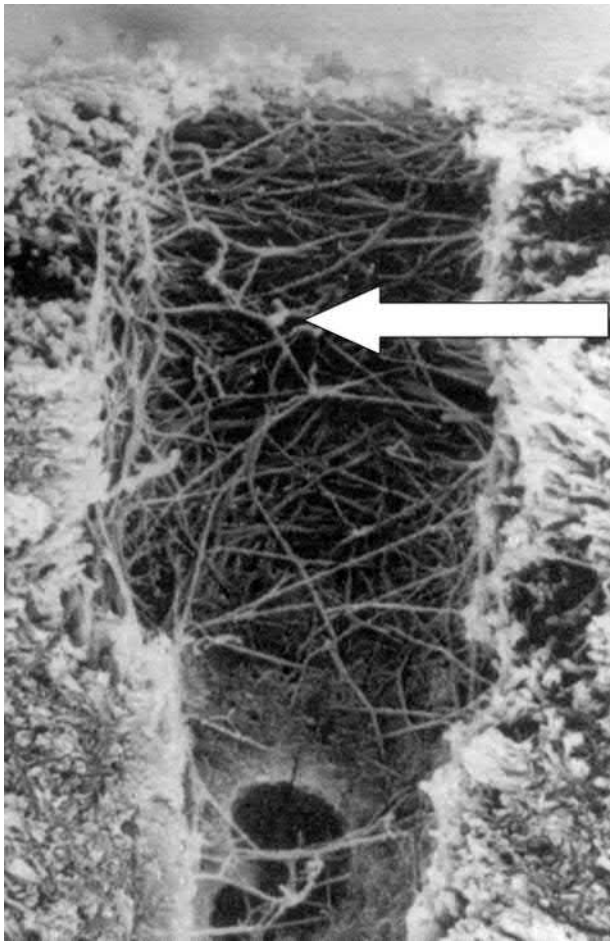
• **Figure 2.5.9.6** Surface of acid-etched dental enamel. In this image, there are alternating regions where the bundles of prism structures are viewed: (1) transversely (end-on); or (2) semilongitudinally. In the case of the transverse prisms, the prism peripheries have been preferentially etched, leaving the prism cores visible.



• **Figure 2.5.9.7** Dentin surface following etching with phosphoric acid solution. The dentin tubules are clearly visible.

Chemistry of Etchants, Primers, and Bonding Agents

Modern effective dentin bonding systems can be considered as incorporating a threefold set of agents, although two or even three of these functions may be combined in a simplified system. The *etchant* or *conditioner* function is provided by either an aqueous phosphoric acid gel or by acidic monomers. The *primer* function is classically achieved by a solution of a hydrophilic monomer, such as hydroxyethyl methacrylate (HEMA), in a solvent such as acetone or ethanol. Subsequently, a "*bonding agent*" consisting of unfilled resin monomers is applied to the dentin.



• **Figure 2.5.9.8** Cross-section of acid-etched and demineralized dentin. The collagen fibrils are visible (*arrowed*) within a tubule.

Hybrid-Layer Creation Via A Three-Stage Approach: Etch, Prime, Bond

The optimal approach is to use a separate acid etchant, and to apply this to the dentin for about 10 s, which removes the smear layer (Fig. 2.5.9.7). This demineralizes the outer dentin layers, leaving residual type I collagen fibrils and proteoglycans. Washing the dentin removes the acid and salt residues. However, drying results in collapse or compaction of the collagen. The second agent, the primer, has the role of reexpanding the collagen, thereby restoring its porosity (Fig. 2.5.9.8). This permits the third agent—unfilled hydrophobic "bond" monomers—to permeate and seal the collagen. When these are photo-cured they form an entangled interpenetrating polymer network (IPN) with the collagen fibers. The resultant interfacial IPN region, typically 4 µm in thickness, is known as the hybrid zone. Effectively, the polymerized resin is taking the place of the original mineral phase in this region. The strength of this bonding zone depends on the continuing integrity of its component elements, principally the collagen fibrils and the polymerized monomers.

Aging and Stability of the Bonded Interface

When properly applied, good adaptation and bonding of the adhesive and restorative material to dentin can be achieved in the short and medium term. Also, a good initial seal of the interfacial zone can be achieved. However, a number of potential weaknesses have been identified (Breschi et al., 2008).

1. *Insufficient resin impregnation of dentin:* There are circumstances where the demineralized collagen is not fully supported by infiltrated resin, leaving a mechanically weak zone.
2. *High permeability of the bonded interface:* The hybrid zone is susceptible to "nano-leakage" by small molecules and ions, which may provide a pathway for degradation reactions over time.
3. *Suboptimal polymerization:* The efficiency of polymerization of the infiltrated monomer may be compromised by the presence of water and dissolved oxygen, thereby weakening the IPN structure.
4. *Phase separation*: Monomer mixtures in situ of varying hydrophilicity may spontaneously phase separate upon polymerization.
5. *Activation of endogenous collagenolytic enzymes:* Recent studies have revealed that dentin matrices may be slowly degraded over time by dentin-derived proteolytic enzymes, particularly matrix metalloproteinases (MMPs). Collagen integrity within the hybrid layers may be promoted by incorporation of chlorhexidine, an antibacterial agent with MMP-inhibiting properties.

Inhibitors for the Preservation of the Hybrid Interfacial Zone Between Adhesives and Human Dentin

The outstanding resistance of the collagenous dentin matrix against thermal and proteolytic disruption has been attributed to the high degree of intermolecular cross-linking and tight mechanical weave of this specialized connective tissue. However, great attention to the potential proteolytic activity of dentin has been raised since complexed and active forms of matrix metalloproteinases (MMPs) were identified in either nonmineralized or mineralized compartments of human dentin. MMPs belong to a group of zinc- and calcium-dependent enzymes that have been shown to be able to cleave native collagenous tissues at neutral pH in the metabolism of all connective tissues. Galardin is a synthetic MMP-inhibitor with potent activity against MMP-1, -2, -3, -8, and -9. It also partially preserved the mechanical integrity of the hybrid layer created by a two-step etch-and-rinse adhesive after artificial aging (Breschi et al., 2010).

Soft-Tissue Adhesives and Sealants

Performance Requirements

Most soft-tissue adhesives are intended to be temporary. On wound surfaces that are wet with tissue fluid or blood, the adhesive must be able to be spread easily on such a surface, provide adequate working time, develop and maintain adhesion, preferably provide hemostasis, facilitate wound healing, and maintain biocompatibility. Positive antimicrobial action would be an additional advantage (Ikada, 1997).

Historical Overview

Few, if any, systems comply with all these requirements. Currently, there are two principal systems in widespread clinical use: cyanoacrylate esters and fibrin tissue adhesives. An important development by Messersmith and co-workers (Brubaker et al., 2010) has led to the synthesis of branched polyethylene glycol (PEG) cores with end groups derivatized with catechol, a functional group abundant in mussel adhesive proteins.

The Relationship Between Soft-Tissue Adhesion and Drug Delivery

Soft-tissue adhesives are not only required for surgical wound healing, but also for the controlled delivery of drugs to specific sites, of which the mucosal membranes are particularly suitable. The process of mucoadhesion involving a polymeric drug-delivery platform is a complex one that includes wetting, adsorption, and interpenetration of polymer chains among various other processes. The success and degree of mucoadhesion bonding are influenced by various polymer-based properties, such as the degree of cross-linking, chain length, and the presence of various functional groupings. The evolution of mucoadhesive formulations has developed from first-generation charged hydrophilic polymer networks to more specific second-generation systems based on lectin, thiol, and various other adhesive functional groups (Andrews et al., 2009).

Cyanoacrylate Esters

Chemistry

These esters are fluid, water-white monomers that polymerize rapidly by an anionic mechanism in the presence of weak bases such as water or NH_2 groups. Initially, methyl (Fig. 2.5.9.2), isobutyl, and n-butyl were used. However, 2-octyl cyanoacrylate gained FDA approval in the United States in 1998 (FDA, 1998). Prior formulations of cyanoacrylates such as n-butyl had shorter chain polymers and as a result were more brittle compared to the longer and more flexible polymer chains of 2-octyl cyanoacrylate (Singer et al., 2008; Bouten et al., 2014). The higher chain length cyanoacrylates spread more rapidly on wound surfaces, and polymerize more rapidly in the presence of blood. Furthermore, they degrade more slowly over several weeks, in contrast to methyl esters, which hydrolyze rapidly and yield formaldehyde. This process causes an acute inflammatory response.

Performance

These materials achieve rapid hemostasis, as well as a strong bond to tissue. However, the polymer film is somewhat brittle even in its newest formulations and can be dislodged on mobile tissue. To help reinforce the

wound–adhesive interface, polymer meshes have been used to increase the stability and strength of the wound closure (Ethicon, 2017).

The current uses of these cyanoacrylate ester materials are as a surface wound dressing in nearly all areas of surgery, especially in periodontics, and in life-threatening applications such as brain arteriovenous malformations. Reports of sarcomas in laboratory animals (Reiter, 1987) and evidence of in vitro cytotoxicity (Ciapetti et al., 1994) blocked N-butyl cyanoacrylate and prior formulations from regulatory approval, but 2-octyl cyanoacrylate has been approved for use in the United States via its improved toxicity profile (FDA, 1998).

Fibrin Sealants

Formulation, Presentation, and Setting Processes

Fibrin sealants involve the production of a synthetic fibrin clot as an adhesive and wound-covering agent. The concept of using fibrin dates back to 1909; the first available commercial materials consisted of two solutions that are mixed immediately before application to provide a controlled fibrin deposition (Matras, 1972). Later a "ready-to-use" formulation (Tisseel Duo) was introduced (Schlag and Redl, 1987). The essential components of these solutions are as follows:

Solution A:	**Solution B:**
Fibrinogen	Thrombin
Factor XIII	$CaCl_2$

The fibrinogen concentration in these sealants is much higher (~70 mg/mL) than that in human plasma. On mixing the two solutions, using a device such as a twin syringe with a mixing nozzle, a reaction similar to that of the final stages of blood clotting occurs. Polymerization of the fibrinogen to fibrin monomers and a white fibrin clot is initiated under the action of thrombin and $CaCl_2$. Aprotinin, an inhibitor of fibrinolysis, may also be included in solution A. The composition may be adjusted to promote hemostasis, for example, or to minimize persistence of the clot to avoid fibrosis.

Advantages and Applications

Originally developed during World War II to stop bleeding from battle injuries, fibrin sealants are presently used during surgery for several different purposes:

- to control bleeding in the area where the surgeon is operating;
- to speed wound healing;
- to seal off hollow body organs or cover holes made by standard sutures;
- to provide slow-release delivery of medication to tissues exposed during surgery.

The adhesive strength is not as high as that of cyanoacrylates, but it is adequate for many clinical situations. Thorough mixing of the ingredients, and application techniques or devices that allow uniform spreading, are both essential to success.

These materials have been used in a wide variety of surgical techniques for hemostasis and sealing: trauma, thoracic, cardiovascular, general, neurosurgical, orthopedic, plastic, and ophthalmic surgery, and as a biodegradable adhesive scaffold for meshed skin grafts in burn patients (Sierra and Salz, 1996; Ikada, 1997; Feldman et al., 1999).

TABLE 2.5.9.3 Characteristics of Soft-Tissue Adhesives

Property	Cyanoacrylate	Fibrin Glue	GRF
Ease of application	Poor	Excellent	Poor

Toxicity	Medium	Low	High
Resorbability	Poor	Good	Poor
Cell infiltration	Poor	Excellent	Poor

After Ikada, Y., 1997. Tissue adhesives. In Chu, C.C., von Fraunhofer, J.A., Greisler, H.P. (Eds.), Wound Closure Biomaterials and Devices. CRC Press, Boca Raton, FL, pp. 317–346.

Attempts to modify fibrin sealants have been directed toward: (1) improvements in their ease of application and control of setting by use of a one-component light-activated product (Scardino et al., 1999); (2) improvements in strength and performance by addition of fibrillar collagen (Sierra and Salz, 1996); and (3) development of a formulation containing gelatin (Ikada, 1997). A summary of sealant characteristics appears in Table 2.5.9.3 (Ikada, 1997). Gelatine-Resorcine-Formaline (GRF) adhesives show excellent tissue bonding, but their ease of application, resorbability and cell infiltration are poor and their toxicity is high.

Bioadhesives

Bioadhesives are involved in cell-to-cell adhesion, adhesion between living and nonliving parts of an organism, and adhesion between an organism and foreign surfaces. Adhesives produced by marine organisms, such as the barnacle and the mussel, have been extensively investigated over the past 40 years because of their apparent stable adhesion to a variety of surfaces under adverse aqueous conditions. Studies have shown that these organisms secrete a liquid acidic protein adhesive that is cross-linked by a simultaneously secreted enzyme system. The bonding likely involves hydrogen bonding and ionic bonding from the acidic groups (Waite, 1989).

The adhesive from the mussel has been identified as a polyphenolic protein, molecular mass about 130,000 Da, which is cross-linked by a catechol oxidase system in about 3 min. The basic unit of the polyphenolic protein has been identified as a specific decapeptide (Waite, 1989; Green, 1996). Recombinant DNA technology and peptide synthesis have been used in attempts to produce an affordable adhesive with superior properties.

Hydrogel Sealants

Hydrogels are formed by in situ deposition of aqueous formulations based on specialized dendritic macromolecules, followed by photopolymerization to highly cross-linked structures.

The macromers are reactive block copolymers consisting of a water-soluble core, such as polyoxyethylene, flanking biodegradable oligomers such as poly(lactic acid) or poly(trimethylene carbonate), and polymerizable end caps such as acrylate esters (Sawhney et al., 1993). Control of the physical properties and degradation rates is achieved by specifying the molecular structures and concentration of the reactants in the formulation (Dai et al., 2011). Photopolymerization can be effected by ultraviolet or visible light using appropriate photoinitiators. Typically, the initiator system eosin Y spirit-soluble (EYss)/triethanolamine (TEA) is employed with visible illumination in the 450–550 nm range.

In most applications for these hydrogels, strong bonding to tissue is required. This is achieved by use of a two-part sealant system consisting of primer and topcoat. Strong, durable bonding to a wide variety of internal tissues has been demonstrated (Coury et al., 1999).

New Research Directions: Biomimetic Approaches

Where relatively temporary (less than 30 days) adhesion is required, as in wound healing, systems based on natural models that allow biodegradation of the adhesive and interface, and subsequent normal tissue remodeling, appear to merit further development.

For longer term (years) durability in both soft and hard tissues, hydrophilic monomers and polymers of low toxicity that can both diffuse into the tissue surface, and form ionic bonds across the interface, seem to be a promising approach. The need for hydrophobic–hydrophilic balance in adhesive monomer systems has been demonstrated (Nakabayashi and Pashley, 1998), and the use of hydrophilic monomers such as hydroxyethyl methacrylate in commercial materials has facilitated surface penetration.

A promising development for hydrogels inspired by mussel adhesives has been described by the Messersmith group (Brubaker et al., 2010). Rather than using natural polypeptides, the synthesis of catechol-terminated polyethylene glycol (cPEG) solutions allows a hydrogel to be formed in about 30 s. Upon implantation, the cPEG adhesive elicited minimal acute or chronic inflammatory responses in C57BL6 mice, and maintained an intact interface with supporting tissue for up to 1 year. In situ cPEG adhesive formation was shown to efficiently immobilize transplanted islets at the epididymal fat pad and external liver surfaces, permitting normoglycemic recovery and graft revascularization. These findings establish the use of synthetic, biologically inspired adhesives for islet transplantation at extrahepatic sites. Another significant development has been the use of PEG-based structures to make smart functional biomaterials (Tirelli et al., 2002; Park et al., 2003).

Finally, a major biomimetic initiative is the creation of self-healing polymer composites (Trask et al., 2007). Many materials in nature are themselves self-healing composite materials. So far this research has been mainly directed toward structural materials (Brown et al., 2005a,b), but it is a short step to apply these concepts and designs to the structural adhesives being designed for hard-tissue bonding.

Sutures

Genesis and Common Uses

A suture, by definition, is any strand of material that is used to ligate (tie) blood vessels or approximate tissue. The word suture, derived from the Latin *sutura*, means *to sew*. The earliest examples of this technology can be traced back thousands of years, when Egyptians, Indians, and other early suture developers used readily available materials, such as silk, linen, cotton, horsehair, and animal tendons and intestines. Currently, sutures comprise the largest portion of wound closure technologies, with the yearly market for sutures approaching a billion dollars in the United States alone.

The suture device is comprised of: (1) the suture strand; (2) the surgical needle; and (3) the packaging material used to protect the suture and needle during storage.

Description of Surgical Sutures

The suture is comprised of three distinct components: suture, needle, and packaging. Table 2.5.9.4 further describes each component, along with example permutations. The major distinguishing factor in suture strands is the absorbability of the suture. Absorbable (occasionally denoted resorbable, biodegradable, or erodible) materials are those which undergo a chemical degradation. In suture materials, this is most commonly the result of hydrolysis or enzymatic degradation. Currently, absorbable sutures maintain measurable strength for 6 months or longer. Absorbable sutures lose strength long before losing mass; it may take months or years after the suture loses strength to fully absorb.

Suture is manufactured in many sizes, and is selected by the surgeon based on a number of factors, including: surgical site; patient age and weight; immune history and response; presence of disease or infection; and personal history with suture materials (Ethicon, 2001). Size is based on diameter, as defined in the *United States Pharmacopeia* (USP) (Table 2.5.9.5), and often materials will exhibit slightly different performance characteristics based on size. Monofilament sutures exhibit lower tissue drag compared to braided multifilament sutures. However, many materials having high modulus and stiffness are not compliant enough to be useful as monofilament. Also, any defect caused during handling can create a weak region in the suture strand. For these reasons, multifilament braided

TABLE 2.5.9.4 Components and Permutations of the Suture Device

Component	Description and Permutations
Suture strand	Component of device that provides securement, only part of device that remains in tissue after implantation: • absorbable or nonabsorbable • sized according to USP[a] or EU[b] guidelines • braided or monofilament • coated or uncoated • natural or dyed
Needle	Component of device that pulls suture through tissue: • size is based on suture diameter • taper point, cutting, spatula, specialty • straight, ¼ circle, 3⁄8 circle, ½ circle, 5⁄8 circle, compound curved • coated or uncoated • swaged or rolled
Packaging	Component that provides a sterile barrier for storage and maintains storage conditions: • Tyvek® or foil • single suture or multipack • dry or with plasticizing fluid • plastic or paper folder

sutures were created. As a combination of fibers with much smaller diameter, relatively stiff materials in a composite structure have a perceived compliance much lower than material properties would suggest. Although multifilament technology allows the creation of suture from relatively stiff materials, there are possible drawbacks to this design. Void space in the braid creates capillarity, and thus potential areas to harbor bacteria. Increased surface roughness associated with a braided construction can cause damage to the implant site due to increased tissue drag. To counteract this tissue drag and to increase lubricity, almost all braided and a few monofilament sutures are coated. Additionally, sutures are supplied as either natural or dyed to increase visual contrast. Table 2.5.9.6 identifies many of the most common sutures and examples of manufacturers.

Needles are supplied in a variety of shapes, each of which is suited to certain applications. Needle and suture are connected at the end of the needle, which can be attached mechanically by swaging, or attached using an eyed needle. The basic needle description includes shape and point geometry (Table 2.5.9.7 and Fig. 2.5.9.9). Needle shapes include straight, curved (described as a fraction of a circle), and compound curved. Fig. 2.5.9.10 provides an illustration of a curved needle, along with pertinent dimensional descriptions. The ideal needle is inert, as slim as possible without compromising strength, stable when held in the needle holder, sharp enough to penetrate tissue with minimum material resistance, rigid enough to not allow bending, ductile enough to not break during use, sterile, and corrosion resistant (Ethicon, 2001).

The primary purpose of the suture package is to maintain sterility during storage.

Surgical Gut Sutures

Gut sutures are primarily derived from bovine intestinal serosa, but also from the submucosa of sheep or goat intestine. The base material is primarily collagen, and requires purification and strengthening before it is suitable as a suture. After harvesting, the material is cleaned, cut into ribbons, and processed with a dilute formaldehyde solution. This increases strength and slows the degradation rate by modifying the activity of the end groups of the collagen (Chu, 1997a). The fibers are ground and polished to create the final suture diameter. Natural (or plain) gut suture is now ready for packaging. Chromic gut sutures are further processed by tanning in the presence of chromium salts, which slows the rate of degradation (Chu, 1997a).

The suture is sized by centerless grinding, in which two grinding wheels remove material around the diameter of the suture. Due to the grinding process, fibrils at the strand surface can be damaged, which can lead to weak points and inconsistent strength. Also, the fiber is easily frayed during tying (Benicewicz and Hopper, 1990). Since gut sutures are a naturally derived material, there are slight inconsistencies in performance, including initial strength and strength retention profile. Coating gut sutures to lower their friction coefficient and propensity to fray was described by Totakura and Shalaby (1997a,b). Gut sutures can be sterilized by irradiation or ethylene oxide gas permeation.

TABLE 2.5.9.7 Common Suture Needles

Type and Description
Taper point: Circular cross-section gradually increasing in diameter from the point to the needle body
Conventional cutting: Triangular cross-section at the needle tip to provide cutting edges, allowing easy penetration into the tissue, which gradually transitions to a square needle body. One cutting edge is on the inside curvature of the needle
Reverse cutting: Triangular cross-section at the needle tip to provide cutting edges. Flat surface on the inside curvature of the needle to minimize risk of needle tearing through the tissue
Hemo seal: Tapered suture at needle-suture interface allows for thinner needle. Decreased size of needle and 1 to 1 ratio of needle to suture allows for decreased blood loss due to trauma of needle insertion.

• **Figure 2.5.9.10** Anatomy of a curved suture needle.

Silk Sutures

Silk suture is a protein fiber typically derived from the *Bombyx mori* silkworm (Chu, 1997a). The silk is stripped of its natural waxes and gums, and braided or twisted to construct the suture thread. As with all braided sutures, it is coated. Typically, this is in the form of a beeswax-based coating or, in some cases, a siloxane-based coating. Successful efforts to substitute the highly tissue-reactive beeswax-based suture with practically nonreactive synthetic polyesters led to the development of a low-reactivity silk suture which can be made antimicrobial (Nagatomi et al., 2008). Although silk is not considered an absorbable suture, the strand loses strength and mass after implantation (Van Winkle and Hastings, 1972; Stashak and Yturraspe, 1978; Benicewicz and Hopper, 1990). This material is broken down by proteolysis, and is typically undetectable after 2 years (Lai et al., 2009). Silk sutures can be sterilized by irradiation and/or ethylene oxide gas permeation.

TABLE 2.5.9.8 Repeat Units for Common Synthetic Nonabsorbable Sutures

Monomer Names	Repeat Unit Structure	Homopolymer
Ethylene	$[CH_2–CH_2]_n$	Polyethylene (PE)
Propylene	$[CH(CH_3)–CH_2]_n$	Polypropylene (PP)
Hexamethylene diamine and adipic acid	$[CO–(CH_2)_4–CO–NH-(CH_2)_6–NH]_n$	Nylon-6,6
Caprolactam	$[CO–(CH_2)_5–NH]_n$	Nylon-6
Ethylene terephthalate		Polyethylene terephthalate (PET)

Polyester Sutures

Nonabsorbable polyester sutures are made from polymers such as poly(ethylene terephthalate) (PET), which is produced by a condensation reaction. This involves condensation of a dialcohol and terephthalic acid or an ester of terephthalic acid. The repeat unit of PET is shown in Table 2.5.9.8. PET is extruded into multifilament fibers and braided into suture. Polyester sutures are sterilized mostly by gamma irradiation.

Nylon Sutures

The polyamides Nylon-6 and Nylon-6,6 are both used as suture materials. Structures for both repeat units are shown in Table 2.5.9.8. Nylon sutures are made into braided or monofilament sutures, although the monofilament sutures may not tie as well, and require additional knots to secure them (Stashak and Yturraspe, 1978; Bellenger, 1982; Guttman and Guttman, 1994). To counteract this, monofilaments can be packaged with a plasticizing fluid to soften them for improved handling (Capperauld and Bucknall, 1984). Although nylon is a nonabsorbable suture, the amide bond is susceptible to hydrolysis and can lose strength over time (Chu, 1997a). Nylon sutures are sterilized by gamma irradiation.

Polypropylene Sutures

Polypropylene can be made with an atactic, isotactic, or syndiotactic chain conformation. Material used for suture

applications is practically isotactic, with an intermediate density. Polymerization is accomplished by polymerization from propylene monomer using a Zeigler-Natta catalyst; the repeat unit can be seen in Table 2.5.9.8. Polypropylene sutures elicit very low tissue response, and are not susceptible to hydrolysis. These sutures can also be difficult to tie securely, due to the smoothness and lubricity of the suture strand (Stashak and Yturraspe, 1978; Bellenger, 1982; Guttman and Guttman, 1994). Polypropylene is easily melt-extruded into monofilament or multifilament yarn, and is well-suited for the production of monofilament suture. Polypropylene sutures are usually sterilized by ethylene oxide, and occasionally by high-energy radiation.

Ultrahigh-Molecular-Weight Polyethylene (UHMWPE) Sutures

Ultrahigh-molecular-weight polyethylene (UHMWPE) suture (structure seen in Table 2.5.9.8) was introduced in the early 2000s; these ultrastrong sutures are 10–100 times stronger by weight than steel. As opposed to other synthetic suture materials, which exhibit about 40% crystallinity, UHMWPE can obtain crystallinity of greater than 85%, and can be highly oriented. The high molecular weight prevents the use of melt extrusion. Therefore, gel spinning techniques are employed to create the multifilament fibers. Gamma irradiation weakens this suture; for this reason they are sterilized by ethylene oxide (Deng et al., 1996).

Ultrahigh-strength sutures are much stronger than standard ones, and a smaller size will have a similar breaking load to that of a larger size standard suture. This allows the surgeon to use a smaller diameter suture for the same application, leaving less foreign material in the implant site. The inherent lubricity of the material results in increased tendency to slip compared to polyester sutures (Barber et al., 2009).

In addition to sutures made of only UHMWPE, there are several composite sutures that are prepared by braiding UHMWPE with PET, nylon, or other materials. Textures imparted by combining different materials allow for more secure tying, which can be a problem with inherently lubricious UHMWPE sutures (Burkart, 2004).

Stainless Steel Sutures

For surgical procedures requiring high-strength materials, such as sternal fixation and tendon repair, stainless steel is a common selection. These sutures are most often prepared from 300-series stainless steels (316L is a common variety and is used in Covidien STEEL sutures, for example). Stainless steel sutures are inert, do not exhibit capillarity, and are very strong. The high modulus of stainless steel, however, can cause irritation at the free end of the suture. These sutures are also prone to kinks, and surgeons must use extra caution during handling (Bellenger, 1982; Capperauld and Bucknall, 1984; Guttman and Guttman, 1994). Stainless steel sutures are available as a braid or monofilament (for small sizes).

TABLE 2.5.9.9 Repeat Units for Common Synthetic Absorbable Sutures

Monomer Names	Repeat Unit Structure	Homopolymer
p-Dioxanone	$[O–CH_2–CH_2–O–CH_2–CO]_n$	Polydioxanone (PDO)
Glycolide	$[CH_2–COO–CH_2–COO]_n$	Polyglycolide (PGA)
L-Lactide	$[CH(CH_3)–COO–CH(CH_3)–COO]_n$	Polylactide (PLA)
ε-caprolactone	$[O–(CH_2)_5–CO]_n$	Polycaprolactone (PCL)
Trimethylene carbonate	$[(CH_2)_3–O–CO–O]_n$	Polytrimethylene carbonate (PTMC)
Ethylene oxide	$[CH_2–CH_2–O]_n$	Polyethylene glycol (PEG, used as polyether-ester constituent in copolymers)

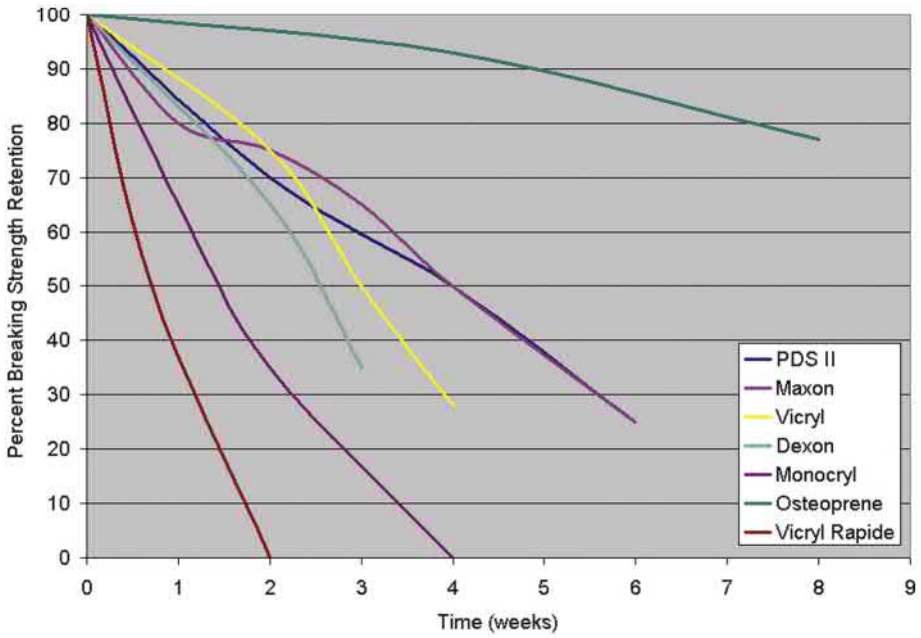
Synthetic Absorbable Sutures

Monomers and Preparation of Polymers

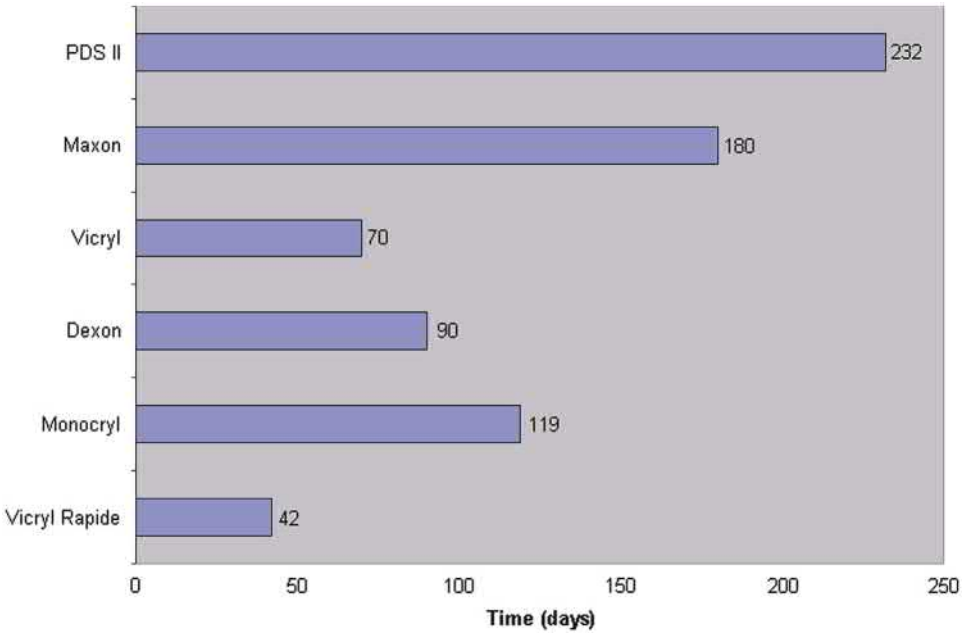
Natural and synthetic nonabsorbable sutures are made from materials which are polymerized from a select group of constituent monomers. These can be combined in a vast array of configurations exhibiting unique properties. These monomers include glycolide, lactide (*d*-, *l*-, and *dl*-), *p*-dioxanone, trimethylene carbonate (TMC), ε-caprolactone, and polyethylene glycol (PEG), which become repeat units in the final polymer. Table 2.5.9.9 includes the repeat unit structure of commonly used absorbable polymers, all of which degrade by hydrolysis of ester bonds.

Polyglycolide and predominantly glycolide-based copolymers are highly crystalline, stiff materials which are very susceptible to hydrolysis, leading to a faster absorption profile. Lactide-based polymers can be crystalline, but are slightly softer than glycolide-based ones, and are not as susceptible to hydrolysis. The *p*-dioxanone polymers are crystalline, but are softer than most of the glycolide- or lactide-based polymers, and are between glycolide and lactide in sensitivity to hydrolysis. These three provide the major constituents for all synthetic absorbable sutures. TMC, ε-caprolactone, and PEG represent minor constituents in a number of sutures, and serve to alter the material properties to improve some aspect of suture performance. For example, many monofilaments are prepared from copolymers made primarily with glycolide as a hard segment and TMC or caprolactone as a softer segment, making the copolymer more flexible, while retaining strength.

Ethylene oxide is the standard method for sterilization of absorbable sutures due to the tendency of the copolymer chains to undergo scission when irradiated. Synthetic absorbable polymers degrade by hydrolysis, and are therefore sensitive to moisture.



• **Figure 2.5.9.11** Breaking strength retention profiles of several common synthetic absorbable sutures (Ethicon, 2001, 2008; Covidien, 2009a,b; Taylor, 2010).



• **Figure 2.5.9.12** Maximum time for sutures to be essentially absorbed (Ethicon, 2001, 2008; Covidien, 2009a,b).

Absorbable sutures are described primarily by their strength retention profile, then by their absorption profile. The strength retention profile indicates the useful life of the device, and is the primary factor for selection in a particular application. The strength retention and absorption profiles for several common sutures are shown in Figs. 2.5.9.11 and 2.5.9.12, respectively.

Poly(Glycolic Acid) (PGA)

Dexon, the first synthetic absorbable suture, is prepared from a homopolymer made of glycolic acid, and was released in 1971 by Davis & Geck, which is now Covidien (Benicewicz and Hopper, 1990). PGA suture is available in braided form, and is coated to improve its handling properties. Current PGA sutures exhibit about 30%–50% crystallinity and retain about 65% of the initial strength after 2 weeks implantation, and 35% after 3 weeks. Absorption is essentially complete after 60–90 days (Covidien, 2005).

Poly(Dioxanone) (PDO) Sutures

PDSII (PolyDioxanoneSuture), the most recent iteration of *p-dioxanone* (PDO) by Ethicon, retains 25% of its initial strength after 6 weeks, making it the longest lasting

TABLE 2.5.9.10 Effect of Block Structure on PGA-co-TMC Copolymer Properties[a]

Block Type	Glycolide Content (wt.%)	Melting Peak (°C)	Tensile Strength (kpsi)	Tensile Modulus (kpsi)	In vivo BSR[b] at 3 Weeks (%)	In vivo Absorption (Days)
Homopolymer	100	227	122	2100	20	<90
Random	88	209	65	970	3	<90
Block	65	216	42	610	53	<180
Modified block	65	213	61	260	69	<180

[a]Roby et al. (1997).
[b]Breaking strength retention.

commonly used suture currently available, allowing it to be used in slow-healing tissue that previously required nonabsorbable sutures (Ethicon, 2001; Capperauld and Bucknall, 1984).

High-Glycolide Copolymeric Sutures

The most well-known synthetic absorbable suture is braided Vicryl, which is a random copolymer containing 90% glycolide and 10% lactide (Guttman and Guttman, 1994). Braided Vicryl retains up to 25% of its initial strength for 4 weeks, and absorption is essentially complete in 56–70 days (Ethicon, 2001). An alternate version of Vicryl, named Vicryl Rapide, was introduced as a faster-absorbing version of the same material. This was accomplished by reducing the molecular weight of the fiber through a radiation sterilization process. Vicryl Rapide was designed as an alternative to Plain Gut suture, and loses strength within 2 weeks of implantation (Ethicon, 2008).

Most customization in this class of synthetic absorbable sutures has been in the area of monofilament sutures. Maxon suture, introduced in 1985 by Davis & Geck (now Covidien) is a triblock copolymer prepared from 67.5% glycolide and 32.5% TMC (Benicewicz and Hopper, 1991). The central block is composed of a random copolymeric initiator made of 85% TMC and 15% glycolide, while the two end grafts are primarily glycolide (Casey and Roby, 1984). This composition and structure resulted from a study comparing various block structures and ratios of the constituent monomers, the results of which can be seen in Table 2.5.9.10. This work highlights the sensitivity of the copolymers to structure, as well as to monomer composition. Increased TMC in the central chain reduces the tensile modulus, extends the strength retention profile, and increases the time required for absorption. The small amount of glycolide in the middle block is necessary because TMC absorbs very slowly; the glycolide allows the material to degrade into short segments that can be metabolized. Maxon suture retains 25% of its initial strength up to 6 weeks post-implantation, and essentially absorbs by 6 months.

To fill the need for a shorter term monofilament, Ethicon developed Monocryl suture. This material was developed as an alternative to gut suture (Bezwada et al., 1995), and is a triblock copolymer containing 75% glycolide and 25% caprolactone. The initiator is reported to be a random copolymer containing 55% glycolide and 45% caprolactone, while the end blocks are primarily made of glycolide (Bezwada et al., 1995). Monocryl suture retains 30%–40% of its initial strength after 2 weeks of implantation, and is essentially absorbed between 91 and 119 days.

This is not inclusive of all sutures currently available, but is an example of a few technologies. Major suture manufacturers are continuing development of other high-glycolide copolymers.

Dyes

Sutures are provided in *natural* or *dyed* colors. The natural color of suture materials is most often white to light tan. When sutures are placed in tissue, the contrast between the suture and host tissue is low. This effect is magnified when in the presence of blood, which can make differentiation between the suture and tissue difficult. For this reason, dyed sutures are often preferred. The US Food and Drug Administration (FDA) regulates the use of colorants, and the approval process is quite stringent. The current approved colors are seen in Table 2.5.9.11. Synthetic sutures are dyed during the extrusion process by adding a small amount of powdered colorant to the polymer just prior to extrusion. Natural materials are dyed in a color solution. Processing conditions and associated requirements may also place limitations on the use of some dyes in the suture strand.

Coatings

Braided and monofilament sutures have been coated with a wide variety of materials for the primary purpose of reducing tissue drag. Coatings also fill void space, thus reducing capillarity and the tendency to wick, and can act as carriers for antimicrobial agents such as triclosan.

TABLE 2.5.9.11 FDA-Approved Dyes for Use in Sutures[a]

FDA-Approved Dye	Color	Used in Sutures Containing
Pyrogallol/ferric ammonium citrate	Blue	Gut
Logwood extract	Black	Silk, nylon

FD&C Blue No. 2	Blue	Nylon
D&C Blue No. 6	Blue	Various
D&C Green No. 6	Green	Various
D&C Violet No. 2	Violet	PDO, PGA, glycolide copolymers

[a]FDA (2007): 21 CFR Parts 73 and 74.

Early coatings were comprised of beeswax and other natural waxes. Other coating materials for nonabsorbable sutures include silicone and poly(tetrafluoroethylene) (PTFE, Teflon) based systems, as used on Deknatel's Tevdek and Polydek polyester sutures. Coatings for absorbable sutures are typically based on absorbable copolymers, and can include polyurethanes, PEG, caprolactone copolymers, and lactide/glycolide copolymers (Mattei, 1980; Bichon et al., 1984; Ethicon, 2001). Calcium stearate and other lubricants may also be included to improve friction properties.

Needles and Attachment

Suture needles are made from high-quality stainless steel. Typically, needles are prepared from 400-series stainless steel, though some specialties prefer 300-series needles (Hu-Friedy Mfg. Co., Inc., 2007). Needles are permanently attached by a swaging process. Monofilament sutures are placed directly into the drilled end for swaging, but braided sutures require tipping to harden the end of the strand so the swaging process holds firmly onto the end of the suture. Tipping is performed with a cyanoacrylate-based adhesive on the last ½ inch of the suture strand. Also, for small-size sutures, epoxy and cyanoacrylate are commonly used for needle attachment.

Packaging

Sutures are sold sterile in individual or multipacks. Packaging for nonabsorbable sutures can be in Tyvek packaging; however, synthetic absorbable sutures are always packaged in hermetically sealed foil packaging. The sealed foil maintains a sterile barrier, as well as protecting the suture from oxygen and moisture which would initiate the degradation of the suture. This is known as a *hermetically* sealed package.

Physical Properties

The function of the suture strand is to provide a holding force while maintaining a stable position in the implant location. There are, however, many aspects to tissue securement. The *United States Pharmacopeia* (USP) is a list of standards and requirements for the testing and production of medical devices, including several guidance documents pertaining to sutures.

Suture is defined by USP size, which is defined numerically on a scale from size 7 (largest) to 11–0 (smallest).

There are three basic strengths tested by the USP: unknotted tensile strength, knotted tensile strength (typically 60%–80% of unknotted), and needle attachment strength. These are critical as the suture must have enough tensile strength to hold the tissue in place under strain and while in a knot. Additionally, the suture must remain on the needle while being pulled through the tissue.

In Vitro and In Vivo Performance

For absorbable sutures, the strength retention profile is the key to material functionality. There are two methods for determining the strength loss profile. In vivo strength is typically analyzed by implanting strands of the suture subcutaneously in Sprague–Dawley rats. In vitro analysis involves placing suture in a physiologic buffered solution, e.g., 7.4 pH phosphate-buffered saline solution (PBS) at 37°C. At predetermined time points, samples are collected and tested for ultimate tensile strength. Information is reported as a percentage of the initial load. In vitro analysis must always be followed up with at least limited in vivo analysis, due to the difficulty of directly correlating performance between the two degradation conditions.

The suture strand must remain securely in place after implantation. To accomplish this, the knot needs to be stable. A single surgeon's knot is typically not sufficient to hold the suture securely, particularly in coated sutures. Additional knots are tied to increase the holding power of the knot. An important contributing factor to knot stability is the frictional property profile of the suture strand. For this reason, friction is another important performance parameter.

The ideal suture provides not only tissue securement, but is also sterile and biocompatible. Medical devices must meet stringent requirements for safety, with guidance by the International Standards Organization (ISO) standard 10993-1

• **Figure 2.5.9.13** Image of spiral cut barbs in Quill SRS suture, marketed by Angiotech Pharmaceuticals.

(ISO, 2009). According to this document, the suture strand must be tested for cytotoxicity, genotoxicity, sensitization, irritation, systemic toxicity, and subchronic toxicity. This represents an extensive set of in vitro and in vivo analyses. For absorbable sutures, the hydrolysis byproducts, along with the polymeric material, are tested.

Newer Trends and Future Developments

In the early 2000s, Ethicon released the first of their *Plus* line of sutures that contain a small amount of the antibiotic/antifungal agent Irgacare, a brand name for triclosan. Since this time, other agents have been incorporated into sutures and explored for antimicrobial effectiveness, including chlorhexidine and octenidine (Matl et al., 2009). Also, various coating polymers have been applied to improve or extend the length of triclosan release from the suture (Nagatomi et al., 2007). Therapeutic release applications have not been limited to antimicrobials, and drug release from the suture coating could be applied to a wide variety of soluble drugs and other active agents (Zhukovsky, 2003). Modified sutures have also been used as carriers in nontraditional applications. An instance of this includes the use of suture strands to position radioactive brachytherapy seeds to treat the cancerous margins after lung resection (Fernando et al., 2005).

New extrusion techniques are allowing for design of nontraditional surgical threads. Multicomponent coextrusion is making it possible to manufacture filaments with "*island in the sea*" and other geometries that could provide enhanced properties. In one instance, a PDO polymer was coextruded with a softer copolymer containing *p*-dioxanone, trimethylene carbonate, and caprolactone, the fibers of which exhibited a much higher knot security compared to a standard PDO suture (Im et al., 2007). Also of interest is the creation of ultrahigh-strength absorbable sutures. Currently, high-lactide copolymers are being investigated for this use, with proposed applications in orthopedic areas.

While traditional sutures depend on knots to secure placement of the suture strand, a novel technique involves the use of a suture with an integral securement mechanism, or barb, as seen in Fig. 2.5.9.13. Quill SRS (Self-Retaining System) barbed suture, marketed by Angiotech, was approved for use in 2004, and is gaining popularity in many soft-tissue procedures. This alternative approach to wound closure provides a faster method of approximation, and avoids extraneous foreign material in the wound due to the bulk of a surgical knot (Angiotech Pharmaceuticals, 2009). The downside to the Quill suture is that the barb is cut directly into the monofilament, which creates a natural weak point in the fiber. Newly released Stratafix is a barbed suture marketed by Ethicon. The barbs are made during the molding process rather than by cutting the already-manufactured monofilament (Ethicon, 2014). This provides the added benefit of a knotless suture without decreasing the strength of the filament.

Use of Biomaterials in Vaccine Development

Introduction

Vaccine-based therapies for the treatment of disease were first described over two centuries ago with the successful application of a smallpox vaccine by Edward Jenner in 1796 (World Health Organization, 2009). Since then, scientists have formulated vaccines against a wide variety of pathogens, including but not limited to measles, pertussis, tetanus, poliomyelitis, and cholera. These diseases, which used to be among the most significant threats to human health and causes of infant mortality, have been largely contained or even eradicated in developed countries and are rapidly declining worldwide (World Health Organization, 2009).

Vaccines work by introducing a killed or weakened whole pathogen or a subunit(s) of the pathogen to the immune system without the disease itself being active and harming the individual to cause a B cell (humoral) and/or T cell (cell-mediated) response. The magnitude and type of response depends on the specific treatment schedule as well as dose, antigen, adjuvant, etc. delivered in the vaccine. The effect of vaccination in most scenarios is ideally a lasting memory response to epitopes of the pathogen-associated antigen. Thus if the pathogen expressing those particular epitopes is subsequently encountered, antibodies already developed in response to the vaccine will bind and mark the pathogen for death (humoral response) to prevent infection. Cellular immunity can also be elicited by the vaccine to result in pathogen reexposure triggering direct cell-mediated lytic or cytokine responses. This allows for the prevention of infection or pathogen clearance in vaccinated individuals (U.S. Dept. of Health and Human Services, 2017).

While vaccines have drastically improved the human lifespan, there is still room for improvement—many vaccines require a booster years after the initial inoculation, which is costly and can lead to a lapse in immunity and allow spreading of disease. Live-attenuated vaccines often cannot be tolerated by immunocompromised individuals due to their potency, leaving a subset of susceptible people at risk. Additionally, there are still pathogens that scientists have not been able to develop vaccines against due to their virulence, ability to rapidly mutate and evolve, the presence of many different subtypes with varying characteristic epitopes, or their inability to induce a strong immune response in subunit form. These pathogens include human immunodeficiency virus, hepatitis C, and malaria, though they have been investigated extensively in the medical research community (Rappuoli et al., 2011). Aside from the need to develop new and more effective vaccines, significant challenges in vaccine research exist in regard to their accessibility in developing countries. One major hurdle is breaking the "cold-chain," or the need for refrigeration of vaccines and other medicines, which is not always available in rural or impoverished areas. This makes access to vaccines very difficult for a large portion of the global population, continuing the spread of preventable diseases that have been mostly eradicated in developed areas (World Health Organization, 2015).

The field of biomaterials has presented a variety of elegant solutions to medical problems throughout history, and thus has been a large part of vaccine research and the attempt to mitigate the drawbacks of currently approved vaccines. This

includes both making more effective vaccines that prevent a wider array of diseases or the need for additional boosters, and more stable formulations that allow for alternate administration routes and enhanced global accessibility. The following sections will review broad biomaterials-based strategies for improving vaccines in the aforementioned areas.

Biomaterials for Improving Vaccine Efficacy

Mounting a powerful, long-lasting immune response to a vaccine can be accomplished using two important components: (1) adjuvants, present in most vaccines, which provide additional immune stimulation, and (2) antigen that can be efficiently presented by antigen-presenting cells (APCs), which result in the priming of antigen-specific T cells that have direct cell-killing functions or can provide "help" through cytokine production that, for example, aids in the development of mature antibody (humoral) responses by B cells. In the last few decades, a large number of biomaterial systems have been characterized that specifically enhance different aspects of this process. Some important criteria for vaccine biomaterials are illustrated in Fig. 2.5.10.1.

Dendritic cells (DCs), macrophages, and B cells are known as professional APCs. Each of these cell types plays diverse and specialized roles in the immune response to vaccination, and thus represents a desirable therapeutic target with which biomaterials can be designed to interact. In this section, we consider the use of biomaterials to deliver adjuvants to APCs, but focus the discussion on DCs and macrophages. B cells are discussed separately and more specifically in the Section "Activation of B Cells and Humoral Immunity."

Use of Biomaterials to Adjuvant the Immune System

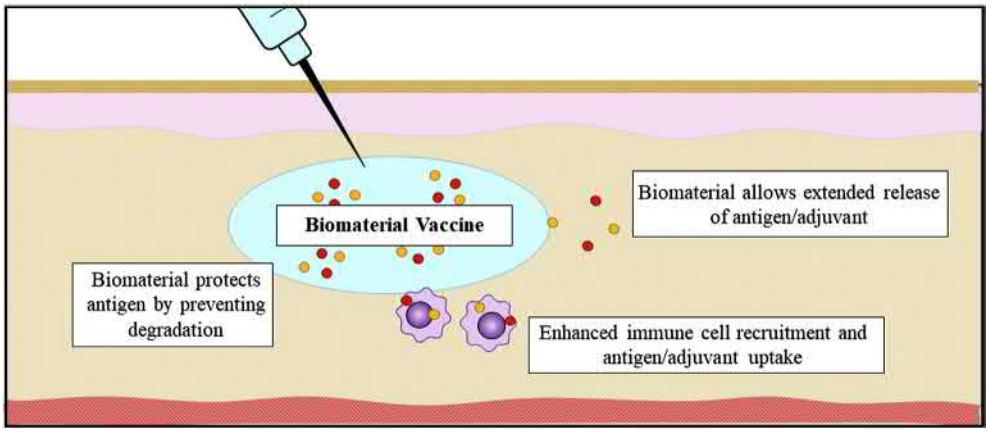
While some vaccines are naturally potent or able to induce a lasting, protective immune response, others rely on a class of materials called adjuvants, which aim to amplify the efficacy of vaccines by providing additional immune stimulation. Traditional adjuvants aim to accomplish the following goals (European Medicines Agency, 2003):

1. Protect antigen from being degraded and increasing its bioavailability;
2. Distribute antigen to target specific cells and improve its presentation;
3. Direct stimulation of target immune cells.

Biocompatible materials have been used as adjuvants for almost a century (Marrack et al., 2009), beginning with the use of insoluble aluminum salts (most commonly known as "alum") to enhance the efficacy of a diphtheria vaccine. Since its original discovery, alum has been used in a wide variety of vaccines and was the only approved vaccine adjuvant for many years. Despite its widespread use, the mechanism by which alum exerts an adjuvant effect is not fully elaborated.

Originally, alum derivatives were thought to adsorb antigen and form a depot in vivo, facilitating slow release of the antigen over time and leading to efficient amplification of antibody titer (Glenny et al., 1926), though formation of a depot has also been reported not to affect the adjuvanticity of alum (Hutchison et al., 2012). Similarly, other Food and Drug Administration (FDA)-approved adjuvants include oil-in-water emulsions such as Montanide or squalene-containing MF59. These operate in a similar manner by protecting and releasing antigen for long periods of time after immunization and have proven safer and more effective than previous iterations, including Freund's adjuvant (Herbert, 1968). Other proposed mechanisms of action for the traditional adjuvants alum and oil-in-water emulsions include their propensity to attract innate immune cells (Calabro et al., 2011) and induce local inflammatory cascades that lead to cytokine release and enhanced types 1 and 2 helper T cell response (Grun and Maurer, 1989). Despite the widespread use of these traditional adjuvants, they have failed to enhance the efficacy for all types of immunization, leading to an increased interest in adjuvants that elicit a direct mechanistic effect.

Some of the principal cellular targets of this newly investigated class of adjuvant are DCs and macrophages, which are



• **Figure 2.5.10.1** Mechanisms of action of biomaterial-incorporated vaccines. Biomaterials can confer extended release, protection, or enhanced immune cell uptake of vaccine antigen and adjuvant.

important in the immune response for sampling their environment and detecting pathogen-associated molecular patterns (PAMPs) indicative of infection (Mosser and Edwards, 2008). These patterns are typically related to bacterial or viral structural and genetic components, such as lipopolysaccharide in bacterial cell membranes or double-stranded viral RNA, which they detect using pattern-recognition receptors such as Toll-like receptors (TLRs). Once PAMPs engage their appropriate receptor, they elicit a signaling cascade that leads to a state of enhanced antigen processing and presentation called maturation, the process by which these cells become "licensed" to activate naïve lymphocytes into effector cells (see Chapter 2.3.2). These TLR ligands are being heavily investigated as vaccine adjuvants that mimic PAMPs to elicit this heightened immune response. One such adjuvant is a TLR4 agonist monophosphoryl lipid A (MPLA), a less toxic form of lipopolysaccharide found in bacteria and is approved in an alum-containing formulation (AS04) or in a liposomal formulation (AS01B) (Center for Disease Control, 2018a,b).

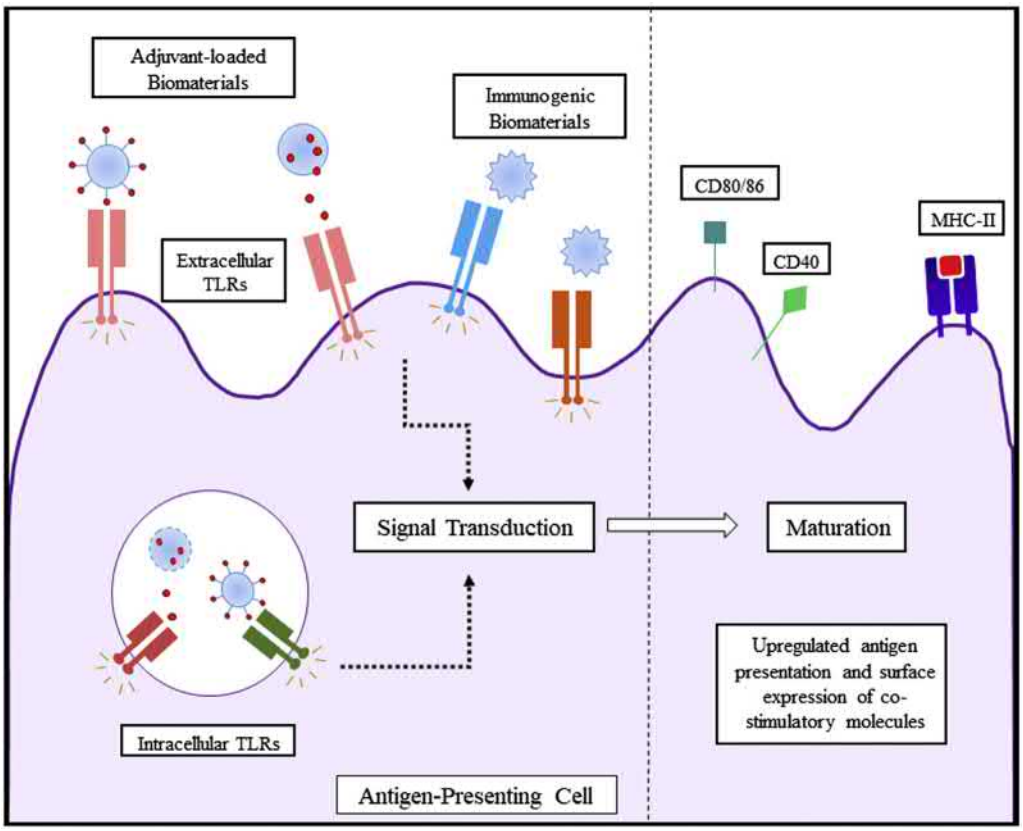
Other heavily investigated experimental TLR ligands include the TLR9 agonist cytosine-phosphate-guanine (CpG), which mimics bacterial and viral DNA, which has been widely researched in the context of both traditional vaccines (Campbell, 2017) and cancer vaccines, the latter particularly due to its ability to enhance the CD8 T cell response (Kochenderfer et al., 2007). Additionally, other molecules such as imidazoquinoline compounds imiquimod and resiquimod have been investigated for their ability to agonize TLR7/8, which typically responds to single-stranded RNA, a viral component (Hemmi et al., 2002). Imiquimod and resiquimod have been shown to cause an antiviral response and are used to treat viral infection (Edwards et al., 1998) and some forms of cancer (Beutner et al., 1999) topically, and thus have been researched for their application to cancer vaccines in particular (Adams et al., 2008). However, to achieve the maximum effect of these adjuvants and reduce systemic immune overactivation, biomaterials have been investigated in the context of direct adjuvant delivery to APCs. These strategies for general adjuvant delivery are outlined in the following section.

Biomaterials have been investigated both for their ability to deliver adjuvant to APCs in a targeted manner, and for their ability to directly adjuvant immune cells in the case of immunogenic materials. Though a wide variety of biomaterial formulations have been reported for the purpose of delivering adjuvant to APCs, several main trends emerge. In terms of the material carrier, poly(lactic-*co*-glycolic acid) (PLGA) is often used for its tunability and well-characterized in vivo response (Varypataki et al., 2016; Ali et al., 2009; Lynn et al., 2015), as well as other common FDA-approved biocompatible polymers, or supramolecular structures made from modified antigen and adjuvant. Overall, spherical carriers for the codelivery of antigen and adjuvant are the most commonly used strategy, with particle sizes ranging from tens of nanometers to target lymph node-resident APCs to hundreds of nanometers to enhance phagocytosis by APCs (Manolova et al., 2008). TLR ligand can be conjugated or adsorbed to the material surface, or encapsulated within it depending on the receptor's location on the extracellular or intracellular/vesicular membrane of the APC, respectively. Examples of this include CpG conjugated to small nanoparticles to activate extracellular TLR9 (Thomas et al., 2014) or MPLA-encapsulated lipid vesicles to adjuvant intracellular TLR4 signaling (Moon et al., 2011). Another non-particle approach to adjuvanting includes injectable gels or polymeric matrices that present stimulating factors for the purpose of attracting and maturing APCs (Ali et al., 2009). Because adjuvant-loaded materials are typically designed for codelivery with antigen, further criteria for the design of these materials will be considered in the Section "Use of Biomaterials to Improve Delivery of Antigen to APCs."

Naturally immunogenic biomaterials have also been explored for their ability to adjuvant immune cells, and may provide an advantage over materials requiring conjugation or encapsulation of adjuvants as their efficacy can be hindered by loading efficiency. Several well-researched biomaterial adjuvants include organic materials like alginate, a block copolymer polysaccharide derived from algae, or its monomers mannuronic and guluronic acid (Yang and Jones, 2009). Additionally, inorganic materials have also been shown to elicit an adjuvant effect, including the mineral hydroxyapatite ($Ca_{10}(PO_4)_6(OH)_2$) (Grandjean-Laquerriere et al., 2007). In both of these cases, the surface of the material mediates immune-stimulation via association with TLRs. Aside from this function, biomaterials can also be engineered to activate the complement cascade, which often results in the material being opsonized or flagged for phagocytosis by APCs. Nucleophilic chemical moieties, namely hydroxyl and amino groups, facilitate the deposition of complement proteins onto the material (Toda et al., 2008). This information has allowed for the design of hydroxyl-functionalized materials for adjuvanting the immune system via complement activation, leading to enhanced vaccine efficacy (Thomas et al., 2011). A summary of the biomaterial strategies for delivery of adjuvant to APCs and their mechanism of action can be visualized in Fig. 2.5.10.2.

Use of Biomaterials to Improve Delivery of Antigen to APCs

Once an antigen is encountered, DCs and macrophages undergo maturation and upregulate expression of major histocompatibility complex (MHC) I and II, which allows presentation of short antigenic peptide sequences to engage with the T cell receptors on $CD8^+$ and $CD4^+$ T cells, respectively. Antigen presentation occurs when a pathogen is phagocytosed from the extracellular space and then destroyed by the highly acidic and reductive environment within phagolysosomes, and antigenic peptide sequences are cleaved (see Chapter 2.3.2). Then, either the endosome fuses with an MHC II-containing vesicle and peptide fragments are loaded, or fragments escape the endosome and are loaded onto MHC I and transported to the cell surface



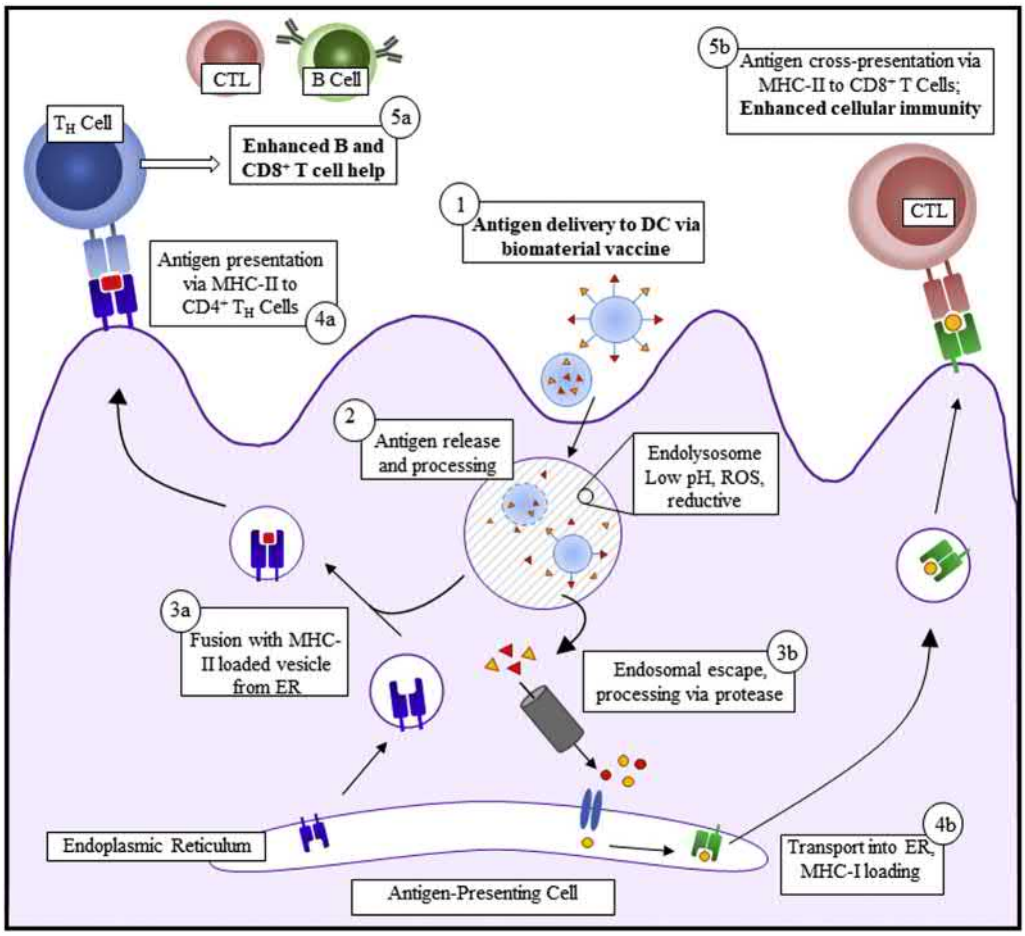
• **Figure 2.5.10.2** Mechanisms of action of adjuvant delivery via biomaterials. Adjuvant-loaded and/or immunogenic biomaterials access APCs, where they engage PRRs such as TLRs (left). The effect is APC maturation (right).

for expression (Joffre et al., 2012), a process termed cross-presentation. Because antigen escape from these phagolysosomes can lead to presentation via either type of MHC molecule, there is significant crosstalk between both pathways leading to antibody production and cytotoxic T cell expansion in response to many types of pathogens depending on the immunological context (Joffre et al., 2012). Biomaterials are utilized in this application because they can be engineered to improve both cell-mediated and humoral responses through designs that support endosomal escape to cause MHC presentation and cross-presentation.

One strategy for enhanced antigen presentation is incorporation into a nanocarrier that enables release into endolysosomal vesicles and efficient endosomal escape, leading to cross-presentation. This has been accomplished mainly by the use of materials that degrade at lysosomal pH, including PLGA (Shen et al., 2006), poly(dimethylaminoethyl methacrylate) (Foster et al., 2010), poly(glycidol) (Yuba et al., 2010), and poly(propylene sulfide) (Hirosue et al., 2010). Additionally, materials that degrade via enzymatic action, such as liposome formulations that are cleaved via endolysosomal lipases, have been considered (Moon et al., 2011). This formulation strategy also provides the benefit of extended release, where antigen is being freed from the endosomal compartment in a continual manner, allowing for persistent cross-presentation. Conjugation of peptide antigen to nanocarriers via cleavable conjugation is also an effective strategy for antigen escape into the cytosol, including the use of reducible disulfide linkages (Hirosue et al., 2010). Besides endosomal escape, cell-penetrating peptides have been used as a mechanism for direct entry of antigen or nanocarrier-associated antigen to efficiently induce potent cytotoxic T cell responses (Nakamura et al., 2008). A summary of the biomaterial strategies for delivery of antigen to APCs and their mechanisms of action can be visualized in Fig. 2.5.10.3.

Activation of B Cells and Humoral Immunity

B cells mediate humoral immunity, which is particularly effective at neutralizing extracellular pathogens before they have a chance to damage host cells. Most existing vaccines are successful as a result of their ability to stimulate B cells and incite an antibody response that mediates prophylactic immunity (Lachmann, 2012). Many pathogens commonly vaccinated against such as polio, tetanus, and diphtheria can rapidly damage tissues if the body is unprepared upon initial contact, so it is critical for preexisting antibodies to be present to quickly neutralize the threat (Lachmann, 2012; Bachmann and Jennings, 2010). The importance of humoral immunity to vaccine efficacy makes methods of increasing B cell activation of great interest in vaccine design, and with



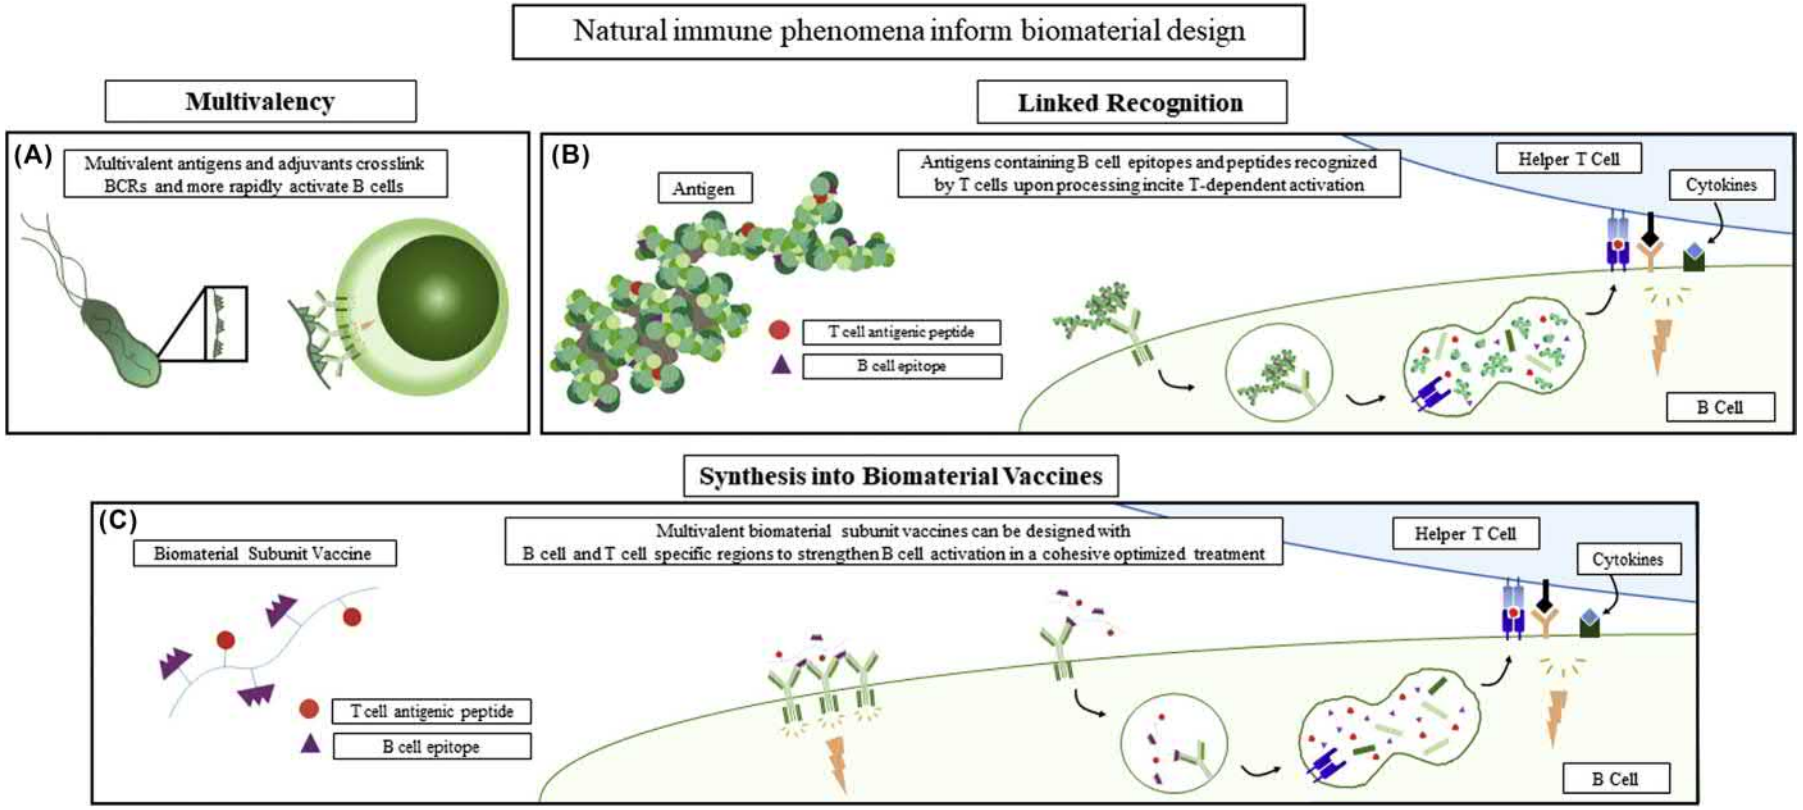
• **Figure 2.5.10.3** Mechanisms of action of antigen delivery via biomaterials. Antigen-loaded biomaterials access APCs (1) and are phagocytosed, leading to antigen release from the biomaterial due to pH, ROS, or reduction-sensitive conjugation schemes or biomaterial composition (2). Antigen then can either be presented via MHC-II (3a, 4a, 5a), or cross-presented via MHC-I (3b, 4b, 5b).

an understanding of the B cell activation process, unique strategies to modulate B cell responses with biomaterials can be rationally designed.

Overview of the B Cell Activation Process

At a fundamental level, B cell activation can be separated into either T cell-dependent or T cell-independent action, and this distinction is dependent upon the characteristics of the antigen causing the response. Central to both activation pathways is the B cell receptor (BCR), which is an immunoglobulin receptor on the B cell's surface that will bind to a specific region of an antigen. However, B cells cannot be fully activated solely by antigen recognition within a single BCR. Instead, their full activation depends on either the crosslinking of multiple BCRs and a secondary signal from an immune stimulant, or on the assistance of a concurrently activated helper T cell (Vos et al., 2000). Crosslinking of multiple BCRs can occur in response to antigens presented to the B cell at high local surface density, which can result in high multivalency, and can enable B cell activation without the need for T cell support (Fig. 2.5.10.4A). Even without sufficient multivalency to activate a B cell entirely, multivalency supports the T cell-dependent pathway as well because it lowers the threshold for activation, therefore benefiting B cell activation in either case and making antigen multivalency a key feature in induction of a humoral response (Bennett et al., 2015).

T cell-dependent activation is more common and occurs through antigen binding at low surface density, frequently in the form of a free protein antigen that binds one BCR at a time (Cruse et al., 2004). BCR binding triggers an endocytosis and signaling cascade that results in internalization of the BCR-bound antigen within an endosome where it is degraded and processed, and some of its component peptides are shuttled back to the B cell's surface within MHC II proteins that the B cell will use to interact with helper T cells (Yuseff et al., 2013; Lanzavecchia, 1985; Harwood and Batista, 2010). As a result, these helper T cells can be specific to epitopes other than those directly recognized by the BCR, so while both the T cell and B cell may recognize different epitopes, their specificity is linked to the same pathogen (Harwood and Batista, 2010; see Chapter 2.3.2). This concept is known as linked recognition, and it is an important consideration in subunit vaccine design that can be leveraged using biomaterials to stimulate potent humoral responses (Fig. 2.5.10.4B).



• **Figure 2.5.10.4** Natural immune phenomena inform biomaterial design. (A) Strength of natural B cell activation is increased by multivalent antigens and adjuvants that crosslink BCRs, (B) Antigens containing B cell epitopes as well as component peptides recognized by T cells incite T-dependent activation with improved strength and immune memory, (C) Biomaterial subunit vaccines can be designed that synthesize both of these natural potent immune activation criteria and strengthen humoral response to a target antigen.

T cell-independent activation has the potential to be much faster, as it only requires the B cell to come into contact with a multivalent antigen and receive a secondary signal that can come from either the foreign substance itself through TLR signaling, or from cytokines released by innate immune cells in the vicinity (Vos et al., 2000). From a biomaterial standpoint, this form of activation may readily be achievable using a multivalent antigen and one of the many adjuvant strategies discussed in the previous section to activate APCs. However, a serious disadvantage of this method of activation is that it also tends to result in low-affinity antibody production, and either less effective immune memory function or none at all (Toellner et al., 2002). In contrast, T cell-dependent activation proceeds more slowly because it is limited by the full timescale of the adaptive immune response, but it also displays sustained immune memory and antibody class switching upon antigen rechallenge. Both mechanisms of B cell activation may be leveraged in vaccine design to increase the efficacy of humoral response, and this may be particularly achievable using biomaterials because of their highly controllable nature.

Biomaterial Design for Enhancing the Humoral Response

Potent humoral immune responses can generally be achieved with vaccines that incorporate multivalent antigens and include linked B and T cell epitopes specific to a target pathogen (Arsiwala et al., 2019; Wen and Collier, 2015; Renaudet et al., 2008) (Fig. 2.5.10.4C). While some vaccines have been successful at achieving strong humoral responses, precise amounts of B and T cell antigens and their specific degree of multivalency can influence immune responses significantly, so vaccine design can benefit from engineered platforms with greater control over these parameters (Wen and Collier, 2015; Purcell et al., 2007). To address this need, multivalent materials containing distinct quantities of B and T cell antigens, termed multiple antigen peptide systems or MAPs, have been an area of research since the 1980s (Tam, 1988). In early experiments, varied ratios of synthetic high-density malaria antigens designed to activate B cells and T cells were tested in mice. Results confirmed that multivalency boosted immune responses and also suggested that equimolar amounts of each antigen were optimal to induce the strongest humoral response to combat the disease (Tam et al., 1990). Decreased peptide density and exclusion of either the B cell-specific or T cell-specific antigen reduced or negated the immune response entirely (Tam et al., 1990). While both B cell and T cell antigen types are included in these vaccines, it is only B cell antigens that directly benefit from multivalency because of its relevance in B cell activation (Bennett et al., 2015). Importantly, in these first experiments, alum was coadministered to adjuvant the response, but subsequent work has shown that in many cases, biomaterial peptide nanocarriers can be designed to be immunogenic enough to serve as their own adjuvants, and can even outperform industry standards such as alum and CpG (Tam et al., 1990; Chen et al., 2013; Rudra et al., 2012). Subsequent research has shown that many different approaches can been implemented to create biomaterials with highly multivalent surface antigens, including synthetic protein nanofibers and a variety of antigen-loaded lipid and polymer nanoparticles (Tam et al., 1990; Bennett et al., 2015; Moon et al., 2012). Recent protein nanofiber designs are particularly versatile because they can be built from a protein backbone linked by controllable quantities of customized epitopes, giving them potential as a platform for vaccination against diverse diseases (Hudalla et al., 2014). An interesting aspect of the protein nanofiber approach is that the nanofiber carrier acts as an adjuvant, which can be valuable in vaccine design because administration of traditional adjuvants unattached to a target antigen can result in less control over the subsequent immune response (Wen and Collier, 2015; Hudalla et al., 2013). Also promising is the use of multilayered lipid nanoparticles designed to both encapsulate target antigen in their core and present it at high multivalency on each layer of their lipid surfaces (Moon et al., 2011). This approach is interesting because it incorporates antigen designed to stimulate both B cells and T cells in a manner favorable to a response in both cell types, and does so in a delivery vehicle that is more efficiently taken up than soluble antigen by APCs (Yuseff et al., 2013). This lipid nanoparticle treatment has been tested with monophosphoryl lipid A as an adjuvant, and shown to prompt a superior antibody response at significantly reduced adjuvant levels than would be needed if the antigen were administered in its soluble, nonbiomaterial form (Moon et al., 2012). In addition, adjuvant can actually be loaded into the lipid vessels with antigen rather than just coadministered in the same injection, and achieve a very strong response (Moon et al., 2011). Other biomaterial designs have also enhanced humoral responses by manipulating surface peptide organization, including additional adjuvants on the material surface, and using complex synthetic antigen carriers designed to be cleaved within B cells at select sites to enable efficient release of T cell-specific antigen upon endocytosis (Bennett et al., 2015; Moon et al., 2012; Jegerlehner et al., 2002). For consideration in biomaterial design, studies of B cell surface features have shown that surface Ig receptors on resting B cells are separated by about 40 nm, and that a strong B cell activation signal requires the crosslinking of 10–20 surface receptors in a cluster (Vos et al., 2000). Antigens displayed with repeat epitope patterns spaced by 5–10 nm have shown great success at initiating B cell activation in an increasingly T-independent manner, so the precise control over antigen spacing offered by biomaterials can have great impacts on multiple different aspects of B cell activation (Bachmann et al., 1995). In addition to multivalency, one of the newer directions in B cell modulation by biomaterials is to control the stiffness of the substrate upon which antigens are presented, because studies have shown that a B cell exposed to the same antigen on a different surface

may react differently, both in the potency of its activation and in the types of antibodies it produces in response (Zeng et al., 2015; Wan et al., 2015). This is particularly true when comparing the strength of B cell responses to membrane-bound antigen as opposed to antigen in its free soluble form, as membrane-bound antigen is able to activate B cells orders of magnitude more effectively (Batista et al., 2001).

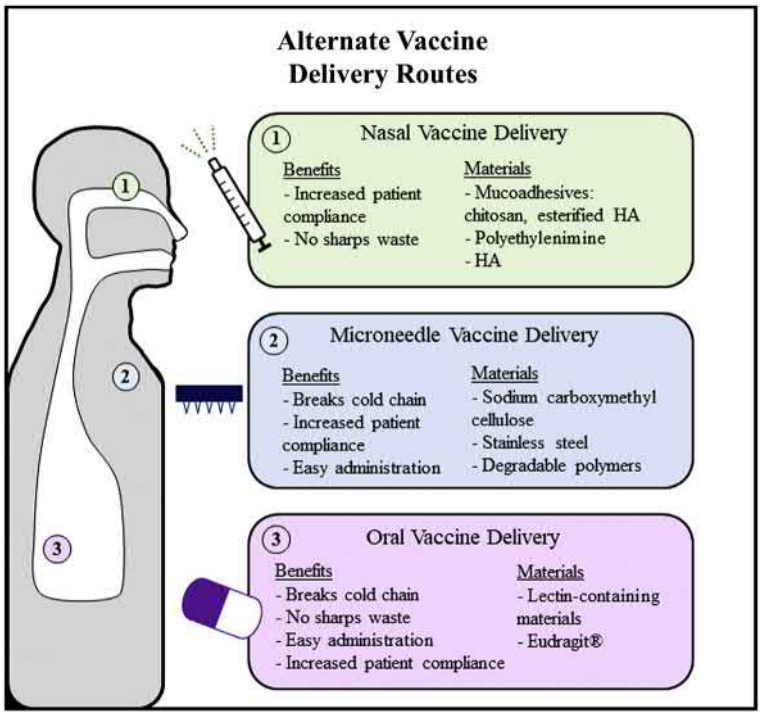
Although surface interactions between B cells and their target antigens are very important to biomaterial design, perhaps equally important is the ability of the biomaterial to actually deliver a vaccine to its target cell. Lymphocytes that survive their rigorous selection and maturation process migrate to secondary lymphoid tissues such as the lymph nodes, where they are housed in specific zones with highly regulated accessibility. It is therefore important for immunomodulatory biomaterials to be designed such that they can access lymph nodes in high concentrations, and for vaccines targeting humoral response to be designed with B cell follicle access in mind. Biomaterial approaches can aid in this process in many ways, including improving activation of DCs and macrophages in the periphery to enhance trafficking of antigen to the lymph node or acting as lymphatic draining carriers for antigen–adjuvant cargo, as discussed previously. However, if interested in specifically improving humoral response, biomaterials optimally sized for lymphatic drainage may offer advantages over free antigen vaccine formulations (Reddy et al., 2007; Mueller et al., 2015). B cells are housed within the lymph node follicles, where they have access to antigens that are either small enough to have passively drained there or have been shuttled there by macrophages and DCs, then transferred to follicular DCs present throughout the follicle (Bachmann and Jennings, 2010; Heesters et al., 2016). Important to this antigen-trafficking process is the subcapsular sinus macrophage (SSM), which lines the lymph node periphery and can mediate antigen transport to B cell follicles, so biomaterial strategies that elevate antigen–adjuvant interactions with SSMs can improve humoral responses to vaccines (Junt et al., 2007). This effect has been shown through experiments testing synthetic TLR4 agonist glucopyranosyl lipid adjuvant (GLA) injected in a squalene emulsion (GLA-SE), which is an adjuvant currently under investigation for inclusion in tuberculosis vaccination (Desbien et al., 2016). While GLA-SE improves both humoral and cell-mediated immunity, the humoral branch of its efficacy has been shown to depend heavily on SSM uptake within the lymph node, which it effectively achieves due to its favorable lymphatic drainage upon intramuscular injection and unique properties of squalene that strengthen the immune response (Desbien et al., 2016; Orr et al., 2013). Better control over B cell follicle access is achievable using biomaterial vaccine platforms, so these engineered approaches represent a promising way to improve humoral immune responses.

Biomaterials for Alternative Vaccine Administration Routes

Another important consideration in vaccine design is administration route. Currently, most vaccines are delivered by injecting directly into the subcutaneous or intramuscular space, allowing antigen and adjuvants to directly interface with the required immune cells. Some vaccines, such as FluMist (AstraZeneca), are delivered via alternate routes, including intranasal (FluMist), oral, or transdermal. This poses an advantage over traditional vaccine delivery requiring hypodermic needles in terms of patient compliance, cost of needles and biohazard disposal, and overall risk of disease spreading through improperly disposed needles. Biomaterials provide a highly useful strategy for this purpose as they can be formulated to optimize delivery to gut- and mucosal-associated lymphoid tissues (Fig. 2.5.10.5).

Among the noninvasive (nonneedle) delivery routes, oral administration would allow for the highest level of patient compliance, as pills and liquid suspensions are highly common drug formulations for other types of medication. However, the extremely low pH and enzymatic activity in the stomach and upper gastrointestinal tract has stunted most research in oral vaccine delivery as these conditions favor degradation of protein antigen before it is able to be taken up and presented by APCs (Russell-Jones, 2000). Here, biomaterials can be engineered to assume a protective role for the antigen or pathogen, preventing its degradation. One class of polymers that have been shown to enhance the stability of orally administered vaccines is acrylic and methacrylic acid copolymers, sold as excipients under the trade name Eudragit (Evonik). These materials offer delayed release kinetics, allowing delivery to the small and large intestines, and have been used heavily in oral vaccine research to deliver smaller antigen-containing particles into Peyer's patches, a collection of lymphoid tissues in the intestinal tract that play an important role in the mucosal immune system (Dea-Ayuela et al., 2006; Mercier et al., 2007; Xu et al., 2018; Zhu et al., 2012). Other strategies to directly target Peyer's patches include active targeting via lectin-containing biomaterials, which leverage the affinity of specialized epithelial "M" cells that coat Peyer's patches for specific lectin (glycoprotein) domains, as well as optimal size for uptake by M cells (5–10 μm) (Van Der Lubben et al., 2001; Artursson et al., 1994; Eldridge et al., 1990).

Similarly, intranasal vaccine delivery presents a promising strategy, and has already been employed in the clinic for the live-attenuated influenza vaccine under the tradename FluMist (MedImmune). Though FluMist potentiates strong immune protection without the incorporation of biomaterials, few antigens are immunogenic enough to cause this type of response. This is partially due to rapid clearance by the mucociliary escalator, which functions to remove particles and pathogens before they arrive at



• **Figure 2.5.10.5** Current biomaterial approaches to alternate vaccine delivery routes, such as intranasal (1), microneedle (2), and oral vaccine delivery (3).

the lungs, insufficient uptake into nasal-associated lymphoid tissues (NALTs), and a lack of adjuvants specifically designed to enhance mucosal immunity (Zaman et al., 2013). Thus a variety of biomaterial adjuvants aimed to protect and deliver antigen to the NALT have been identified, including but not limited to polyethylenimine and hyaluronic acid, which exhibit a cationic surface allowing for increased endocytosis via mucosal tissue-resident APCs (Fan et al., 2015; Wegmann et al., 2012). An additional strategy is the use of mucoadhesive materials such as chitosan and esterified hyaluronic acid, which have been shown to adhere to mucus and exhibit an enhanced retention time before clearance by the mucociliary escalator, allowing for more APC processing and immune recognition (Singh et al., 2001; Primard et al., 2013).

Lastly, microneedles (MNs) present a highly promising strategy to combat all of the unfavorable aspects of traditional vaccination, not only including cost and patient compliance but also breaking the cold-chain and enhancing stability during dissemination through underdeveloped countries (Arya and Prausnitz, 2016). MNs consist of a patch containing an array of micron-scale needles that can deliver vaccines or other medication transdermally without the use of an injection. Many different MN formulations have been investigated for the application of vaccines, including hollow or coated metal needles as well as degradable polymer needles that break off after pressing into skin, which have each been widely investigated for vaccine delivery to improve patient compliance and reduce sharps waste (Choi et al., 2013; Holland et al., 2008; Kim et al., 2010; Kommareddy et al., 2012).

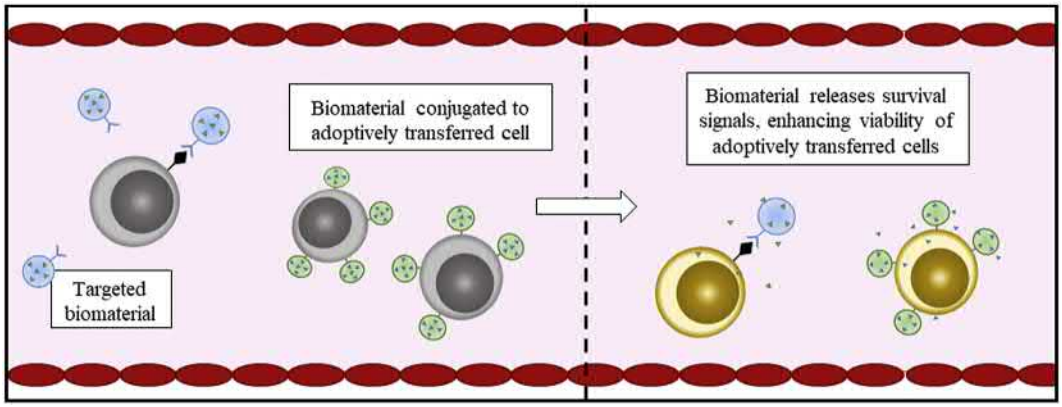
Biomaterials for Improved Vaccine Manufacturing and Accessibility

Biomaterials have been investigated for their potential to allow for long-distance shipping of stable, nonrefrigerated vaccines that would enhance global access to vaccination and lead to eradication of diseases already rare in first-world countries. Additionally, MN formulations (discussed earlier) may also play a huge role in breaking the cold-chain, and have shown safety and immunogenicity in early clinical trials (Rouphael et al., 2017; Kim et al., 2010).

In addition to enhancing vaccine stability, biomaterials are also being researched for the application of streamlined manufacturing, including formulations that could allow for the manufacturing of vaccines on demand as in the case of immediate worldwide need (Kanthamneni et al., 2012; Chen et al., 2011).

Conclusion/Future Directions

From this section, it was clear that effective vaccination is an important aspect of current and future medical challenges. Though vaccines have revolutionized medicine in the last century, boosters are still required for many vaccinations and a host of dangerous pathogens currently have no available prophylactic treatment available. Biomaterials have proven useful in many areas of medicine, particularly drug delivery, indicating their potential application to the field of vaccinology. Accordingly, many biomaterials have been engineered to enhance antigen and adjuvant exposure to lymphoid tissues from a variety of administration routes and increase



• **Figure 2.5.10.6** One strategy for biomaterial delivery to adoptively-transferred T cells *in vivo*. Biomaterial containing necessary growth and survival signals can be conjugated to a ligand that targets the adoptively transferred cells, or to cells themselves, leading to enhanced viability.

APC maturation, antigen uptake, and cross-presentation, leading to robust T and B cell responses and effective protection against pathogens of interest. Additionally, humoral immunity is of particular importance because it can facilitate prophylactic responses before host cells are infected, and the highly customizable nature of biomaterial approaches offers many advantages over traditional vaccines in this area. Both B and T cell epitopes against a target pathogen may readily be incorporated into biomaterial vaccine designs, and control over multivalency of B cell-specific epitopes in dense, repetitive patterns strengthens humoral response. Biomaterials are also being explored for previously ineffective routes of vaccine administration, which could enable safer, more thermostable, and more cost-effective vaccinations worldwide. This has led to a large database of biomaterial formulations that demonstrate success in preclinical small animal models, many of which are in the process of human clinical investigation.

Use of Biomaterials in T Cell Modulation

Introduction

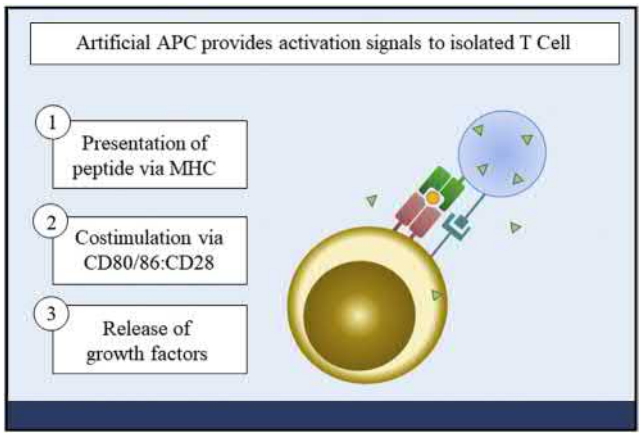
T cells play a critical role in the immune response to virtually all types of disease, including but not limited to autoimmune conditions, bacterial and viral infections, and cancer. However, therapies that modulate T cells directly are underexplored. This makes the use of biomaterials for T cell targeting and direct modulation a promising solution that has been increasingly explored over the last several years. Though many therapies for a variety of applications have been shown to modulate T cell phenotype or populations via the targeting of APCs or other immune cell subtypes, this is not a form of direct T cell modulation, and will not be discussed here.

Biomaterials for Targeting and Modulation of T Cell Therapies

Despite the success of new T cell-based immunotherapies such as adoptively transferred or chimeric antigen receptor (CAR) T cells, these therapies are still not entirely effective due to eventual cell death or exhaustion. Adoptively transferred T cells suffer from loss of effector function after reintroduction in vivo due to the immunosuppressive nature of the tumor microenvironment that T cells are ideally being trafficked to, and because of this both therapies often require coadministration of free cytokines, such as interleukin 2 (IL-2) (Dudley et al., 2005), to allow for improved survival. However, freely administered cytokines usually cause harsh systemic overactivation of other immune cells, leading to autoimmune-like side effects (Lerner et al., 1999; Vial and Descotes, 1992). Biomaterials have been investigated as a strategy to mitigate this current limitation to ensure higher efficacy and safety of adoptively transferred and CAR T cells in vivo (Fig. 2.5.10.6).

One strategy to accomplish this is to first incorporate a targeting molecule into the adoptively transferred or CAR T cell upon genetic modification to specifically deliver cytokines once the cells have been reintroduced into the patient in vivo. Then, a targeting antibody against the incorporated ligand can be conjugated to biomaterial liposomes containing a survival cytokine, such that free cytokine administration is not required and only the T cells of interest receive stimulation (Zheng et al., 2013). This concept could also be applied to the elimination of adoptively transferred cells that have successfully treated the tumor or other antigenic target of interest, and are presently causing symptoms of immune overactivation, as is an issue with remaining CAR T cells postcancer treatment. Though not widely studied, this concept has implications for general cell-targeted drug delivery via biomaterials.

Another more specialized strategy to modulate CAR- or adoptively transferred T cells in vivo is to physically conjugate a biomaterial to the T cell surface that provides an individual reservoir for cytokine survival signals such that they do not have to be freely administered. These materials have been made from the assembled protein cytokines themselves, and in some applications, disassemble and locally release to the T cell based on changing redox potential after activation (Tang et al., 2018), though this work is in a nascent stage of development thus far.



• **Figure 2.5.10.7** Mechanism of action of some *in vitro* biomaterial-based artificial APC systems. The biomaterial-based artificial APC provides peptide-MHC presentation as well as co-stimulation and growth factors to isolated T cells, allowing activation and survival.

Biomaterials for Enhanced T Cell Manufacturing

In addition to improving the in vivo efficacy of adoptively transferred or CAR T cells, some work has been done in improving the ability of these cells to be manufactured. Throughout the process of isolation, activation, expansion, and/or genetic modification, many of these T cells die, which introduces specific manufacturing constraints that drive up costs and make the therapy prohibitively expensive for many patients. Biomaterials have been used for in vitro culture and directed differentiation of a variety of other cell types (Engler et al., 2006; Pierschbacher and Ruoslahti, 1984), and thus show promise in being applied to the problem of T cell manufacturing. Though this field is in an early stage, some work has been done to improve the ability of T cells to be manufactured in a more efficient or cost-effective manner.

T cell activation depends on a specific interaction with APCs in which the T cell receptor interacts with its cognate peptide antigen bound to MHC presented by the APC, which provides activation signals, and CD28 interacts with CD80/86 on the APC, which provides survival signals. The process of T cell activation is important not only for our immune response to disease, but also especially in the case of adoptive cell therapy in which a patient's circulating T cells are taken from blood and activated and expanded ex vivo, which is extremely cost effective due to the difficult nature of the process. Therefore, artificial activation of T cells via biomaterials is a promising strategy to increase the efficiency of T cell manufacturing and decrease cost.

Artificial APCs have been investigated in recent literature for ex vivo activation and expansion of tumor-specific T cells in particular, though the concept could be used to expand any desired population of effector cells (Fig. 2.5.10.7). These artificial APCs usually consist of a combination of the peptide antigen of interest bound to MHC for activation and anti-CD28 for survival, and have been made from common synthetic polymers such as PLGA (Steenblock et al., 2011), as well as inorganic metal formulations, including gold (Matic et al., 2013) and iron (Perica et al., 2014, 2015). In several works, magnetic particles are used to artificially cluster anti-CD3 on the particle bound to CD3 on the T cell when a magnetic field is applied, thus inducing activation, and in other applications a magnetic field is used to separate out bound and therefore activated T cells (Perica et al., 2014, 2015). Additionally, other proliferation signals such as IL-2 are artificially delivered to T cells ex vivo in extended release formulations to increase survival over the course of several days (Steenblock et al., 2011).

Conclusions/Future Directions

Overall, though the field of T cell modulation is still actively growing, the wide variety of diseases for which treatment requires T cell modulation as well as the thorough characterization of biomaterials for other applications will allow for rapid development of new therapies to emerge, particularly in the autoimmune disease space, and improve the safety and efficacy of current T cell cancer treatments. The ability to perform targeted modulation of any particular cell type has broader implications in the field of biomaterial-assisted drug delivery, and is being actively investigated by biomaterials researchers. Additionally, biomaterials are expected to have a large role in improving current manufacturing processes for ex vivo T cell expansion and genetic modification due to their current, promising role in 3D scaffolds for cell culture and differentiation, for example. In the coming years, biomaterial-based technologies for rapid, cheap, and even bedside isolation and expansion of patient-derived T cells are expected to drastically improve the accessibility of these therapies.

Use of Biomaterials to Induce Tolerance

Introduction

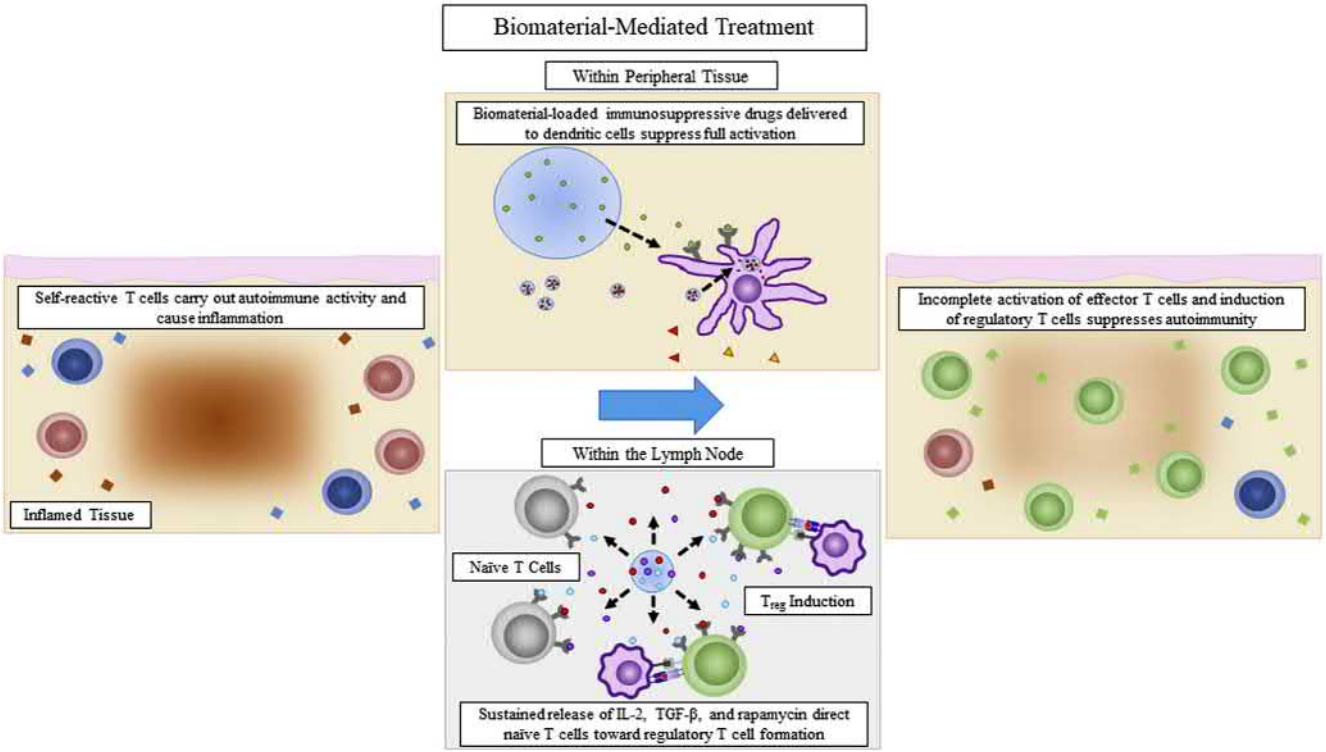
Previous sections of this chapter have focused on amplifying immune effector responses to antigens, but there are also many situations in which we would prefer to use biomaterials to induce immune tolerance to an antigen, rather than immunity. Controlling immune tolerance is of great interest in the treatment of autoimmune disorders such as diabetes, multiple sclerosis, and lupus, which can significantly diminish quality of life and even be fatal (Graham et al., 2013; Look et al., 2013). Current treatment options for autoimmune diseases require long-term systemic immune suppression, which can be effective, but can also cause serious side effects and weaken the body's defenses against all pathogens. Biomaterial approaches offer an alternative to systemic treatments and have the potential for much more fine-tuned and effective outcomes, many of which will be discussed in the following sections.

Induction of Tolerance in Autoimmune Disorders

Autoimmune diseases can be mediated through many different mechanisms of action, but are generally helper T cell controlled (Noack and Miossec, 2014; Azar et al., 1999). Helper T cells are implicated in these diseases because in the properly functioning immune system they are required to fully activate cytotoxic T cells and B cells in the majority of cases, and a subset of helper T cells known as regulatory T cells (Tregs) plays a very important role in suppression of self-reactive T cells (Kim et al., 2007). Aberrant lymphocyte behavior occurs occasionally and causes improper effector function against self-antigens, but biomaterial strategies can be used to combat this. In general, tolerance can be induced through T cell anergy or deletion, elevated Treg activity, or suppression of B cell activation to a specific antigen (Lewis and Allen, 2016). A summary of the following concepts is illustrated in Fig. 2.5.10.8.

T Cell Anergy and Deletion Through Incomplete Dendritic Cell Activation

Full activation of a T cell requires a multistep surface peptide interaction sequence with a mature DC. Critical steps in this process are the interaction of an MHC-bound antigen with the T cell receptor, and a secondary costimulatory interaction between the B7 and CD28 ligands on the DC and T cell, respectively. However, if this secondary signal is not presented, full activation of the T cell cannot occur and the T cell can enter into an unresponsive, or anergic state as a natural tolerance mechanism (Mueller et al., 1989). DCs will only express B7 if fully activated upon their initial antigen encounter, which implicates incomplete DC activation against a target self-antigen as a potential therapeutic pathway for treatment of autoimmune diseases. This concept has been demonstrated using PLGA microparticles with surface anti-CD11c and anti-DEC205 antibodies (Lewis et al., 2012). These surface features specifically bind DC surface proteins, enabling significantly enhanced DC interactions and uptake. A series of in vitro and in vivo studies have shown that these biomaterials increase uptake and trafficking to the lymph node without causing the DC to release normal activation cytokines (Lewis et al., 2012). Biomaterial designs such as this one can be used to suppress function of specific autoreactive lymphocytes if administered at the same time as a target antigen because the antigen will be picked up by DCs in a tolerance-inducing environment (Iberg et al., 2017). A further study using microparticles encapsulating immunosuppressive drugs such as rapamycin and retinoic acid showed that DCs that took up these particles displayed reduced activation markers and resisted activation upon exposure to lipopolysaccharide, a known immune stimulant (Lewis et al., 2014). In addition, these DCs suppressed T cell activation in vitro, indicating a meaningful impact of the DC treatment on T cell effector function. These studies enable localized induction of



• **Figure 2.5.10.8** Biomaterial-mediated treatment of autoimmunity. Biomaterials loaded with immunosuppressive cytokines or drugs can take action within the lymph node to induce regulatory T cell formation or within peripheral tissue to suppress antigen presenting cell activation.

tolerance through T cell suppression, with the potential to be applied to targeted self-antigen tolerance to treat autoimmune diseases.

An alternative approach to targeted incomplete DC activation builds upon the observation that when a cell undergoes apoptosis, it releases antiinflammatory signals that suppress DC activation. This occurs as a safety mechanism in the body to prevent autoimmune activity against self-antigens released in the apoptosis process. Strategies to induce tolerance have been designed around this phenomenon by mixing self-peptides known to be involved in autoimmune disease with cells ex vivo, inducing apoptosis of these cells, and then injecting this solution of antiinflammatory signals with the self-peptide of interest into the body (Liu et al., 2002). This technique is currently in clinical trials, but because it requires whole cells, effective scaleup is uncertain (Kontos et al., 2012). An alternative acellular biomaterial strategy proposed for this problem is to instead design a fusion protein between the self-antigen of interest and a red blood cell surface-binding motif to bind the self-peptide to red blood cells already within the body and trigger DC uptake when these cells naturally go through apoptosis (Kontos et al., 2012). In the human body, 1% of red blood cells naturally go through apoptosis on a daily basis, so tolerance induction of peptide bound to any given red blood cell's surface can occur fairly quickly. DCs that take up the self-antigen of interest among the lysed red blood cell debris do so in antiinflammatory signaling conditions, resulting in incomplete activation, and T cell deletion or anergy upon presentation to the self-antigen specific T cells causing the autoimmune disease (Kontos et al., 2012). As this example suggests, biomaterial solutions can provide simple yet effective improvements over existing treatment options under consideration.

Elevation of Treg Activity to Induce Tolerance

Another natural tolerance mechanism in the body occurs through Treg action. These specialized T cells suppress activation and function of other cells, and as a result, reduced Treg activity is associated with decreased immune regulation, increased incidence of autoimmune disease, and transplant rejection (Cao, 2010). Options for Treg-mediated treatment include ex vivo expansion of Tregs followed by injection back into the body and in situ induction of naïve T cells toward a Treg phenotype using cytokine signaling. Of these two options, ex vivo expansion is more costly and time consuming, making in situ induction more appealing (Riley et al., 2010). Still, inducing a Treg phenotype has its own challenges and requires the controlled and sustained presence of the cytokines IL-2, transforming growth factor (TGF) beta, and rapamycin, making this naturally conducive to a biomaterial approach. Successful induction of Tregs from naïve T cells has in fact been achieved in vitro using PLGA microparticles encapsulating IL-2, TGF-beta, and rapamycin with controlled release rates over a 5-week period (Jhunjhunwala et al., 2012; McHugh et al., 2015). This platform is promising because the chosen particle size causes subcutaneously injected particles to remain at the injection site, offering localized and targeted immunosuppression. In fact, additional studies have shown that these microparticles can be used to treat allergic contact dermatitis following subcutaneous microparticle injection at a skin site that has come in contact with an allergen (Balmert et al., 2017). This is still a fairly new area of study and in vivo studies are not yet fully optimized, but in situ Treg control strategies made possible by biomaterials are on the horizon.

Suppression of B Cell Activation

Though much of the discussion to this point has dealt with controlling autoreactive T cells, humoral-mediated autoimmunity can also be controlled directly from the B cell source (Goodnow et al., 2005). Much like DCs and T cells, B cells also have natural tolerance induction mechanisms that may be exploited through biomaterial strategies (Crocker and Varki, 2011). B cells express many suppressive surface ligands of the SIGLEC family, including CD22, that engage at later stages of B cell activation to prevent overstimulation (Crocker and Yasukawa, 2011). Experiments have shown that when a BCR and CD22 ligand are forcibly held together, CD22 effectively inhibits activation, making this an interesting therapeutic approach (Duong et al., 2009). Polymers used to tether CD22 ligand and T cell-independent antigens were able to completely prevent antibody production against the antigen and even suppressed response upon free antigen rechallenge until an adjuvant was added (Duong et al., 2009). This effect has also been observed for T cell-dependent antigens. Liposomal nanoparticles coated with CD22 ligand and autoreactive self-antigens implicated in hemophilia are capable of completely suppressing production of self-antigen-specific antibodies and show functional improvement in treated mice being able to form blood clots (Macauley et al., 2013).

Concluding Remarks

Biomaterials find diverse applications in the induction of immune tolerance because they offer precise control over interactions between immune cells and specific antigens, and this makes them very effective at leveraging the many natural regulatory mechanisms the immune system has to offer. Successful tolerance-inducing strategies include induction of anergy or deletion in self-reactive lymphocytes, and in directing helper T cell activation toward the regulatory pathway to suppress unwanted effector function of other T cells. As was true in vaccine design, biomaterials enable engineered solutions to complex biological problems, and show promise to reshape our ability to reliably treat aberrant immune activity and autoimmune diseases in the future

Exercises

1. The antigen included in a vaccine for Virus A is a protein present on the virus' surface. What "type" of vaccine is it? List the advantages and disadvantages of this kind of vaccine, and list several reasons why other types of vaccines may be unsuitable for immunizing against Virus A.
   - The vaccine is likely a subunit vaccine, which only include a component of the original pathogen (protein, polysaccharide) as the antigen. Other types of vaccines mentioned in the text are live/attenuated and inactivated whole pathogen, and toxoid vaccines, which include either the whole pathogen or a toxic byproduct as antigen.
     - These other vaccine subtypes may be unsuitable if Virus A is too virulent to be included in live-attenuated form, or if it does not produce a toxic byproduct that can be immunized against.
   - Advantages: Subunit vaccines are very safe, meaning they may be administered to the elderly and immunocompromised versus other vaccine types. Additionally, they immunize against a specific epitope, meaning that the resulting immune response can be more carefully controlled.
   - Disadvantages: Immune responses with subunit vaccines tend to be shorter-lived and can require additional boosters.
2. List several of the ways in which Alum improves the efficacy of currently approved vaccines as an adjuvant, and suggest an alternate biomaterial strategy for each.
   - Extended release of adsorbed antigen: Strategies may include conjugation or adsorption of antigen to the surface of or encapsulation within a biomaterial particle or surface, such as a nano/microparticle, or to/within a depot-forming biomaterial substrate. Additional strategies could include degradable biomaterial formulations, linkages, etc.
   - Protection of antigen: Strategies listed above and below could accomplish protection of antigen, particularly encapsulation of antigen in biomaterial particle or depot.
   - Formation of depot (controversial, though is a valid answer): Injectable gels or polymeric matrices are strategies that would allow formation of a depot at the injection site.
   - Attraction of immune cells to site of injection: Use of immunogenic biomaterials such as alginate or hydroxyapatite (mentioned in the text) to induce a local immune response and attract additional immune cells.
3. Below are several components of a currently approved vaccine. For each of these components, list a biomaterial design that could enhance the safety or efficacy of the vaccine. Please use information from the chapter, or cite if obtained from an outside source.
   a. Whole inactivated virus (antigen)
   b. Adjuvant
   c. Stabilizing agents and preservatives
      - Answers may vary, this question is designed to be open-ended.
      - Antigen: More control could be exerted over an inactivated vaccine in terms of antigen presentation by incorporating a subunit from the pathogen into a biomaterial nanoparticle, provided that the pathogen has an immunogenic characteristic peptide. Additionally, this antigen could be conjugated to a biomaterial for enhanced delivery to APCs, or encapsulated within for added protection from proteases. Use of materials that degrade in the endosomal environment (low pH, ROS, reductive) could allow for enhanced antigen presentation and cross-presentation. Additionally, antigen could be incorporated within a depot-forming material for slow release from the injection site.
      - Adjuvant: Similarly, adjuvant could be incorporated into the same biomaterial nanocarrier as the antigen for co-delivery to the same APC in order to further enhance maturation and presentation/cross-presentation, or incorporated into the depot-forming material for extended release.
      - Stabilizing agents and preservatives: Typical vaccines are comprised of several excipients that extend the life of the antigen. Incorporating a biomaterial into the vaccine that protects or encapsulates the antigen could allow for stabilization such that fewer preservatives are needed, improving the safety of the vaccine as well as the efficacy as the antigen or pathogen is protected until it reaches its cellular target.
4. Your lab aims to design a vaccine that eliminates the need for multiple doses. List several broad strategies that could be utilized to accomplish this.
   - Stronger activation of immune system by targeted delivery to APCs. This can be accomplished using depot-forming materials, or nano/micro-particulate carriers to protect and co-deliver antigen and adjuvant.
   - Use of biomaterial that adjuvants the immune system itself.
   - Extended release formulation. This can be accomplished with depot-forming materials, slow-degrading polymers that allow protection of antigen for long periods of time.
   - Other answers may be acceptable provided they are reasonable or discussed in the chapter.
5. An existing vaccine is needed in an underdeveloped nation without adequate refrigeration or access to medical professionals, and thus needs to be reformulated in order ensure stability in a new environment.
   a. List three engineering constraints of this new vaccine, and how biomaterials could provide a solution.
   b. Design a formulation using specific biomaterials listed in this Chapter or in the literature (please cite if obtained from an outside source).

- 1) The vaccine needs to be stable without refrigeration, meaning it must be formulated to allow the antigen to be stable in a range of temperatures. Biomaterials could be used to stabilize the antigen by encapsulating it and thus protecting it from its environment, potentially allowing a lyophilized version to be utilized until delivering to patients. A microneedle strategy could be employed here for the above reasons.
- 2) The vaccine should be formulated in a manner that avoids the use of medical professionals. Biomaterials can help with this by potentially allowing for oral administration in pill form, which is easy and highly portable. It also allows breaking of the cold chain.
- 3) The vaccine should be long-lasting so that patients do not have to travel long distances for additional boosters. This can be accomplished by extended release formulations, biomaterials that protect antigen from degradation, or materials that allow for direct delivery to APCs.
- Design a formulation using specific biomaterials listed in the Chapter: Answers will vary, this question is designed to be open-ended.

6. Say you are looking to engineer a biomaterial therapy that eliminates adoptively transferred T cells in a patient's body after they are cured. Using strategies outlined in the chapter or in literature, hypothesize a biomaterial strategy that could accomplish this.
   - Similar to providing growth/survival factors to adoptively transferred cells *ex vivo*, the cells could be altered to express a unique marker that is targetable. At the desired time, one could administer a biomaterial containing 1) factors that would deplete the cells and 2) a targeting domain that is specific for the unique marker. However, there may be a variety of answers.
7. You are developing a new prophylactic vaccine in a mouse model and performing tests to assess its efficacy. Experiments show that your vaccine is not very effective in its current formulation. You check antibody titers in the blood and discover that insufficient quantities of antibody that can bind your pathogen are being produced.
   a. Why are antibody levels in the blood of interest when investigating prophylactic immunity?
   b. How might you modify your vaccine formulation to increase its potential to induce antibody production?

   Prophylactic immunity is intended to prevent damage from a pathogen before it even begins, which can be achieved if the pathogen is neutralized before it has the ability to harm cells and is still within the extracellular space. The best way to achieve effective prophylactic immunity against a pathogen is to have B cells that have already been exposed to it producing antibodies that bind to specific epitopes on that pathogen so that it can be neutralized. These antibodies circulate through the body and initiate neutralization of the pathogen very quickly upon encountering it.

   Your vaccine can be designed to increase its potential to activate B cells by building antigenic components of you target pathogen into a biomaterial with multivalency of B cell epitopes and incorporation of T cell-specific antigens also associated with that pathogen to engage helper T cells in B cell activation. Including an adjuvant or using a different type of adjuvant if already using one may also be valuable.
8. Describe how biomaterials may be engineered to bias immune activation toward a humoral response or toward a cytotoxic T cell (cell-mediated) response.

   Biomaterial vaccines designed with antigen multivalency and antigens associated with linked recognition may help stimulate B cell activation and increase humoral response. Designs with biomaterial carriers that degrade at endosomal pH or in the presence of endolysosomal lipases can increase the incidence of endosomal escape, resulting in more cross presentation by APCs and enhanced activation of cytotoxic T cells.
9. List the methods of tolerance induction discussed in this chapter. Would any of these treatments be compatible in combination with each other? Why or why not?
   - Incomplete dendritic cell activation causing T cell anergy or deletion
   - Elevation of Treg activity
   - Suppression of B cell activation
   - Yes, some of these treatments could be used in combination with each other because they act upon different stages of the adaptive immune response and on different cell types. For example, biomaterials administered to suppress full activation of dendritic cells could reduce the priming of new self-antigen specific effector T cells, while simultaneous treatment with biomaterials releasing IL-2, TGF-beta, and rapamycin could further direct T cells in the lymph node toward Treg function.
10. Look up an autoimmune disease of your choice and identify the mechanism of action for this disease (what is the biological cause of the disease or its symptoms?). What current treatment options are available? How might you design a biomaterial to induce tolerance in a way that improves upon these treatments?

    Answers will vary – this is meant to be open ended to stimulate independent study of ways biomaterials can improve the current state of medical treatment.

2.5.11

Biomaterials-Based Model Systems to Study Tumor–Microenvironment Interactions

BRITTANY E. SCHUTRUM[1,*], MATTHEW A. WHITMAN[1,*], CLAUDIA FISCHBACH[1,2]

Introduction

Cancer is the second leading cause of death, but treatment options remain limited. Statistically, each individual has a 38% chance of developing some form of cancer in his/her lifetime (Noone et al., 2018), and 18 million new cases were diagnosed worldwide in 2018 alone (Bray et al., 2018). In addition, cancer is associated with a significant economic burden and costs $1.16 trillion per year globally (WHO, 2018). These numbers become even more alarming considering that the incidence of cancer significantly increases with aging and that the number of Americans ages 65 and older is projected to more than double within the next 50 years (Mather et al., 2015). Despite significant research into the mechanisms underlying cancer, clinical outcomes have improved only slightly over the past decades, which is in contrast to other medical conditions where an increase in knowledge has more directly advanced patient prognosis (Benjamin et al., 2017; Cronin et al., 2018).

Cancer is traditionally thought to be caused by genetic abnormalities, but it is now clear that changes to the cells' microenvironment are equally important. Indeed, biochemical and biophysical perturbations of the tumor microenvironment (TME) including altered cell–cell and cell–extracellular matrix (ECM) interactions as well as perturbed transport and mechanical properties promote tumorigenesis by altering both the cells' phenotype and genotype (Bissell, 2007). For example, interactions of tumor cells with their surrounding ECM have been found to influence DNA damage responses with functional implications for DNA repair and thus, disease development (Hodkinson et al., 2006; Lewis et al., 2002).

Despite increasing appreciation of the microenvironment's role in regulating cancer development and progression, most in vitro studies still utilize 2D cell culture techniques originally pioneered in the early 20th century (Weigelt et al., 2014). The traditional approach of growing immortalized cancer cell lines as a monolayer on a Petri dish is often preferred as an easy way to expand, harvest, genotype, image, or treat a large number of cells with therapeutics. However, reducing the complexity of tumor models overlooks the importance of microenvironmental conditions and their impact on tumor heterogeneity, in regulating the pathogenesis, and therapeutic response of cancer. These shortcomings and the fact that cancers and the TME evolve over time may help explain why many anticancer compounds show promise in vitro, but often fail in vivo (Breslin and O'Driscoll, 2013).

Biomaterials are now increasingly used in combination with tissue engineering, microfabrication, or 3D printing technologies to create physiologically relevant model systems for cancer studies. For example, various types of biomaterials from natural and synthetic origins, and modifications thereof, not only allow recapitulating cancer-specific ECM composition, structure, and mechanics, but also readily permit coculture with heterogeneous cell populations and incorporation of vascular conduits. Furthermore, utilizing biomaterials together with biomanufacturing and body-on-a-chip approaches provides emerging opportunities to mimic both local phenomena and systemic signaling that can influence cancer development, progression, and therapy response. As such, biomaterials-based, engineered model systems provide

• **Figure 2.5.11.1** Microenvironmental changes during different stages of tumorigenesis. Carcinomas including breast, prostate, skin, and lung cancer all initiate in epithelial tissues. (A, B) Primary tumor development involves uncontrolled growth that leads to changes in tissue dimensionality and epithelial-to-mesenchymal transition (EMT) as well as stromal cell recruitment [e.g., cancer-associated fibroblasts (CAFs) and various immune cells (e.g., macrophages and T-cells)] and ECM remodeling. (B) These collective changes modulate blood vessel functions and increase intratumoral pressure both contributing to varied mass transport and, thus, gradients of nutrients and soluble factors. During invasion tumor cells migrate into adjacent healthy tissues using both single and collective cell migration modes. (C) Following intravasation into blood or lymphatic vessels, tumor cells travel through the circulation where they are exposed to shear forces. (D) After extravasation and dissemination to distant metastatic sites such as the bone, lungs, or the brain they may remain dormant for variable periods of time allowing them to evade therapy. However, local changes to their microenvironment (e.g., cellular composition or mechanical stimuli) can activate dormant tumor cells and enable the growth of metastatic tumors at these distant sites.

relevant platforms for basic and translational research and offer potential for patient-specific analysis of cancer malignancy and drug response in precision medicine settings.

This chapter will outline the biological, physical, and chemical changes intrinsic to the cancer microenvironment motivating critical design parameters for physiologically relevant tumor models. Subsequently, it will describe specific examples of natural and (semi-)synthetic materials and their respective advantages and disadvantages for tumor engineering. Finally, specific examples of biomaterials-based, state-of-the-art model systems will be described as well as opportunities for advanced applications of such systems in cancer research and drug testing.

Biological Design Considerations

Cancer is a group of diseases classified by an overproliferation of cells that ultimately results in their invasion of surrounding normal host tissue and spreading to distant sites in a process called metastasis (Fig. 2.5.11.1). This chapter focuses on carcinomas, which arise from epithelial tissues and are the most commonly diagnosed cancer type, but much of its content can be applied more broadly.

Tissue Dimensionality

The most fundamental biological adaptation in cancer cells is sustained proliferation, i.e., the ability of cells to divide independent of the presence of signaling molecules required for normal cell growth (Hanahan and Weinberg, 2011). Due to the resulting increase in volume, tumors lose many physical, epithelial monolayer-associated growth constraints and experience a disruption of their basement membrane during a process involving epithelial-to-mesenchymal transition (EMT) (Fig. 2.5.11.1A) (Kalluri and Weinberg, 2009). Dimensional changes to a cell's environment, as in the change from a 2D epithelial sheet to a 3D tumor, have profound effects on cell behavior, signaling, response to therapy, and cause phenotypic changes in the tumor cells themselves (Bissell, 2007; dit Faute et al., 2002; Fischbach et al., 2009).

Transport Phenomena and Interstitial Pressure

Because of the proliferation-induced change in tissue dimensionality and rapid increase in size, many tumors quickly outgrow the nutritive capacity of existing vasculature (Fig. 2.5.11.1B). The resulting deficit in nutrients and oxygen supply and accumulation of metabolic byproducts exposes cancer cells to hypoxic, acidic, and stressful conditions (Vaupel et al., 1989). Consequently, they often undergo a metabolic shift, known as the Warburg effect, where glycolysis is used to generate energy even in the presence of oxygen, in turn lowering microenvironmental pH through production of lactic acid (Hsu and Sabatini, 2008). Limited

• BOX 2.5.11.1 Tumor-Associated ECM Remodeling

Stromal cells are the primary mediators of protumorigenic ECM remodeling by altering both the biological and physical properties of the ECM (Lee et al., 2011). In particular, CAFs deposit increased amounts of collagen I, II, III, V, and IX, fibronectin, and heparan sulfate proteoglycans (Chandler et al., 2011; Lu et al., 2012) altering the composition of the ECM during tumor progression. They also release growth factors and cytokines and ECM remodeling enzymes including matrix-metalloproteinases (MMPs) (Gaggioli et al., 2007; Kalluri, 2016). CAFs are highly contractile cells that exert forces on the ECM. These forces contribute to the alignment of tumor-associated collagen fibers perpendicularly to the tumor boundary in invasive tumors (Conklin et al., 2011). CAFs can pull, stretch, and soften the basement membrane, enabling primary tumor invasion in an MMP-independent manner (Glentis et al., 2017). When CAFs exert tension on fibronectin fibers they can expose cryptic binding sites that modulate signaling directly or via differential sequestration of cytokines and growth factors (Arnoldini et al., 2017; Ortiz Franyuti et al., 2018).

vascularization also increases fluid pressure within a tumor, which in turn can alter cell malignancy and responsiveness to therapeutics (Nathan et al., 2005). Increased interstitial pressure can also limit solute transport via compression of blood and lymphatic vessels further fueling tumor progression and therapy resistance (Martin et al., 2016).

ECM Physicochemical Properties

Cancer-associated changes in ECM composition, structure, and mechanical properties are primarily mediated by stromal cells (Naba et al., 2012). Myofibroblasts—often referred to as cancer-associated fibroblasts (CAFs)—deposit fibrillar networks of ECM proteins, which they modify by proteolytic remodeling and force-mediated tension (Box 2.5.11.1; Fig. 2.5.11.1B). The resulting increase in ECM fiber thickness, alignment, and stiffness correlates with a more malignant and invasive tumor phenotype (Conklin et al., 2011; Levental et al., 2009). Indeed, changes in collagen fiber alignment and tumor stiffness direct tumor cell invasion by modulating cellular mechanosignaling (Provenzano et al., 2006; Wang et al., 2014) and can be useful prognostically (Conklin et al., 2011). Tumor-associated, ECM-dependent differences in tissue density and stiffness can be detected clinically via mammography and/or elastography and promote tumor cell malignancy independent of other factors (Fischer et al., 2013; Li et al., 2005; Paszek et al., 2005). While the mechanical properties of tumors are often described by their elastic moduli, tissues and their ECM are not linearly elastic but rather behave like viscoelastic materials, a difference that impacts disease progression and thus, should be considered in model design (Chaudhuri et al., 2016; Gong et al., 2018).

Immunological Changes

Typically, a properly functioning immune system is well prepared to protect against the development of cancer. However, many cancers have evolved alternative mechanisms that allow them to avoid immune destruction and even hijack the body's natural defense mechanisms, such as inflammatory or immunomodulatory signals, to enhance tumorigenesis (Grivennikov et al., 2010). For example, some immune cells secrete factors that promote invasion or angiogenesis, whereas others suppress the cytotoxic activity of other immune cells or upregulate enzymes that degrade the matrix and promote tumor spreading. A prominent example is M2-type macrophages, which, unlike their M1 counterparts, are involved in wound healing and increase tumor progression by remodeling ECM, inhibiting inflammation, and stimulating vasculogenesis (Mantovani et al., 1992; Pollard, 2004). Importantly, changes in substrate structure and mechanical properties can directly influence macrophage phenotype (Gruber et al., 2018; McWhorter et al., 2013; Springer and Fischbach, 2016). Furthermore, increased ECM density and intratumoral pressure serve as physical barriers to immune cell invasion, thus linking tumor-associated microenvironmental changes with immune suppression (Nyga et al., 2016). As collagen alignment has a promigratory effect on CD8+ T-cells, a change in the directionality of fiber alignment with respect to the tumor can promote or prevent T-cell infiltration depending on whether it is parallel or perpendicular to the tumor (Pruitt et al., 2019).

Biomaterials to Study the Tumor Microenvironment

As the ECM is centrally involved in regulating the aberrant interplay between many of the above-described biochemical and biophysical factors, engineered tumor models are mostly based on natural or synthetic biomaterials that mimic aspects of healthy and tumor-associated ECM (Table 2.5.11.1). Naturally derived biomaterials are intrinsically cytocompatible and—in most cases—present cell adhesion sites. However, they are subject to batch-to-batch variations and can be costly. In contrast, synthetic biomaterials can be produced in large quantities, are relatively cost-efficient, and allow for the establishment of models with tunable biological and physical properties including mechanics, adhesion receptor-binding sites, degradability, soluble factor sequestration, and introduction of moieties that enable dynamic modification during the culture period (Mabry et al., 2015; Tse and Engler, 2010). Nevertheless, while synthetic materials allow for more control over material properties, they do so at the cost of reduced in vivo-like biologic interactions.

Natural Biomaterials

Protein-Based Materials

Matrigel is one of the most commonly used, naturally derived materials for tumor modeling (Lee et al., 2007). As it contains tumor-derived morphogens including basement membrane components laminin, collagen IV, and entactin as well as growth factors, cytokines, enzymes, and proteoglycans, it

TABLE 2.5.11.1 Natural and Synthetic Biomaterials for Cancer Research With Select Application Examples and Available Commercial Products

Class	Material	Material Origin	Advantages	Disadvantages	References
Natural	Matrigel	- Mixture of basement membrane proteins - Isolated from Engelbreth-Holm-Swarm (EHS) mouse sarcoma	- Inherent ease of use - Contains many different morphogens - Contains many different ECM components - Cells can remodel and degrade - Supports the growth and invasion of many different cell types	- Large batch-to-batch variability - High cost - inability to tune structural and mechanical properties - contains tumor-derived morphogens that prevent isolating ECM effects - Low stiffness prevents use in certain biomanufacturing applications	Lee et al. (2007) Drost et al. (2016) Poincloux et al. (2011) Corning (2019)
	MaxGel				Millipore Sigma (2019a)
	Collagen I	- Most abundant ECM component - Isolated from bovine skin and tendons, or porcine skin	- Forms hydrogels with fibrillar structure - Possible to control fiber diameter, pore size, and density by adjusting gelation conditions - Contains natural integrin-binding sites - Cells can remodel and degrade	- Lacks complexity of native ECM - Limited range of mechanical properties	Wolf et al. (2009) Jeon et al. (2013) Polacheck et al. (2011) Choi et al. (2019)
	SpongeCol PureCol				Millipore Sigma (2019b) Advanced BioMatrix (2019)
	Hyaluronic acid (HA)	- Polysaccharide composed of repeating units of β-1,4-D-glucuronic acid - β-1,3-*N*-acetyl-D-glucosamine - Isolated from bovine testicles or rooster combs or produced recombinantly	- Enzymatically degradable by hyaluronidase - contains binding sites for cell adhesion receptors including CD44 and CD168 - Can be modified to enable synthetic control of materials properties - chemical modifications permit control over mechanical and degradation features	- Limited mechanical tunability if unmodified - Requires chemical modification for cell binding via integrins - CD44-binding site can interfere with cellular functions - Functionalization may interfere with cell binding sites	Xiao et al. (2018) Xu et al. (2012) Gurski et al. (2009) Lou et al. (2018)
	HyStem				Millipore Sigma (2019c)
	Alginate	- Block copolymer comprised of guluronate and mannuronate - Derived from brown algae	- ionic cross-linking using bivalent cations is cell-compatible - Stiffness and architecture can be independently modified	- Nonadhesive to cells - Integrin-binding sites must be chemically introduced - Lacks fibrillar structure	Fischbach et al. (2009); Wisdom et al. (2018) Stowers et al. (2017) Xu et al. (2013)
	AlgiMatrix 3D				(ThermoFisher, n.d.)
	Agarose	- Polysaccharide comprised of D-galactose and 3,6-anhydro-alpha-L-galactopyranose isolated from red algae	- Nonadherent for cells allowing for attachment-free culture such as spheroid generation - Historically used in colony formation assays to determine tumorigenicity of cells	- Lacks physiologically relevant microstructures	Vidavsky et al. (2018) Friedrich et al. (2009)
	Cell-derived matrices (CDM)	Matrix deposited by cells seeded on coverslips in vitro	- cellularly derived matrices have properties unique to the cell type of origin - Preserves native ECM protein and proteoglycan composition - Retains microscale structural features of ECM	- Time and labor intensive to produce - Cells can only be seeded on top - Naturally heterogeneous with batch-to-batch variability - Mechanical properties cannot be tuned readily	Serebriiskii et al. (2008) Seo et al. (2015)
	Whole-tissue decellularization	- Cells removed from a whole tissue keeping the large-scale structure and matrix composition intact	- Preserves native 3D architecture and large-scale structure - Larger size and thickness allows for a true 3D cell culture unlike CDMs - Preserves native ECM protein and proteoglycan composition	- Difficult to produce - May require perfusion setup - Low throughput due to time- and skill-intensive setup	Tian et al. (2018) Marturano-Kruik et al. (2018) Piccoli et al. (2018)

Synthetic	Polyacrylamide (PA)	- Acrylamide monomers cross-linked with bis-acrylamide	- Can be modified with different cell adhesion ligands - Wide stiffness range - independent control of stiffness and cell adhesion motifs possible	- Cannot be used for cell encapsulation due to monomer toxicity - Nondegradable - Static stiffness	Labernadie et al. (2017) Pathak and Kumar (2012) Nasrollahi et al. (2017)
	Poly (ethylene glycol) (PEG)	- Comprised of repeating units of ethylene glycol of varying lengths - Terminally functionalized and polymerized via many chemistries	- Can be chemically modified to allow for different reaction chemistries, mechanical properties, degradation mechanisms, and cellular interactions - Easily modified affording the resulting hydrogels a broad range of materials properties - chemical modification can yield a dynamic material	- Lacks inherent degradability - modification with cell adhesion sites is necessary for cellular interactions - Lack of ECM complexity and fibrillar structure - Reliance on UV-mediated cross-linking may bring harm to cells	Lohmann et al. (2017) Gill et al. (2012) Sieh et al. (2012)
	Poly (lactic-co-glycolic acid) (PLGA)	Linear copolymer made of lactic acid (LA) and glycolic acid (GA)	- Can be fabricated into porous or fibrous in substrates - Biodegradable with precisely tunable degradation rates by varying the molecular ratio of LA and GA - Can be surface modified to promote cell–material interactions	- Decreases the pH around cells during degradation - Limited tunability of mechanical properties - Substrates are typically stiffer than native ECM	Pathi et al. (2011) Fischbach et al. (2007) Kim et al. (2011)

readily supports the growth and invasion of many tumor cell types without further manipulation or materials modification. However, large batch-to-batch variability, high cost, and an inability to mimic the structural and mechanical properties of the ECM in human tumors are primary disadvantages of its use (Debnath and Brugge, 2005). Included tumor-derived morphogens may prevent isolating the independent effect of specific biomolecules on tumor growth. Finally, Matrigel is a very soft material and, thus, cannot be used in certain biomanufactured culture models. For example, it is not readily possible to pattern microfluidic conduits into Matrigel to mimic blood vessel-mediated transport properties.

Given its high abundance in tumor-associated ECM, collagen is another ECM component that is frequently used to create 3D culture models of cancer. As the most abundant and easy to process, type I collagen is the primary type used for cancer studies. Type I collagen consists of proteins with a triple helical structure that self-assemble into aggregates called fibrils and then larger collagen fibers (Parenteau-Bareil et al., 2010). In vitro fibrillar architecture and biochemical composition can vary depending on the source of collagen (Wolf et al., 2013). It is possible to adjust biophysical properties by modifying gelation conditions and/or introducing additional physical or chemical cross-links. For example, highly tunable gels with controlled fiber structure and porosity can be formed by adjusting the gelation temperature, the ionic strength of the gelation medium, and/or the pH of the collagen solution (Sapudom et al., 2015; Wolf et al., 2009). Furthermore, fiber alignment can be achieved by casting collagen into prestretched molds that are relaxed following gelation (Brownfield et al., 2013; McCoy et al., 2018). Collagen is biodegradable, biocompatible, remodelable, and contains intrinsic cell adhesion sites. However, collagen only allows limited variation of mechanical properties. While procedures such as nonenzymatic glycation can be used to cover a wider range of rigidities, they are often not suitable to recreate mechanical properties of hard tissues relevant to cancer (e.g., bones) and may also cause secondary, stiffness-independent effects in cells, e.g., through activation of RAGE receptors (Roy et al., 2009; Sharaf et al., 2015). Introducing cross-links with chemicals such as aldehydes, carbodiimides, or isocyanates can yield a broader range of stiffnesses, but may be toxic to cells (Parenteau-Bareil et al., 2010). Finally, structural features of the collagen fibers produced in vitro differ from those produced in vivo. In vitro, many thin disorganized fibers spontaneously form, while thick cross-linked fibers form as a result of enzymatic lysyl oxidase (LOX) activity in vivo (Pawelec et al., 2016).

Carbohydrate-Based Materials

Hyaluronic acid (HA) is most abundant in the brain and, thus, is frequently used for studies of brain cancer (Chen et al., 2018). Nevertheless, HA is also present in the ECM of a desmoplastic ECM in tumors (Bertrand et al., 1992). Consequently, HA produced using recombinant technologies or isolated from bovine testicles or rooster combs is increasingly used for engineering models of the tumor microenvironment. In addition, HA is cell-remodelable through enzymatic degradation by hyaluronidase and readily binds to cell adhesion receptors including CD44 and CD168; to allow for interactions via integrins, integrin-binding ligands such as RGD can be introduced chemically (Park et al., 2003). HA can be modified with many functional groups to enable polymerization into a hydrogel via addition/condensation reactions or through photochemically induced radical polymerization (Burdick and Prestwich, 2011). These chemical modifications can also be used to control mechanical and degradative features of the material (Burdick and Prestwich, 2011). However, varying the physicochemical properties of HA through chemical modifications can interfere with available cell adhesion domains.

Carbohydrate-based alginate is frequently used to study tumor cells in both 2D and 3D culture formats. Its cross-linking density and thus, stiffness, can be controlled via adjusting the density of ionic cross-links through modulating the concentration of bivalent cations such as Ca^{2+}, varying the molecular weight or ratio of guluronic to mannuronic acid monomers, and/or introducing chemical cross-links (Lee and Mooney, 2012). Alginate is typically nonadhesive to cells but can be readily modified with adhesion ligands such as RGD to enable integrin engagement. Hence, alginate substrates can be used to compare cell behavior under 2D and 3D culture conditions with and without integrin engagement (Fischbach et al., 2009). Furthermore, cross-linking alginate in the presence of collagen can be used to produce interpenetrated networks that offer independent control over mechanical properties, gel structures, and adhesive ligand presentation (Branco da Cunha et al., 2014).

Agarose is commonly used for colony formation assays that test a cell's ability to survive under anchorage-independent conditions, an indicator of their tumorigenicity (Borowicz et al., 2014). Agarose is biocompatible, undergoes thermoreversible self-gelation, and can be chemically modified for a multitude of applications (Zarrintaj et al., 2018). When combined with collagen, agarose can be used to increase the elasticity of 3D collagen networks over two orders of magnitude with negligible effects on collagen fiber organization (Ulrich et al., 2010). Such platforms enable studies of cell migration as a function of cell-induced stress dissipation via individual ECM fibers versus deformation of the continuum network.

Cell- and Tissue-Derived Materials

To preserve the composition, structure, and mechanical properties of native ECM, decellularized scaffold systems have been developed (Crapo et al., 2011). So-called cell-derived matrices (CDMs) are produced by letting a monolayer of cells grow and deposit ECM. Subsequent removal of these cells using detergent-based protocols leaves behind matrices that contain both protein- and carbohydrate-based ECM components. The stability, mechanical properties, or biochemical composition of CDMs can be altered by modifying the culture protocol. For example, supplementing ascorbic acid to the cell culture medium increases collagen production, while varied glucose concentrations can be used to modulate

deposition of fibronectin and collagen IV (Miller et al., 2014). Alterations can also be made by chemically cross-linking cell-free matrices (Franco-Barraza et al., 2016). To study the behavior of premalignant or cancer cells as a function of varied ECM characteristics, CDMs can be prepared from normal or tumor-associated stromal cells or from stromal cells residing in tissues known to control tumorigenesis (e.g., adipose stromal cells) (Beachley et al., 2015; Franco-Barraza et al., 2016; Seo et al., 2015). While CDMs are suitable to mimic microscale features of the ECM in vitro, the resulting substrates are relatively thin (approx. 10–20 μm) and do not recapitulate macroscale features of the ECM. Furthermore, cellular ECM deposition depends on the underlying substrates (Kubow et al., 2009; Loebel et al., 2019). Hence, culturing cells on plastic for CDM generation may induce artifacts. Whole-organ and tissue-level decellularization may be used to circumvent these limitations while preserving the native 3D architecture and complexity of tissues and organs (Mayorca-Guiliani et al., 2017). Indeed, decellularized tissues and organs, which are formed through perfusion of mild detergents, salt solutions, and cell culture media, have been used as model systems for research as well as in clinical applications (Faulk et al., 2014). In addition to presenting macroscale tissue architecture, decellularized tissues and organs retain microscale features such as blood vessels and/or spatial variations of specific matrix niches. These features allow for studying cells in 3D matrix microenvironments with compositional and structural features most like what is seen in vivo. Tissue or organ decellularization methods are subject to diffusional constraints of decellularization fluids and thus, often require perfusion setups. Furthermore, limits on the number of tissues and the time needed to prepare such platforms reduces the throughput achievable with this approach.

Synthetic Biomaterials

Synthetic Hydrogels

Polyacrylamide (PA) is widely used to study cell behavior on hydrogel surfaces of varying stiffness (Wang and Pelham, 1998). PA hydrogels are composed of acrylamide monomers cross-linked with bis-acrylamide in different ratios to control the mechanical properties of the resulting gels. These hydrogels are typically formed on aminosilane functionalized coverslips and the gel surface can be modified with cell adhesion ligands. By conjugating different types or concentrations of cell adhesion ligands onto PA gels of different stiffnesses it becomes possible to study the individual versus combined effects of substrate chemistry and mechanics on cell behavior (Caliari and Burdick, 2016; Peyton and Putnam, 2005). A significant drawback of PA-based platforms is that cells cannot be encapsulated inside the gels due to toxicity of the hydrogel precursors. This prompted the need to develop biocompatible hydrogel materials for 3D culture applications.

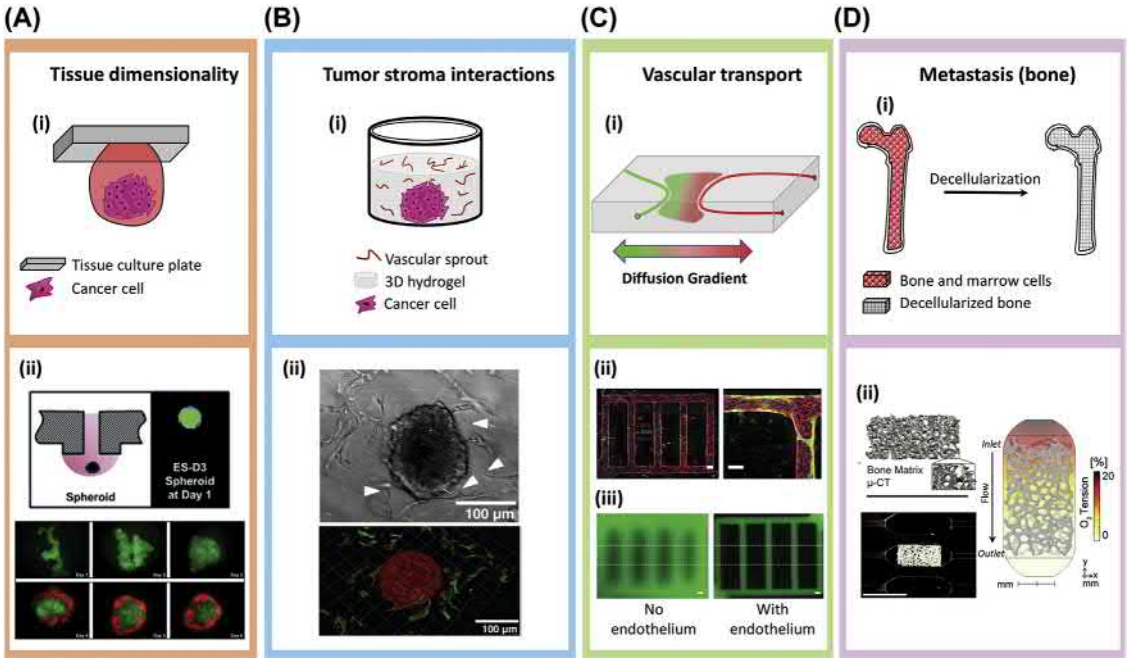
Due to highly tunable chemistries, mechanical properties, degradation mechanisms, and cellular interactions, poly(ethylene glycol) (PEG) is commonly used (Cushing and Anseth, 2007; Lin and Anseth, 2009). PEG's broad utility is demonstrated by its use for photoencapsulation of osteoblasts (Burdick and Anseth, 2002), as an MMP-degradable hydrogel for the study of stromal or tumor cells (Lutolf et al., 2003), and as a vehicle for controlled release of biomolecules (Lin and Anseth, 2009). PEG's lack of complexity and fibrillar structure, and reliance on cross-linking techniques which may bring harm to cells are notable drawbacks. In particular, cross-linking via photopolymerization uses UV light and a photoinitiator to start the cross-linking can affect cell viability and activate DNA damage response pathways, influencing tumorigenesis confounding results (Fedorovich et al., 2009; Smith et al., 1995).

Polyesters

Biodegradable polyesters like polylactic acid (PLA), polyglycolic acid (PGA), and poly(lactic-co-glycolic) acid (PLGA) can be processed into cell culture scaffolds with different porosities (e.g., by gas-foaming particulate leaching) or fibrillar architectures (e.g., by electrospinning) to mimic the structural properties of the ECM (Brown et al., 2012; Fischbach et al., 2007). While cellular interactions with such scaffolds are typically enabled via adsorbed serum proteins, surface modification with defined adhesion ligands is also possible (Hersel et al., 2003). Polyester-based scaffolds have limited tunability of mechanical properties and decrease local pH with acidic degradation products (Fu et al., 2000). Decreased tumor pH has been associated with selective survival of cancer cells, inhibition of DNA repair leading to further mutations and transformations, and stimulation of invasion (Gatenby and Gillies, 2004). Thus, decoupling scaffold from tumor-induced changes in pH when using PGA, PLA, or PLGA scaffolds for cancer research is essential.

Composite Materials

Materials composed of both natural and synthetic biomaterials take advantage of the well-defined nature and sophisticated tunability of synthetic components while providing the functionality and complexity of native ECM molecules. For instance, functionalized PEG can be cross-linked to modified heparin molecules in various ratios to achieve independent control of stiffness, cell binding, and growth factor sequestration (Lohmann et al., 2017). Other groups take the opposite approach and modify natural ECM components like HA with synthetic moieties (Rosales et al., 2018). Direct chemical modification of HA can preserve its native cell-binding sites and cytocompatibility and expand the range and dynamics of the physical properties of HA. Natural inorganic components can also be combined with synthetic polymers. Both bone powder and nanoparticles of the bone mineral hydroxyapatite have been incorporated into PLGA scaffolds to study tumor–mineral interactions that may be relevant to bone metastasis (Lynch et al., 2016; Pathi et al., 2010). Finally, other materials draw inspiration from natural components and chemistry such as glutamine-to-lysine peptide bridge formation during fibrin clot formation to create PEG hydrogels with fibrin-like characteristics that can be cross-linked by the addition of factor XIIIa (Ehrbar et al., 2007).



• **Figure 2.5.11.2** Examples of biomaterials-based model systems to analyze tumor–microenvironment interactions. (A) Tissue dimensionality: (i) Multicellular spheroids simulating 3D cell–cell and cell–ECM interactions can be formed on a tissue culture plate using the hanging drop method. (ii) To generate uniformly sized and complex spheroids injection molded polystyrene plates with microfluidic channels that open at the bottom may be used. This approach enables multistage cell seeding to produce concentric layers of one or more cell types. (B) Tumor stroma interactions: (i) Encapsulating tumor spheroids into hydrogels containing different stromal cell types (e.g., endothelial cells) mimics aspects of tumor–stroma interactions. (ii) Hepatocarcinoma spheroids coembedded with endothelial cells into peptide-modified, growth factor-sequestering starPEG-heparin hydrogels stimulate vascular sprout formation (green: CD31; red: F-actin). (C) Vascular transport: (i) Microfluidic platforms allow for intricate arrangements of channels that can simulate mass transport through tumors. (ii) Perfusable and pericyte (green)-associated vascular networks can be established using microfabricated collagen-I hydrogels. (iii) Perfusion of FITC-labeled dextran through vessels without (left) and with endothelial cell coating (right) demonstrate the importance of endothelialization for modeling diffusivity of molecules into surrounding matrix. (D) Metastasis (bone): (i) Decellularized organs and tissues such as bone can provide culture substrates that preserve organic matrix structure and naturally occurring soluble factors that may not be effectively modeled by synthetic systems. (ii) μ-Computed tomography (μ-CT) shows that decellularized bone maintains its mineral content and structure. When embedded into microfluidic devices and seeded with endothelial cells and bone marrow-derived MSCs, decellularized bone serves to establish culture environments with varied oxygen tension for studies of bone metastasis. Applications of Biomaterials-Based Tumor Models

Analyzing the Effect of Tissue Dimensionality

By enabling 3D cell–cell and cell–ECM interactions, multicellular spheroids recapitulate many important characteristics of 3D tumors including changes in cell morphology, tissue-scale structural features, and mass transport dynamics (Tung et al., 2011). Spheroids can be formed via the hanging drop method, which involves simply pipetting small volumes of cell suspension onto a polystyrene (PS) surface, inverting it, and placing it in an incubator to encourage the formation of cell aggregates (Fig. 2.5.11.2Ai). However, the resulting spheroids are in a low volume of culture medium per droplet and tend to be irregularly shaped. Circumventing some of these limitations, droplets of culture medium and cancer cells can be suspended vertically from a specially made PS plate (Fig. 2.5.11.2Aii) (Tung et al., 2011)

resulting in uniformly shaped spheroids that can be produced in different sizes, enabling testing of drug and nutrient diffusion as a function of tumor growth. Spheroids can also be generated in 96-well plates coated with low-melt agarose gel, which prevents cell adhesion (Friedrich et al., 2009; Vidavsky et al., 2018; Yuhas et al., 1977), using commercially available ultralow attachment culture surfaces, or by growing cells in pyramidal microwells (Strathearn and Rothernberg, 2012; Ungrin et al., 2008).

Instead of inducing cell–cell contacts by physically aggregating cells, 3D cellular interactions can also be mimicked by seeding tumor cells into polymeric scaffolds or hydrogels. For example, tumor cells seeded into porous PLGA scaffolds form 3D histological structures that resemble those of tumors formed by the same cells implanted into mice (Fischbach et al., 2007). Exposing cancer cells to 3D tissue contexts significantly changes their signaling (Fischbach et al., 2009) and gene expression (Bissell, 2007) due to a variety of mechanisms including differential integrin engagement, cell–cell contact, as well as responses to tumor-intrinsic microenvironmental cues including hypoxia (DelNero et al., 2015; Fischbach et al., 2009; Tan et al., 2009).

To more directly identify the molecular mechanisms by which changes in direct cell–cell contact may influence cell behavior, it is possible to covalently couple adhesion molecules normally expressed on a cell's membrane onto a PDMS stamped micropatterned PEG hydrogel designed for single-cell culture (Lutolf et al., 2009). For example, PEG hydrogel microwells can be surface-modified with intercellular adhesion proteins such as N-cadherin, VE-cadherin, I-CAM, V-CAM, P-Sel, and Jag-1. Single cells seeded into the modified microwells interact with these proteins as if they were expressed by other cells. Such a system allows for isolation and direct study of cell–cell contacts via interaction of specific protein-binding pairs. This has identified how single-cell division kinetics are impacted by intercellular adhesion proteins and how these correlate to in vivo function (Lutolf et al., 2009). Furthermore, modification of the mechanical properties of PEG in this platform allows for studies of cellular interactions as a function of both adhesion domains and substrate mechanics.

Modeling Tumor–Stroma Interactions

To determine the impact of nontumor cells such as vascular cells, fibroblasts and immune cells on tumorigenesis, 3D coculture models have been developed. Perhaps most simplistically, incorporation of stromal cells such as CAFs into tumor spheroids permits studying how interactions between both cell types influence cancer cell behavior and has revealed increased expression of alpha-smooth muscle actin, epidermal growth factor receptor, and reduced expression of beta-catenin and E-cadherin, consistent with EMT phenotypes (Kim et al., 2015). While coculture spheroids can be studied in isolation, they can also be combined with artificial ECMs. For example, seeding coculture spheroids onto PA gels of varied stiffness elucidated that mechanically active heterotypic adhesion between CAFs and tumor cells can drive cancer cell invasion (Labernadie et al., 2017). Nevertheless, during initial stages of tumor development, stromal cells primarily grow peripherally to a newly forming tumor rather than inside. Thus, seeding individual stromal cells and cancer spheroids separately into hydrogels may more closely simulate this early-stage cancer scenario (Fig. 2.5.11.2Bi). Indeed, culturing endothelial cells and mesenchymal stem cells (MSCs), together with tumor cells in peptide-modified, MMP-degradable PEG-heparin hydrogels recapitulates processes such as tumor-associated angiogenesis and stromal remodeling (Fig. 2.5.11.2Bii). Furthermore, such a platform can help identify the role of specific ECM-binding motifs in driving tumor cell invasion as a function of varied stromal compositions (Taubenberger et al., 2016).

Given the central role of the immune system in regulating cancer progression, dendritic cells, T cells, macrophages, natural killer cells, and lymphocytes have all been combined with cancer cells in coculture models (Nyga et al., 2016). The goal of such coculture models is to generate humanized immunocompetent cancer models for in vitro studies of tumor evasion of immune responses. For example, Algimatrix, a commercially available porous alginate scaffold, permitted coculture of breast cancer cells, fibroblasts, and macrophages, and revealed that spheroid formation was promoted with the triple coculture but reduced in the absence of macrophages (Rama-Esendagli et al., 2014). Incorporating regulatory T cells and natural killer cells into biomaterial cultures has been accomplished in Matrigel, and showed that NK cells alone reduced cancer cell growth, while regulatory T cells alone did not significantly reduce the size of the cancer aggregates, suggesting an important role for NK cells in cancer control (Augustine et al., 2015).

Platforms to Interrogate Cell–ECM Interactions

To study the effect of cell–ECM interactions on various processes contributing to tumor malignancy, nonadhesive hydrogels can be covalently modified with full-length ECM proteins or specific peptide sequences of these ECM proteins (Fischbach et al., 2009; Tibbitt and Anseth, 2009). For example, coupling RGD (fibronectin), IKVAV (laminin), and GFOGER (collagen type 1) into synthetic or composite materials at varying concentrations allows isolating the effect of varied integrin clustering and signaling on cell behavior (Taubenberger et al., 2016). Such studies can be performed in isolation and/or in the presence of altered hydrogel mechanical properties, which permits elucidating the integrated effects of tumor-associated changes in ECM composition and mechanics on cellular phenotypes (Hogrebe et al., 2018; Peyton et al., 2006). One specific example enabling such studies includes alginate hydrogels. Their mechanical properties can be readily adjusted by varying the cross-linking density, while integrin ligation (Box 2.5.11.2) can be modified by changing adhesion peptide presentation and/or mixing with Matrigel to form alginate-based interpenetrated networks (Chaudhuri et al., 2016, 2014). Similar studies can be performed with PEG hydrogels (Kyburz and Anseth, 2013; Zhu, 2010), but PEG-based hydrogels do not recapitulate the fibrillar features of native tumor ECM.

• BOX 2.5.11.2 Integrins

Cells sense and interact with their ECM environment through integrins, which are transmembrane heterodimers that consist of different alpha and beta subunits. Integrins link the ECM to the cytoskeleton and regulate cell signaling through many different pathways including growth factor receptor signaling and mechanotransduction (Alberts et al., 2002). In addition to this outside-in signaling, integrins are also involved in inside-out signaling where changes in cell signaling mediate differences in ECM remodeling (Hynes, 2002; Miranti and Brugge, 2002).

• BOX 2.5.11.3 Traction Force Microscopy (TFM)

To measure the forces cells exert on an underlying substrate and gain clues about mechanosignaling, researchers use TFM. In this technique, fluorescent beads are embedded into PA gels of varying stiffness. Following modification of the gel surface with ECM adhesion molecules, cells are seeded on top and images are captured to mark the locations of the beads under tension from the cell. Next, trypsin, an enzyme, is used to remove the cells from the gel surface and images are acquired of the relaxed gel (Dembo and Wang, 1999). The forces the cell exerts on the gel are calculated from the displacement of the beads (Munevar et al., 2001; Plotnikov et al., 2014). These same principles can be applied to 3D systems through encapsulation of cells within MMP-degradable, fluorescent bead-containing PEG hydrogels (Legant et al., 2010). However, determining 3D traction forces is computationally challenging and requires special expertise, limiting its usability by nonexpert labs (Polacheck and Chen, 2016). Furthermore, the temporal and spatial resolution of confocal-based TFM is limited. Therefore, alternative TFM methods have been developed employing other imaging techniques such as optical coherence microscopy (Mulligan et al., 2017).

To mimic the structural properties of ECM in vitro, methacrylated dextran can be electrospun to produce substrates with fibrillar microarchitecture whose bulk and fiber elastic moduli may be tuned separately (Baker et al., 2015). Studies using this system revealed that cells adhering to matrices with soft fibers spread more than cells adhering to matrices with stiff fibers, but similar bulk stiffness. These experiments identified a new mechanism for how cells probe and respond to fibrillar ECM and suggested that bulk mechanical properties are not the only regulator of mechanosignaling (Baker et al., 2015).

In addition to varied fiber characteristics, pore size also changes in tumor-associated ECM and plays a role in determining whether tumor cells use individual or collective cell migration modes to invade interstitial spaces in vivo (Friedl et al., 2012a,b). Enabling such studies are, for example, collagen gels whose pore size can be adjusted by varying the gelation temperature or pH (Wolf et al., 2009). However, varying the pore size of collagen simultaneously changes fiber thickness, which may independently influence cell behavior (Liu et al., 2019). To separate pore size-dependent differences in cell confinement from substrate stiffness, micropatterned PA gels with independent control over channel size and material stiffness may be used (Pathak and Kumar, 2012). Experiments using such a 3D platform revealed that within similarly stiff substrates, cells migrate faster in small channels than in wide channels or on 2D controls. Additionally channels formed within stiffer substrates promoted cell migration speed, whereas high substrate stiffnesses may reduce cell migration speed in 2D culture (Peyton and Putnam, 2005). Despite the many insights that may be generated with the above models it has to be noted that fibers contained in tumor ECM not only vary in their microscale structure, but may additionally exhibit conformational changes (Arnoldini et al., 2017; Chandler et al., 2011; Wang et al., 2015). To more fully understand the effect of nano-, micro-, and macroscale matrix properties on tumorigenesis, experimental platforms will be needed that allow assessing the interactions between cells and tumor-associated ECM across multiple length scales.

While most commonly used hydrogels to study cell–ECM interactions exhibit purely elastic behavior and, thus, can be used to estimate differences in cellular mechanosignaling using traction force microscopy (TFM) (Box 2.5.11.3), biological tissues and ECMs behave like viscoelastic materials with functional consequences on cell behavior (Chaudhuri et al., 2016). Unlike in purely elastic materials, which recover from stress rapidly, the cell–material response of a viscoelastic material depends on both the timing of the molecular response within the cell and the rate of relaxation of the material (Gong et al., 2018). To account for these differences and study cell behavior as a function of ECM viscoelasticity, alternative materials systems have been developed. For example, alginate covalently bound to PEG spacers and ionically cross-linked via Ca^{2+} ions responds to stress viscoelastically (Chaudhuri et al., 2016; Nam et al., 2019). Stress relaxation rates in this system can be tuned by adjusting the molecular weight of alginate and concentrations of the PEG. Cells encapsulated within an alginate–PEG hydrogel differentiate, spread, and proliferate differently than cells in elastic materials. Entrapping linear, high-molecular-weight PA chains into cross-linked PA networks may also be used to characterize the effect of substrate viscous dissipation on cellular mechanosignaling (Charrier et al., 2018). Indeed, studies using such a platform revealed that cells adhering to viscoelastic matrices develop lower traction forces due to substrate-dependent energy dissipation. While both the above materials systems can be used to recapitulate ECM viscoelastic properties, they lack the fibrillar structure of native ECM. As an alternative, HA–collagen interpenetrating networks merge structure with viscoelasticity and were found to promote focal adhesion formation and matrix remodeling (Lou et al., 2018).

Dynamic Materials Systems for Studies of Mechanical Memory

The tumor microenvironment is not static but is subject to constant changes that can mediate the selection and transformation of specific tumor and stromal cell types. To study the

underlying mechanisms, a variety of sequential cell culture approaches or dynamic model systems may be used. For example, preconditioning cancerous and noncancerous epithelial cells on stiff PA gels mediates their transition to a more migratory phenotype that is maintained even after cells are transferred to softer gels (Nasrollahi et al., 2017). Similarly, fibroblasts cultured on 2D silicone substrates with tumorlike stiffness undergo a phenotypic shift to myofibroblasts. This phenotypic switching is time-dependent, as myofibroblast differentiation on stiff substrates for short culture periods is reversible, but irreversible after long culture periods (Balestrini et al., 2012). A time-dependent mechanical memory was also demonstrated in hMSCs precultured on PEG gels or silicone substrates of varying stiffness (Yang et al., 2014) and was attributable to microRNAs that preserved a mechanically induced fibrotic response phenotype (Li et al., 2017). Collectively, these results suggest that both tumor and stromal cells have a memory of their past mechanical environment and that these changes may contribute to tumor-associated fibrotic remodeling.

To more directly test dynamic effects of material degradation or mechanical properties on encapsulated cells, delayed secondary cross-linking approaches can be utilized (Khetan et al., 2013; Lutolf et al., 2003; Mabry et al., 2015; Moon et al., 2010; Rosales et al., 2018). Incorporating MMP-degradable peptide sequences into HA or other hydrogels enables cells to drive secondary modification via MMP-mediated degradation and remodeling (Lutolf et al., 2003; Moon et al., 2010). A secondary cross-linking reaction later during the culture period inhibits additional enzymatic degradation and isolates the effect of degradation-induced changes on cell phenotype (Khetan et al., 2013). To model MMP-independent, reversible changes in substrate mechanical properties, cells may be encapsulated within HA-based hydrogels that contain supramolecular cross-links formed via azobenzene bound to β-cyclodextrin (Rosales et al., 2018). Exposing these systems to either 400–500 or 365 nm light can be used to reversibly stiffen or soften these materials in a spatially and temporally controlled manner. Dynamic stiffening can also be accomplished with PEG-based systems using delayed thiolene polymerization (Mabry et al., 2015). Experiments using such systems suggest that myofibroblast differentiation in 3D MMP-degradable environments depends on cell spreading rather than substrate stiffness as soft hydrogels not only promoted cell spreading, but also myofibroblast differentiation. In contrast, delayed stiffening of soft, myofibroblast-incorporating hydrogels led to fibroblast deactivation. These results complement the above-described 2D studies on substrate-mediated dynamic changes of myofibroblast differentiation and highlight the importance of culture dimensionality in driving not only tumor, but also stromal cell, behavior.

Analyzing the Effect of Local and Systemic Transport Phenomena

As perturbed vascularization is the primary mediator of diffusional constraints and increased interstitial pressure in tumors, several approaches have been developed to mimic blood vessels by integrating microfluidic channels into polymeric systems. One technique to create channels into PEG diacrylate (PEGDA) hydrogels uses laser ablation to cause local polymer structure breakdown (Heintz et al., 2016). Alternatively, it is possible to integrate vascular structures into hydrogel scaffolds by patterning cell adhesion peptides into otherwise nonadhesive materials using two-photon laser scanning photolithography (Culver et al., 2012). Soft-lithography can also be used to define networks of endothelialized microchannels within natural hydrogel matrices to study various tumor vascularization phenomena in long-term (1–2 weeks) cultures (Fig. 2.5.11.2C) (Morgan et al., 2013; Zheng et al., 2012). Instead of patterning the channels directly, it is possible to predefine channels for subsequent coating with endothelial cells by embedding a needle that creates a lumen upon removal (Chrobak et al., 2006) or by encasing fibers of a sacrificial material, such as polysaccharides, that leave behind a lumen upon dissolution (Bellan et al., 2009; Miller et al., 2012). Many of these lithographic approaches yield channel diameters of 75–750 μm, while capillaries are an order of magnitude smaller. This limitation can be circumvented using polydimethylsiloxane (PDMS)-based, microfluidic devices in which endothelial cells are seeded into a central, ECM-filled chamber and allowed to form perfusable vessels spontaneously (Fig. 2.5.11.2C) (Moya et al., 2013; Shin et al., 2012).

Three-dimensional (3D) bioprinting may be an alternative to technically challenging microfabrication approaches. Indeed, 3D printing can be used to design complex tissue macrostructures that incorporate parenchymal and stromal elements with microscale detail. In one such application, cells were suspended in inks composed of gelatin methacrylate, cell-culture media, and photoinitiator (Kolesky et al., 2014). After printing, gels were cross-linked with UV light, sacrificial materials were dissolved, and the channels were lined with endothelial cells. This resulted in intertwined patterns of defined regions of fibroblasts and vasculature all encapsulated in GelMA—methacrylate-modified denatured collagen. Importantly, systems like this allow for investigations of cell–vascular interactions in a spatially defined manner that would be very informative in tumor stroma studies.

In addition to altering mass transport, perturbed vessel function also modulates tumor interstitial fluid flow and pressure, which can independently affect tumorigenesis (Munson and Shieh, 2014). Indeed, collagen-embedded cancer cells subjected to interstitial flow conditions within a microfluidic device migrate either against or with direction of flow in a cell density, flow strength, and CCR7 activation-dependent manner (Munson et al., 2013; Polacheck et al., 2011). To better understand the role of interstitial flow and pressure on other cell types in the tumor microenvironment, fibronectin-coated PDMS-based microfluidic devices have also been used. With such models it has been shown, for example, that interstitial flow and shear stress impact endothelial cell sprouting, i.e., a key step in both lymph- and vascular angiogenesis (Song and Munn, 2011). As increased fluid pressure within a tumor impairs effective drug delivery by creating a fluid flow gradient

that works opposite to drug diffusion, similar models may be designed to more broadly study tumor cell responsiveness to therapeutics (Nathan et al., 2005).

Metastasis

Advanced cancers commonly spread to the lungs, liver, brain, and bones, and the specific microenvironmental conditions of these organs determine whether metastases form or not. One key difference between these metastatic sites is their ECM composition. For example, bone ECM contains high levels of collagen I, while brain ECM contains fibronectin, vitronectin, tenascin C, and laminin (Barney et al., 2015). To test the effect of particular ECM components on the metastatic capability of tumor cells, glass coverslips can be surface-treated with silane chemistry, coated with ECM components representative of these tissues, and then used to study the organ tropism of cancer cells (Barney et al., 2015). The effect of organ-specific ECM compositions can also be examined by isolating matrix from decellularized tissues, which not only preserves the ECM composition, but also bound signaling molecules. In one study, organ-specific metastasis models were created by pulverizing the decellularized tissue, reconstituting it, and allowing it to self-polymerize onto cell culture plates (Tian et al., 2018). Colorectal cancer cells seeded on top of these substrates formed large spheroids not seen on plastic. Additionally, these metastasis modeling substrates supported growth of cellular aggregates that were histologically similar to in vivo metastases and responded to treatments differently than when they were grown on plastic. While this particular method does not preserve geometry, structure, or mechanical properties of the metastatic tissues, whole-tissue decellularization can maintain these features. Indeed, decellularized tissues have been used to compare cancer cell behavior on healthy versus tumor matrix, but could also be useful in the study of metastasis-associated cell–matrix interactions (Piccoli et al., 2018; Villasante et al., 2014). When combined with host cells and appropriate mechanical stimuli such as interstitial flow conditions, decellularized tissue models will enable many important insights such as the role of perivascular niche conditions in the chemotherapeutic resistance of disseminated tumor cells (Fig. 2.5.11.2D) (Marturano-Kruik et al., 2018).

An even greater level of complexity can be achieved with microfabricated tissue and organ models. To engineer a fully functional bone marrow compartment for studies of bone metastasis, collagen I is cast into microfabricated PDMS molds together with demineralized bone powder, and growth factors important for bone development (Torisawa et al., 2014). Implantation of the resulting collagen constructs into mice yields bonelike tissue containing a marrow-rich region with hematopoietic cells and some adipocytes. By placing the explanted tissue into a microfluidic device, the viability of these constructs can be maintained for at least 1 week, making it possible to study metastasis-associated interactions of tumor cells in the context of whole-bone complexity (Torisawa et al., 2014). To recapitulate organ-level function of the lung that may be implicated in metastasis, multifunctional microdevices can be created that possess structural, functional, and mechanical properties of the alveolar–capillary interface (Huh et al., 2010). This interfacial region is responsible for the gas exchange function of the lung and, thus, is an essential element when modeling lung tissue and its potential role in metastasis. Previously engineered lung-mimetic devices consist of vertically opposing microchannels separated by a stretchable PDMS membrane. Human endothelial cells and alveolar epithelial cells can be seeded on either side of the membrane, which is subsequently stretched to simulate lung movement. In toxicology studies, the artificial lung responded to toxins and inflammatory cytokines similarly to native lung, suggesting its potential value in studies of lung metastasis.

CASE STUDY: BONE METASTASIS

Approximately 85 percent of advanced breast cancer patients develop skeletal metastases in their lifetime (Coleman and Rubens, 1987). Bone metastases are characterized by painful, often osteolytic, lesions that increase fracture risk, decrease quality of life, and have no cure (Kozlow and Guise, 2005). Tumor cells activate osteolysis by releasing factors that stimulate osteoclastogenesis and inhibit osteogenesis (Fig. 2.5.11.3A). The resulting osteolytic bone degradation leads to the release of otherwise sequestered growth factors and cytokines that increase tumor cell proliferation, thereby activating the vicious cycle of osteolytic metastasis that is challenging to treat.

From a biomaterials perspective, bone is a hierarchical material composed of collagen fibers reinforced with hydroxyapatite endowing bone with its unique biomechanical properties (Fratzl and Weinkamer, 2007). As a result, the fibrillar structure and mineralization of bone ECM are critical design parameters for in vitro models of bone metastasis. To study the effect of bone mineralization on tumor cell behavior in vitro, bone ECM can be modeled using osteoblast-derived ECMs (Mastro et al., 2004; Taubenberger et al., 2013), mineral-containing culture models (Pathi et al., 2011; Suárez-González et al., 2010; Choi et al., 2015), or mineralized collagen systems (Choi et al., 2019) (Fig. 2.5.11.3Bi, ii). For example, casting collagen into PDMS microwells and incubating these substrates in a calcium phosphate solution containing polyaspartic acid yields collagen scaffolds with biomimetic intrafibrillar mineralization (Choi et al., 2019). Studying breast cancer cell interactions with these substrates demonstrated mineral-mediated differences in cell contractility, focal adhesion formation, and cell traction forces that may be relevant to metastasis. Nevertheless, tumor cell dissemination to bone is also critically determined by interactions with bone marrow niches and the integrated vascular structures (Carlson et al., 2019; Croucher et al., 2016). To mimic tumor cell–endothelial cell interactions and their role in regulating tumor cell dormancy and therapy response, microvascular niches can be engineered by coculturing endothelial cells with bone marrow-derived MSCs, which supports the formation of interconnected vascular networks (Fig. 2.5.11.3Biii). When breast cancer cells were seeded on top of the endothelial networks it was found that dormancy is maintained by thrombospondin-1 (TSP-1) associated with stable vascular regions, whereas reduced levels of TSP-1 at sprouting neovascular tips activated tumor cells to escape from dormancy.
